At the recent Atlantic City convention of the American Street and Interurban Railway Engineering Association three papers on the steam turbine were presented by representatives of as many manufacturers, each covering different features of turbine use. As the power plants of traction companies have alone rivaled central stations as sources of information concerning steam turbine practice, it was but natural that these prime movers should receive special attention at the convention, and in the three papers some helpful indications of present tendencies in the use of turbines can be perceived. For example, Mr. St. John Chilton, of the Allis-Chalmers Co., recommends in one of the papers a steam pressure of about 150 lb. as being the most economical in the operation of turbines, stating that a greater saving may be effected by the use of a small amount of superheat than by increasing the initial pressure above that amount. He remarks that an increase in pressure to 175 lb. results in a gain of but 2 per cent in steam economy, an additional 3 per cent being gained in an increase to 200 lb., against which should be placed the increased cost of piping, boilers and possibly of the turbine itself. He brings out the point that a higher vacuum is not required with turbines than with reciprocating engines, but that the turbine can utilize high vacuum to better advantage. The difference in economy within the range between 6 and 3 in. absolute terminal pressure is approximately 5 per cent per inch, the rate of increase of economy proceeding at a greater ratio as the terminal pressure goes below 3 ins. The use of superheated steam increases the economy, but the increment of saving becomes smaller as the superheat is increased, the reduction in steam consumption with 50° F. superheat approximating 7 per cent., with 100° F. 10 per cent., and with 150° F. 12.5 per cent.

Another feature of turbine operation was brought out by Mr. A. H. Kruesi, of the General Electric Co., namely, the adaptability of the turbine to the loads that arise on interurban and heavy traction systems operating relatively few cars on infrequent headways. The test of a 9000-kw. turbine by the Commonwealth Electric Co., of Chicago, showed water rates of from 12.9 to 13.6 lb. per kw.-hour on loads ranging from about 50 to 150 per cent. of the rating. This the author mentions as representing the "highest attainment thus far reached in the generation of power from steam." He shows that steam at the pressure and superheat employed in three tests referred to and expanded to 1.5 ins. absolute terminal pressure would give an economy of 9.27 lb. water per kw.-hour in a theoretically perfect engine or turbine with a generator of unity efficiency, and that the turbine in these tests has atained an efficiency of 76.4 per cent. of that theoretically obtainable, which "indicates that we are approaching the practical limit of perfection in the production of power from steam." On the subject of pressure, vacuum and superheat, Mr. Kruesi's statements agree with those in Mr. Chilton's paper. In the matter of superheat the suggestion is made that much of the trouble which has attended the use of superheated steam is due to the want of elasticity in the parts affected, it being probable that water may exist under certain conditions with superheated steam, the resulting variations in temperature, due to the spraying of heated surfaces, being enormously increased thereby. Changes in design of pipe fittings, valves, boilers and superheaters to care for this factor are suggested in order to permit of higher degrees of superheat. Improvement in economy arising from better vacuum is mentioned as that most easily attained, and an improvement in condensing equipment the easiest manner in which to lighten the duty on the boilers.

A recent development in turbine power plant designs, exemplified in the station of the Fort Wayne & Wabash Valley Traction Co., was explained in a paper by Mr. J. R. Bibbins. The station handles a combined railway and lighting load, as is fairly common with companies of its character. The author shows the manner in which the lighting load makes up for the early morning deficiency in the railway load, the latter usually falling off in the evening as the lighting load increases, and although the two systems are independent as to generators and turbines, steam is supplied to meet the average load of both systems, resulting in a much more effective working of the boiler capacity. Relating to this subject of improvement of efficiency with betterment of the load factor, the author presents curves showing the effect of the load factor on operating costs under the conditions obtaining at Fort Wayne. These curves show that an increase in low load factors brings greater increase in efficiency than a corresponding increase in higher load factors.

The Fort Wayne station is of peculiar design, consisting of a two-story building with the generating machinery on the second floor over the boilers, allowing simple, short and direct steam piping, with continuous upward slope from boiler nozzles to turbine throttles and barometric jet condensers entirely below the exhaust outlets of the turbines. While the remaining features of the design are those commonly found in stations of approximately this capacity—7,000 kw.—yet there is an absence of engineering frills for securing the highest possible efficiency, this being compensated for by lower capital cost. This low first cost, as well as the small area of station per kilowatt capacity, are the two important features of this type of station as brought out by the paper. The general arrangement, that of turbines and generators on a second floor above the boilers, accomplishes the second—small ground area, while it aids materially in the first—low cost. The cost of the building is certainly low—10.97 per kilowatt, figuring the ultimate capacity of 8,500 kw. It is shown that with larger boiler units a more compact arrangement might be made, while it is quite possible that with a demand for stations of this type a boiler could be obtained giving a narrower battery. The arrangement, while an ideal one for steam piping requirements, is also conducive to low cost of piping, this charge being about $2.50 per kilowatt. Economizers were not considered necessary on account of the low cost of fuel. Mechanical stokers are used, both to provide forcing capacity and to reduce labor cost, the present saving in labor being estimated at about $16 per shift of twelve hours. Barometric jet condensers are used, the condenser head being suspended beneath the turbine. A vacuum of 26.5 to 27 in. at full load is maintained in warm weather, the cost of the condensing equipment being only about $2.50 per kilowatt, including pumps and piping. The turbines are of the Parsons type, part of the generators being 25 cycle and part 60 cycle, for the railway and lighting load, respectively. The exciters are direct connected to the turbines, and while adding 2.6 per cent to the cost of the main generating unit, represent a saving of 20 per cent. as compared to the cost of independent exciting units. The operating costs, considered strictly alone, are not especially low, but are expected to reduce with the better load factor which will be the result of contemplated extensions in the traction lines. The labor cost is fairly low, being 0.12 per cent. per kw.-hour at present. Taking into consideration, however, interest, taxes and depreciation, the total power cost, including these items, is quite low, being 0.79 per cent. per kw.-hour with the present load factor of 24 per cent. Curves are presented showing that with 33 per cent. load factor this total cost will be reduced to 0.57 per cent., and with a possible load factor of 50 per cent. to 0.41 per cent. per kw.-hour. This low total cost of course is possibly due to the very low cost of the completed power station, which is shown to be but $66.25 per kilowatt, exclusive of land. Interest and taxes are taken as 7 per cent., while a sinking fund of 4.2 per cent., equivalent to 6.43 per cent. depreciation, is allowed in figuring total cost of power.

HEAVY FOUNDATIONS FOR THE NEW STEEL WORKS AT GARY, IND.

The soil conditions at the site of the immense new steel works of the United States Steel Corporation at Gary, Ind., are such that comparatively little difficulty is experienced in securing perfectly stable foundations for the heavy structures and machines which are included in those works. The blast furnaces, the machinery and equipment and the ore-handling docks and storage piles for the works are being built, however, on a scale that has never been undertaken heretofore, with the result that foundations and footings of unusual magnitude are required. The site of the works is along the shore of the extreme southern end of Lake Michigan, where a stratum of fine, clean lake sand, from 30 to 60 ft. in depth, covers the surface. The original ground level was a succession of alternate sand dunes and hollows, parallel to the shore line of the lake, with an average height of about 20 ft. above the water level in the latter. Under this sand, at a depth of 30 ft. below the lake level is a stratum of good clay which increases in hardnesss with the depth. The ground-water level rises on a slope of about 2 in. to 100 ft. going inland from the lake. The foundations and footings in many instances extend below the water level, but the heavy continuous bed of fine sand precludes any necessity of deep foundations, or of special provisions to carry the heavy loads imposed by many of the various structures.

The principal work required to prepare the site for the construction of the steel works was to level the sand dunes and the hollows to a uniform height of about 20 ft. above the lake level, although considerable areas are also being reclaimed from the lake, which is shallow along the site. While the leveling work was largely all done in advance of the construction, the sites of several large buildings and other structures were either excavated at the time, or were left until such time as they were to be utilized. The preparation of the site of the works, which is nearly a mile square, in this manner required great quantities of materials to be moved, but the excellent foundations afforded render this grading work an undertaking entirely of magnitude, rather than of difficulty.

The new works are to include sixteen blast furnaces, which are to be in a row parallel to a harbor about 6,000 ft. long and 250 ft. wide; These furnaces are being built partly on reclaimed land and partly on existing ground. A complete description of the plant and methods used in constructing the harbor was published in The Engineering Record of Aug. 17, 1907. Between the harbor and the row of furnaces are large traveling bridges for unloading ore from the vessels, rehandling bridges, ore storage piles, and pits for the charging skips of the furnaces. On the other side of the furnaces are the various buildings of the works, chief among which, from the standpoint of heavy foundations, are a blowing-engine house, a building for electrical generators and five large buildings for open-hearth furnaces. The foundations for most of these structures are massive concreae built directly on the sand. This concrete is all made in the proportions of 1 part cement, 3 parts limestone screenings and 6 parts crushed limestone. Universal and Newago Portland cement are used; the screenings vary from fine dust to pieces 1/4 in. in extreme dimensions and the crushed stone will all pass a screen with 2-in. meshes but be retained on one with 1-in. meshes.

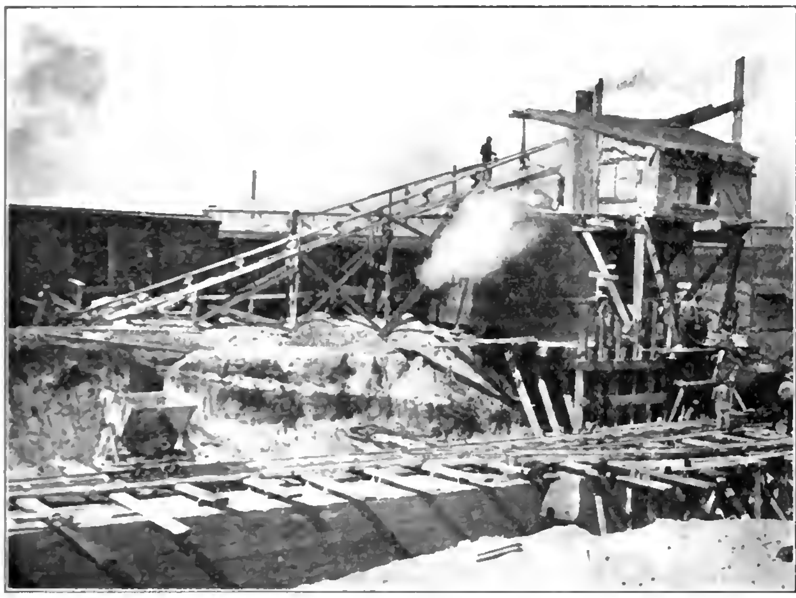
The construction of the greater part of the foundations that have been put under way is being carried on by Messrs. Lanquist & Illsley, general contractors, of Chicago. The plant and methods used in handling and mixing the great volumes of concrete in these foundations and footings have been specially developed to conform with the conditions presented. Railroad switching connections are in all cases extended directly to the work under way in order that plant and materials may be delivered expeditiously. In most cases the opportunity has also been afforded to handle the work in a logical manner. These conditions, and the great quantities of concrete to be placed in comparatively small areas render central mixing plants, with a large amount of equipment for handling the materials to, and the concrete away from these plants, the most productive and economical arrangement that could be made.

One general type of mixing plant has been adopted, and six of these plants have been erected adjacent to the heaviest work. Briefly, each of these plants embraces a belt conveyor, which delivers the concrete material from cars on a switch track to a mixer in an elevated tower; the mixer discharges into steel dump cars on portable narrow-gauge tracks extended to various parts of the work, or into bottom-dump buckets running on cars on these tracks to derricks which handle the buckets to place in the forms. The details and arrangement of these plants have been altered to suit conditions, but in all cases mechanical equipment has been used to eliminate manual labor as far as possible, and this equipment has been adopted in such form that it will handle the materials and concrete rapidly and in the most effective manner.

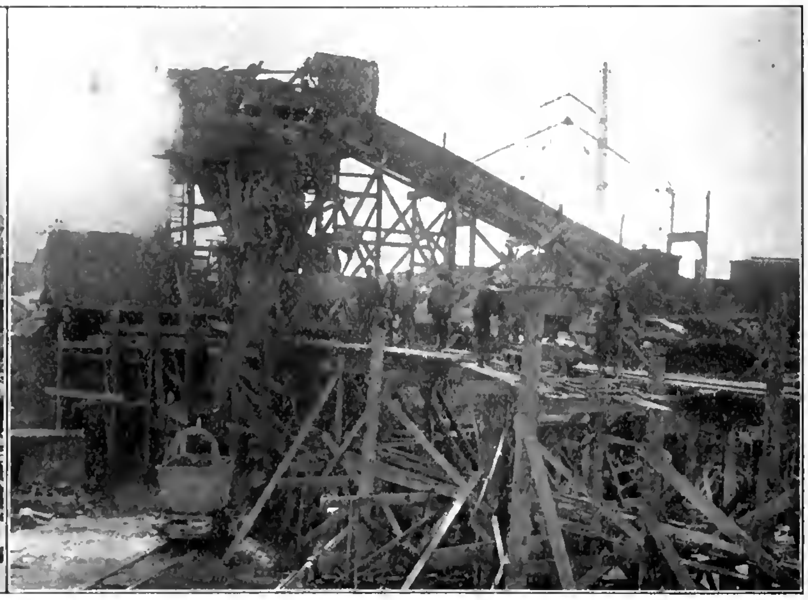
The foundations and footings for the blowing-engine house and the electrical generating station are among the most massive in the whole steel works, and the mixing plants that have been used during their construction are good examples of the general type. The blowing-engine house is approximately 135x600 ft. in plan, and will contain ten large blowing engines, operating on gases from the blast furnaces. The electrical generating station, of about the same size in plan, will contain fifteen gas-engine-generator units, each rated at 2,000 kw. These two buildings are adjacent, their longitudinal center lines being parallel.

The substructure of each building has as a base a monolithic concrete slab, about 135x600 ft. in plan and 5 ft. thick, or containing in round numbers, 15,000 cu. yd. of concrete. On this slab are built the foundations for the large blowing engine and generator units. These units are to be placed closely together in both buildings, so that but little space is available between the foundations of adjacent units; in most cases also the foundations extend from one side of the substructure to the other, a narrow space being left along on each side of the row of foundations, between the latter and the concrete walls, which are carried from the heavy base slab up to the superstructure walls. The foundations for the blowing engines are particularly heavy. The bottom of the 5-ft. base slab on which these foundations are built is at Chicago city datum, or about 1.5 ft. below the mean water level in the lake and 20 ft. below the finished ground surface. The foundations rise to 23 ft. above Chicago datum, or 18 ft. above the base, and are 40x80 ft. in plan in extreme dimensions. In the substructure of the electrical generating station the heavy base slab is at the same depth below the surface as in the blowing-engine house, and the foundations for the units in the station are about as heavy, each being, in general dimensions, also 40x80 ft. in plan and 18 ft. in height above the base slab.

The concrete for the substructure of each of these buildings was practically all mixed in a separate plant, although during the final work on the station substructure concrete for that work was furnished from the plant at the blowing-engine house. The arrangements and methods of operating both of these plants are so similar that a description of the plant for the substructure of the blowing-engine house will suffice for both.



Concrete Mixing Plant for Heavy Walls of Ore Bins.



Mixing Plant Delivering to Cars at Three Elevations.

This plant was erected at the inland end of the building, where two switch tracks could be extended up to one corner of the building without interfering with operations on the latter, or with any of the other large construction work which is under way on all sides. A heavy timber tower was built at the middle of the end of the building, in the edge of the excavation for the substructure, a platform for the mixer being placed in this tower at about the existing ground level. A charging hopper, having sufficient capacity for some storage, was built in the tower over the mixer. The hopper was divided into two compartments, one for crushed stone and one for screenings, and is placed so its top is 20 ft. above the ground. A small charging hopper for the cement was also placed over the mixer, at a lower level.

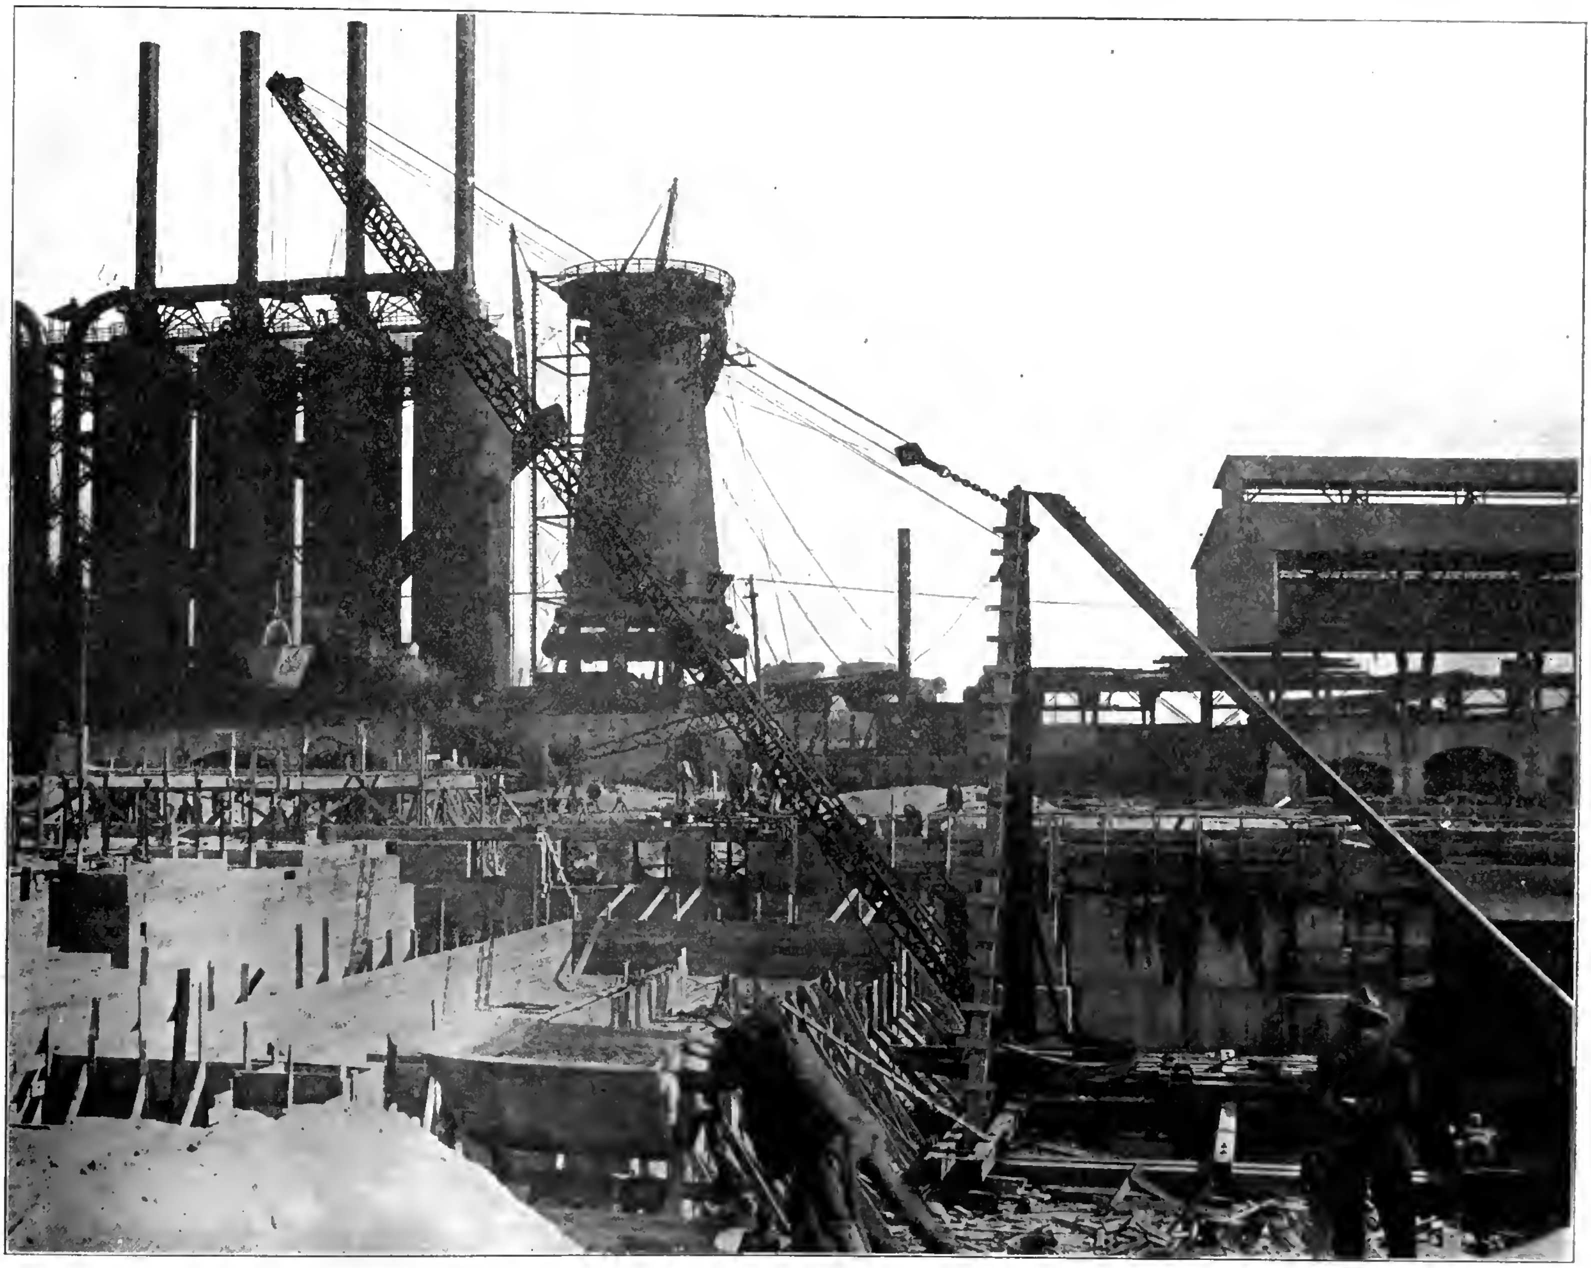
The cement, screenings and crushed stone are delivered from cars on the two switch tracks to these elevated hoppers by belt conveyors. A horizontal belt conveyor is placed in a frame between the two tracks, which are 16 ft. apart on centers. This conveyor is low enough to permit materials to be discharged on it from Williamson side-dump cars on both tracks with a minimum amount of shoveling. The horizontal conveyor is 300 ft. in length so seven cars can be placed along it in a string on one track, one car for cement, two for screenings and four for crushed stone. Portable platforms are extended from the floor of the car to an opening in the top of the frame carrying the conveyor in order that the screenings and stone may be shoveled on the latter without loss.

The horizontal conveyor is a 28-in. belt traveling at a speed of 300 ft. per minute, and has a rated capacity of 60 cu. yd. an hour. It discharges the materials at the end on an inclined 24-in. belt conveyor, extending up to the charging hoppers, into which the materials are delivered by it. A swinging baffle board is arranged over the hoppers in such manner that when screenings or stone are being handled they can be diverted into their respective hoppers. A man on the mixer signals to the shovelers in the cars whether screenings or stone are wanted, both classes of material, of course, being supplied to the charging hoppers separately. The cement is delivered in sacks which are handled from the car to the conveyor at any time whether stone or screenings are being handled. A man stationed near the top of the conveyor picks the sacks from the latter and places them on a short chute leading to a platform around the cement hopper. After the sacks are opened on this platform, the cement is poured into the charging hopper by hand.

The concrete mixer installed in this plant and also in the other plants on the work was designed specially for this work by the contractor. Essentially, it is of the continuous-mix pug-mill type, with an automatic feeding and measuring device. The latter has a short, solid cast-iron cylinder, with a series of four rows of pockets in its outer face; this cylinder is placed to a fairly close fit in a drum over one end of the drum of the mixer. The materials are fed into the mixer from the charging hoppers through this measuring device, the pockets in the cylinder of the latter being proportioned so the proper quantities of cement, screenings and crushed stone are supplied. The mixer and the measuring device are driven by the same engine, so the ratio between the rate of supply and the rate of mixing are constant, but may be varied.

The mixer is driven by a sprocket chain on a 40-h.-p., double-cylinder, steam engine. The conveyors are also driven by this engine, power being transmitted to them by a wire-cable rope drive. The engine is fitted with a reversing-motion link so the mixer and belts can be turned backward in case of an emergency. This arrangement has been found particularly satisfactory since it permits large stones, bolts and the like that occasionally become lodged in the mixer or belts to be removed without difficulty. Steam is supplied to the engine by a 60-h.-p., locomotive-type, boiler set up at the side of the plant the idea being in the choice of both engine and boiler to have ample power for all demands.

The arrangement of tracks for handling concrete in the dump cars and buckets from the mixer to place was altered from time to time to suit conditions as the work progressed. The 5-ft. base slab under the substructure was nearly all finished before work was started on the engine foundations. In order, however, to hasten the beginning of work on the latter, a section of the slab 20 ft. in width was carried forward on each side, from the mixing plant to



Derrick with 115-Foot Boom for Handling Concrete in Heavy Foundation Work at Gary, Ind.

the opposite end of the substructure, after which the closing section at the middle was finished back toward the plant. This arrangement permitted an earlier installation, at the end farthest from the mixing plant, of a large derrick for handling the bottom-dump buckets used in placing the concrete in the upper part of the foundations.

The concrete in the base slab and in the engine foundations up to a height of 5 ft. about the slab was all delivered in the side-dump cars running on portable track, which extended from the mixing plant to the point where work was in progress. Above that height the concrete was placed from the bottom-dump buckets by the derrick. The portable track, of which the contractors have in the neighborhood of 10,000 linear feet on the whole work, was built in 15 ft. lengths by the Arthur Koppel Co. The cars are of the standard 1-yd. Koppel side-dump design having steel bodies, steel frames and ball-bearing wheels. Concrete is also dumped from these cars into the forms for the side walls of the substructure by placing an inclined deflector at the top of the form.

The bottom-dump buckets were designed by the contractors and have a capacity of 1½ cu. yd. each. Their bottoms are made in one piece which is hinged at one side and is locked in place at the other side by a hook clamp that is easily loosened when the contents are to be dumped. The sides of the bucket all converged toward the bottom in order to facilitate the removal of the concrete.

While concrete was being placed in the base slab the portable tracks were blocked up on the finished work, the cars being dumped on one side of the track, which was shifted as the work progressed. Within 150 to 200 ft. of the mixing plant the cars were pushed from the latter to place by hand. At a distance in excess of that the cars were drawn in pairs by a horse to the point where concrete was being laid. After work had been started on the engine foundations tracks were laid on temporary trestles extending over the forms for the foundations at a height of 12 ft. above the top of the slab. Later, as the walls around the substructure were being built tracks were laid from the mixer at a third level, 18 ft. above the slab and were continued along the tops of the forms of the walls. Finally, the lowest level of track was also utilized to deliver concrete to the derrick in the bottom-dumping buckets. The work was prosecuted in such sequence, however, that the concrete was being handled in all four ways simultaneously. The mixer discharged directly into the cars at the lowest level at first; then as the work at the higher levels was started a short bucket elevator, driven by the mixer engine, was installed in the discharge chute leading from the mixer, in order to deliver the concrete to those levels without requiring the mixer to be placed on a high expensive tower, which would also have necessitated longer inclined conveyors leading to the charging hopper. The chute into which the bucket elevator discharged was arranged with hinged deflectors so the concrete could be diverted into secondary chutes leading to the different levels.

When the mixing plant for the substructure of the electrical station was discontinued an incline was built from the second level of tracks at the mixer for the substructure of the blowing-engine house, up over the forms for the side walls of this substructure to a connection with the highest level tracks for the other substructure. The cars were drawn up this incline by a hoisting engine, and were fitted with a simple brake so two men could ride them down the incline with safety.

Except in the vicinity of the mixers the portable tracks at all three levels in both these substructures were laid singly, but were arranged with passing tracks which enabled several cars going in both directions to be in service on the single track. The arrangement of the tracks at the mixer permitted four cars to be set in position to receive concrete, thus avoiding any delay by waiting for cars. The latter could also be brought to and taken away from the mixer without interfering with the cars in position at the mixer. This method of arranging tracks to facilitate the delivery of cars to and from the mixer and to permit the operation of the largest economical number of cars on the running tracks, has been carefully and fully developed in a similar manner in connection with all of the mixing plants that have been built. At the same time, even with this complete system the output of the mixing plants is limited chiefly by a lack of ability to remove the concrete as fast as it can be produced.

The derrick used in handling the bottom-dump buckets in which the concrete is delivered to it for the upper parts of the engine foundations was also designed for this particular work by the contractors. It has a 40-ft. latticed steel mast with four wooden stiff legs and a bull-wheel. The boom is 115 ft. in length, which is believed to be one of the longest, if not the longest boom of this type that has been built. It is made up of four 6-in. steel angles, placed at the corners of a 24-in. square and latticed together. A platform on heavy timber sills carries the derrick and the double-drum 50-h.p. Monaghan hoisting engine used to operate it. The platform sills are on rollers running on the portion of the base slab of the substructure which has been finished, so the derrick can readily be moved.

The completion of the upper part of the engine foundations, for which the derrick delivers the concrete, was started at the end of the substructure farthest from the mixing plant, the derrick being placed far enough from that end so it could just reach the work in the latter. As the foundations were finished up to the derrick the latter was moved back until the work was completed about 50 ft. from the one end. Meanwhile, the lower part of the foundations in the rear of the derrick had been built nearly to mixer plant; the derrick is to be turned around so it can be used to finish this section of the foundations, after which it will be dismantled and the foundations in the closing section built from tracks by dumping from the cars.

The equipment, arrangement and operation of the other five mixing plants which have been built, and particularly of the plant for the substructure of the electrical station, are very similar to those of the plant that has been described. The equipment for all of them is practically the same, while the arrangement has been varied in details to suit the locality. The horizontal run of the belt conveyors is placed in the same manner as in the case of the one described, although in some of the plants only a single switch track is available. The position of the inclined run of the conveyors is governed by the proximity of the switch tracks to the mixing plant, as it has been found that a grade of 4 in. to the foot is the steepest at which crushed stone can be handled on the belt. The construction and arrangement of the mixer tower, however, is the same in all the plants; the general conditions governing the arrangement of the tracks on which the concrete is delivered from the mixer have been explained.

Horizontal Conveyor Belt for Delivering Concrete Materials from the Cars to a Mixing Plant.

The method of handling the work on the different heavy foundations is varied from the program followed in connection with the substructure of the blowing-engine house in order to suit local conditions. The work on the foundations for the substructure of one of the open-hearth furnace buildings will illustrate some of the changes that have to be made. These buildings are each 165x1,200 ft. in plan, their substructures having as a base a solid slab of concrete 2½ to 3½ ft. thick and 165x1,400 ft. in plan, the base being extended beyond both ends of the building. On this base are erected the massive concrete foundations for the open-hearth furnaces, for the columns of the building and for the heavy equipment in the latter. In executing this work a mixing plant was first set up at one end of the building and delivered concrete for most of the building subsructure for a distance of 1,000 ft. from it. Then, in order to permit the erection of the superstructure to be started, the mixing plant was moved to the opposite end of the building, where it remained until the work was finished.

The sequence of operations on this building were much the same as on the one already described. Two traveling stiff-leg derricks with 35-ft. steels masts and 100-ft. steel booms were installed to handle the bottom-dump buckets used in placing the concrete in the upper part of the foundations, after the base slab and the lower part of the foundations had been placed from cars. These derricks were built prior to the construction of the one with the 115-ft. boom, the satisfactory results secured in their

operation having much to do with the installation of the one with the longer boom. At the same time it should be noted in this connection that these derricks handle about 2½ tons as maximum loads, their great advantage being in their long range at comparatively low heights.

The walls which carry the traveling ore unloaders and the rehandling bridges, and those along the ore storage bins parallel with the row of furnaces, all of which walls are parallel and close together, contain large quantities of concrete. The walls for the ore unloaders are 17 ft. wide at the base, 18 ft. high and 8 ft. wide on top; one leg of the rehandling bridges is carried by one of the walls for the unloaders, while the other leg is carried by a wall 17 ft. wide at the base, 10 ft. high and 8 ft. wide on top. The walls for the ore bins are not so high, but are more massive. A section of all these walls, 2,400 ft. in length, is being built by Messrs. Landquist & Illsley, who have erected two mixer plants for this work. In building the wide sections of the walls two parallel portable tracks are provided for the operation of the dump cars to and from the mixer plants. On the narrow sections of the walls single tracks with turnouts at frequent intervals are employed.

The quantities of concrete that are required to provide foundations for the principal structures of the new steel plant that are under construction are enormous. The contractors whose plant and methods have been considered herewith have already placed over 200,000 cu. yd. of concrete since they commenced operations in July, 1906, and their work will involve approximately 350,000 cu. yd. in the aggregate, besides requiring the handling of over 500,000 cu. yd. of sand. There is, furthermore, a large amount of concrete required in the other structures, buildings, dock walls and so forth in the steel works, not covered by their contract in addition to which may be included the concrete used for the municipal works of the town of Gary. These works were fully described in The Engineering Record of July 20, 1907.

Practically since the inception of operations the contractors have had in operation three to four mixing plants. The actual normal output of each of these plants is in the neighborhood of 350 cu. yd. per 10-hr. day, although occasionally a plant will deliver 450 cu. yd. in that time. In order to keep the plants in operation 30 to 50 cars of cement, screenings and stone have to be delivered each day. The materials are all furnished by the management of the steel plant, and due to an excellent system of switching which is followed, very little delay is experienced in delivering them. The stone and screenings are brought to the works in special trains directly from the extensive quarries of the Dolese & Shepard Co.

The design and construction of the new steel plant are under the direction of Mr. G. G. Thorp, vice-president of the Indiana Steel Co.; Mr. A. B. Neumann is chief engineer, and Mr. W. P. Gleason is superintendent of that company.

Fuel Requirements in the vicinity of Boston are responsible for a decided novelty in the Atlantic coast-wise coal trade. The New England Coal & Coke Co. has under contract three 11-knot steam colliers which will replace sailing vessels in the coal trade from Virginia. The sailing colliers are often delayed for many days at a time in rounding Cape Cod, and as a result there are threatened shortages in fuel supplies and congestion at the unloading points when heavy weather continues for some time. The new steam colliers are designed to carry 7,200 tons each, and are to be fitted with appliances permitting them to be loaded and unloaded in 6 and 10 hr. respectively.

New Reinforced Concrete Regulations in Philadelphia.

The following regulations of the Bureau of Building Inspection of Philadelphia in regard to the use of reinforced concrete were approved by Director Henry Clay, of the Department of Public Safety, on October 8.

The term "reinforced concrete" shall be understood to mean an approved concrete mixture reinforced by steel or iron of any shape, so that the steel or iron will take up all the tensional stresses and assist in the resistance to compression and shear.

Before a permit to erect any reinforced concrete structure is issued, complete specifications and drawings shall be filed with the Bureau of Building Inspection, showing all details of the construction, size and position of all reinforcing rods, stirrups, etc., and giving the composition and proportions of the concrete.

The execution of the work shall be performed by workmen under the direct supervision of a competent foreman or superintendent.

Reinforced concrete construction will be accepted for fireproof buildings of the first class, if designed as hereinafter prescribed; provided, that the aggregate for such concrete shall be clean, broken, hard stone, or clean graded gravel, together with clean siliceous sand or fine grained gravel; should the concrete be used for flooring between rolled steel beams, clean furnace clinkers entirely free of combustible matter, or suitable seasoned furnace slag may be used; when stone is used with sand gravel it must be of a size to pass through a 1-in. ring, and 25 per cent. of the whole must not be more than one-half the maximum size; and provided further, that the minimum thickness of concrete surrounding the reinforcing members of reinforced concrete beams and girders shall be 2 in. on the bottom and 1½ in. on the sides of the said beams and girders. The minimum thickness of concrete under slab rods shall be 1 in. All reinforcement in columns to have a minimum protection of 2 in. of concrete.

All the requirements herein specified for the protection of steel and for fire-resisting purposes shall apply to reinforced concrete flooring betweeen rolled-steel beams as well as to reinforced concrete beams and to entire structures in reinforced concrete. Any concrete structure or the floor filling in same, reinforced or otherwise, which may be erected on a permanent centering of sheet metal, of metal lathing and curved bars or a metal centering of any other form, must be strong enough to carry its load without assistance from the centering, unless the concrete is so applied as to protect the centering as herein specified for metal reinforcement.

Exposed metal centering or exposed metal of any kind will not be considered a factor in the strength of any part of any concrete structure, and a plaster finish applied over the metal shall not be deemed sufficient protection unless applied of sufficient thickness and properly secured, as approved by the Chief of the Bureau of Building Inspection.

All concrete shall be mixed in a mechanical batch mixer to be approved by the Bureau of Building Inspection, except when limited quantities are required or when the condition of the work makes hand mixing preferable; hand mixing to be done only when approved by the Bureau of Building Inspection. In all mixing the material shall be measured for each batch.

When hand mixing is done under the aforesaid limitations, the cement and fine gravel or coarse sand shall be first thoroughly mixed dry and then made into a mortar by gradually adding the proper amount of water. The crushed stone or gravel shall be spread out to a depth not to exceed 6 in., in a tight box or upon a proper floor, and be sprinkled with water as directed; the mortar is then to be evenly spread over the crushed stone, and the whole mass turned over a sufficient number of times, to effect the thorough mixing of the ingredients.

All forms and centering for concrete shall be built plumb and in a substantial manner, made tight so that no part of the concrete mixture will leak out through cracks or holes, or joints, and after completion shall be thoroughly cleaned, removing shavings, chips, pieces of wood and other material, and no debris of any kind shall be permitted to remain in the forms. All forms to be properly supported and braced in a manner to safely sustain the dead load and the load that may be imposed upon them during construction

The reinforcing steel shall be accurately located in the forms and secured against displacement.

Concrete shall be placed immediately after mixing.

Whenever fresh concrete joins concrete that is set, or partially set, the surface of the old concrete shall be roughened, cleaned and spread with cement mortar, which mortar shall be mixed in proportions of one of cement to two of sand.

Concrete shall not be mixed or deposited in freezing weather, unless precautions are taken to avoid the use of material covered with ice or snow or that are in any other way unfit for use, and that further precautions are taken to prevent the concrete from freezing after being put in place. All forms under concrete so placed to remain until all evidences of frost are absent from the concrete and the natural hardening of the concrete has proceeded to the point of safety.

Concrete laid during hot weather shall be drenched with water twice daily, Sunday included, during the first week. The broken stone, if hot and dry, must be wet before going to the mixer.

The time at which props or shores may safely be removed from under floors and roofs will vary with the condition of the weather, but in no case should they be removed in less than two weeks; provided, that column forms shall not be removed in less than four days; provided further, that the centering from the bottom of slabs and sides of beams and girders may be removed after the concrete has set one week, provided, that the floor has obtained sufficient hardness to sustain the dead weight of the said floor and that no load or weight shall be placed on any portion of the construction where the said centers have been removed.

The concrete for all girders, beams, slabs and columns, shall be mixed in the proportions of one of cement, two of sand or fine gravel, and four of other aggregates as before provided. The concrete used in reinforced concrete-steel construction must be what is usually known as a "wet" mixture. When the concrete is placed in water it must be placed in a semi-dry state.

Only Portland cement shall be permitted in reinforced concrete constructed buildings. All cement shall be tested, in carload lots when so delivered or in quantities equal to same, and report filed with the Bureau of Building Inspection before using it in the work. Cement failing to meet the requirements of the accelerated test will be rejected.

Soundness, Accelerated Test.—Pats of neat cement will be allowed to harden 24 hours in moist air, and then be submitted to the accelerated test as follows: A pat is exposed in any convenient way in an atmosphere of steam, above boiling water, in a loosely-closed vessel, for 3 hours, after which, before the pat cools, it is placed in the boiling water for 5 additional hours.

To pass the accelerated test satisfactorily, the

pats shall remain firm and hard, and show no signs of cracking, distortion or disintegration.

Such cements, when tested shall have a minimum tensile strength as follows: Neat cement shall, after one day in moist air, develop a tensile strength of at least 150 lb. per square inch; and after one day in air and six days in water shall develop a tensile strength of at least 500 lb. per square inch; and after one day in air and 27 days in water shall develop a tensile strength of at least 600 lb. per square inch. Cement and sand tests composed of one part of cement and three parts of crushed quartz shall, after one day in air and six days in water, develop a tensile strength of at least 175 lb. per square inch, and after one day in air and 27 days in water shall develop a tensile strength of at least 240 lb. per squre inch. These and other tests as to fineness, set, etc., made in accordance with the standard method prescribed by the American Society of Civil Engineers, may, from time to time, be required by the Bureau of Building Inspection.

Walls.—Reinforced concrete may be used in place of brick and stone walls, in which cases the thickness may be two-thirds of that required for brick walls as shown in the Schedule, Section 18 of the Act of Assembly No. 123, of the Commonwealth of Pennsylvania, approved June 5, 1901, provided the unit stresses as set forth in these regulations are not exceeded.

Concrete walls in such cases must be reinforced in both directions in a manner to meet the approval of the Chief of the Bureau of Building Inspection.

Steel.—All reinforcements used in reinforced concrete shall be of standard grade of structural steel or iron of either grade to meet the "Manufacturers' Standard Specifications," revised February 3, 1903.

Reinforced concrete slabs, beams and girders shall be designed in accordance with the following assumptions and requirements:

(*a*) The common theory of flexure to be applied to all beams and members resisting bending.

(*b*) The adhesion between the concrete and the steel is sufficient to make the two materials act together.

(*c*) The design shall be based on the assumption of a load four times as great as the total load (ordinary dead load plus ordinary live load).

(*d*) The steel to take all the tensile stresses.

(*e*) The stress-strain curve of concrete in compression is a straight line.

(*f*) The ratio of the moduli of elasticity of concrete to steel:

Stone or gravel concrete................1 to 12.
Slag concrete ....1 to 15.
Cinder concrete ....1 to 30.

The allowable unit transverse stress upon concrete in compression:

Stone or gravel concrete.........600 lb. per sq. in.
Slag concrete ....400 " " " "
Cinder concrete ....250 " " " "

The allowable unit transverse stress in tension:

Iron ....12,000 lb. per sq. in.
Steel ....16,000 " " " "

The allowable unit shearing strength upon concrete:

Stone or gravel concrete..........75 lb. per sq. in.
Slag concrete ....50 " " " "
Cinder concrete ....25 " " " "

The allowable unit adhesive strength of concrete:

Stone or gravel concrete.........50 lb. per sq. in.
Slag concrete ....40 " " " "
Cinder concrete ....15 " " " "

The allowable unit stresses upon concrete in direct compression in columns:

Stone or gravel concrete.........500 lb. per sq. in.
Slag concrete ....300 " " " "
Cinder concrete ....150 " " " "

The allowable unit stress upon hoop columns composed of stone or gravel concrete shall not be over 1,000 lb. per square inch, figuring the net area of the circle within the hooping. The percentage of longitudinal rods and the spacing of the hoops to be such as to permit the concrete to safely devolp the above unit stress with a factor of safety of four.

When steel or iron is in the compression sides of beams the proportion of stress taken by the steel or iron shall be in the ratio of the modulus of elasticity of the steel or iron to the modulus of elasticity of the concrete provided that the rods are well tied with stirrups connecting with the lower rods of the beams; provided, further, that when rods are used in compression, the approval of the Chief of the Bureau of Building Inspection must be obtained.

In the design of structures involving reinforced concrete beams and girders, as well as slabs, the beams and girders shall be treated as T-beams, with a portion of the slab acting as flange in each case. The portion of the slab that may be used to take compression shall be dependent upon the horizontal shearing stress that may exist in the beam, and in no case shall the slab portion exceed twenty times the thickness of the slab.

All reinforced concrete T-beams must be reinforced against the shearing stress along the plane of junction of the rib and the flange, using stirups throughout the length of the beam. Where reinforced concrete girders carry reinforced concrete beams, the portion of the floor slab acting as flange to the girder must be reinforced with bars near the top, at right angles to the girder, to enable it to transmit local loads directly to the girder and not through the beams, thus avoiding an integration of compressive stresses due to simultaneous action as floor slab and girder flange.

In the execution of work in the field, work must be so carried on that the ribs of all girders and beams shall be monolithic with the floor slabs.

In all reinforced concrete structures special care must be taken with the design of joints to provide against local stresses and secondary stresses due to the continuity of the structures.

Shrinkage and thermal stresses shall be provided for by the introduction of steel.

In the determination of bending moments due to the external forces, beams and girders shall be considered as simply supported at the ends, no allowance being made for continuous construction over supports. Floor slabs, when constructed continuously, and when provided with reinforcement at top of slab over the supports, may be treated as continuous beams, the bending moment for uniformly distributed loads being taken at not less than $WL/10$ in cases of square floor slabs which are reinforced in both directions and supported on all sides, the bending moment may be taken at $WL/20$; provided, that in floor slabs in juxtaposition to the walls of the building the bending moment shall be considered as $WL/8$, when reinforced in one direction, and if the floor slab is square and reinforced in both directions, the bending moment shall be taken as $WL/16$.

When the shearing stresses developed in any part of a reinforced concrete building exceed under the multiplied loads the shearing strength as fixed in this section, a sufficient amount of steel shall be introduced in such a position that the deficiency in the resistance to shear is overcome.

When the safe limit of adhesion between the concrete and steel is exceeded, provision must be made for transmitting the strength of the steel to the concrete.

Reinforced concrete may be used for columns in which the ratio of the length to least side or diameter does not exceed 15. If more than 15 diameters the allowable stress shall be decreased proportionally. Reinforcing rods that are introduced for lateral stresses must be tied together at intervals of not more than the least side or diameter of the columns.

Longitudinal reinforcing rods will not be considered as taking any direct compression.

The contractor must be prepared to make load tests in any portion of a reinforced concrete building within a reasonable time after erection, and as soon as may be required by the Chief of the Bureau of Building Inspection. The tests must show that the construction will sustain a load equal to twice the calculated live load without signs of cracks.

Systems of construction differing from the standard already approved and tested, may be required to pass a load, fire and water test, as present in Section 2 of the Act of Assembly, No. 236, of the Commonwealth of Pennsylvania, approved April 25, 1903.

The Chief of the Bureau of Building Inspection may, from time to time, issue such modifications to these regulations as may be found necessary to conform to modern practice.

General Appearance of Retail Coal Pockets at Hoboken.

Glass Telegraph Poles are to be manufactured in a factory recently built at Grossahmerode, Germany. An architect, of Cassel, has been granted patents in Germany and other European countries and in the United States for a machine to be used in their manufacture, according to United States Consular Agent Gustav C. Kothe, of Cassel. The glass is reinforced by wires suitably disposed. These poles, it is believed, will be particularly adapted for use in countries where wooden poles are quickly destroyed by insects or climatic conditions. The Imperial Post Department of Germany has ordered these poles for use on one of its telephone or telegraph lines. A pole 23 ft. long costs about $6 now but the regular selling price for market quotation has not yet been announced.

A Modern Retail Coal Pocket.

By Charles J. Steffens, Manager Guarantee Construction Co., New York.

The past few years have shown a marked advance in many branches of engineering, but none more marked than in that of the mechanical handling of materials. With the steadily increasing cost of labor, especially in the larger cities, it is becoming more essential as time passes that the labor cost at plants of every description be reduced to a minimum, and this requirement has resulted in the development and improvement of labor-saving appliances. While many technical articles have recently appeared on the subject, especially in connection with the handling of coal and disposal of ashes at the large power stations now being erected or recently completed, little has been written of the mechanical handling of coal at the retail yards. When one considers the enormous tonnage required to supply the inhabitants of any large city, the importance of this problem may readily be appreciated.

Simple as it may appear to design a plant of this character, yet in reality, if the plant, when completed, is to result in a minimum cost for operating expense and a minimum amount of breakage to the coal handled, it involves close study of the local conditions and a thorough knowledge of the various appliances for handling coal which are now on the market.

To the retail dealer there are but three ways of increasing his profits and thus meeting competition. The cost of coal at the mines is a fixed charge, as also is the freight, and these he cannot alter. His profits therefore can only be increased by a reduction of expenses after the coal is delivered at his plant, and this may be accomplished by reducing the percentage of coal broken in handling, by improved facilities which will enable him to handle his output at less expense, and by reducing the amount of waste product of his plant, consisting of screenings.

While it is true that the local conditions vary, and that no rule may be made which would apply to all cases—while in some instances an elevated trestle is undoubtedly the most economical form of plant—yet in general it may be said that the elevated pocket best suits the requirements of modern conditions. In a plant of this character, if properly designed, coal may be taken from the cars, loaded into the pocket and screened and delivered to the trucks at a cost which should not exceed two cents per ton, and is often more nearly 1½ cents. A plant of this character will cost when completed approximately $6.50 per ton of storage. This would, of course, include all foundations and machinery.

One of the largest retail coal firms in the east is the Jagels, Bellis Co., of Hoboken, N. J., who handle about 250,000 to 300,000 tons of coal per year and have several plants located in Hoboken, Jersey City and Weehawken. One of these plants is at 15th and Bloomfield Streets, Hoboken, N. J., of which a picture is given. Coal may be received by either rail or water, and the plant being within three blocks of the ferry to New York, the location leaves little to be desired.

At one side of the picture may be seen the hoisting tower, which forms the northerly end of the plant and is connected to the pocket by a timber trestle. At the south end of the pocket is a wooden bridge, spanning the street and extending to the elevator towers, where coal is taken from the cars. Beyond the elevator is a steel bridge over the tracks of the Hoboken Shore Road and connecting with the power-house of the Public Service Corporation, which the Jagels, Bellis Co. supplies. A screen pocket is located near the hoisting tower and here the screenings from the chutes of the pocket are resized for commercial use. The office, which is two stories high, is located opposite the south end of the pocket.

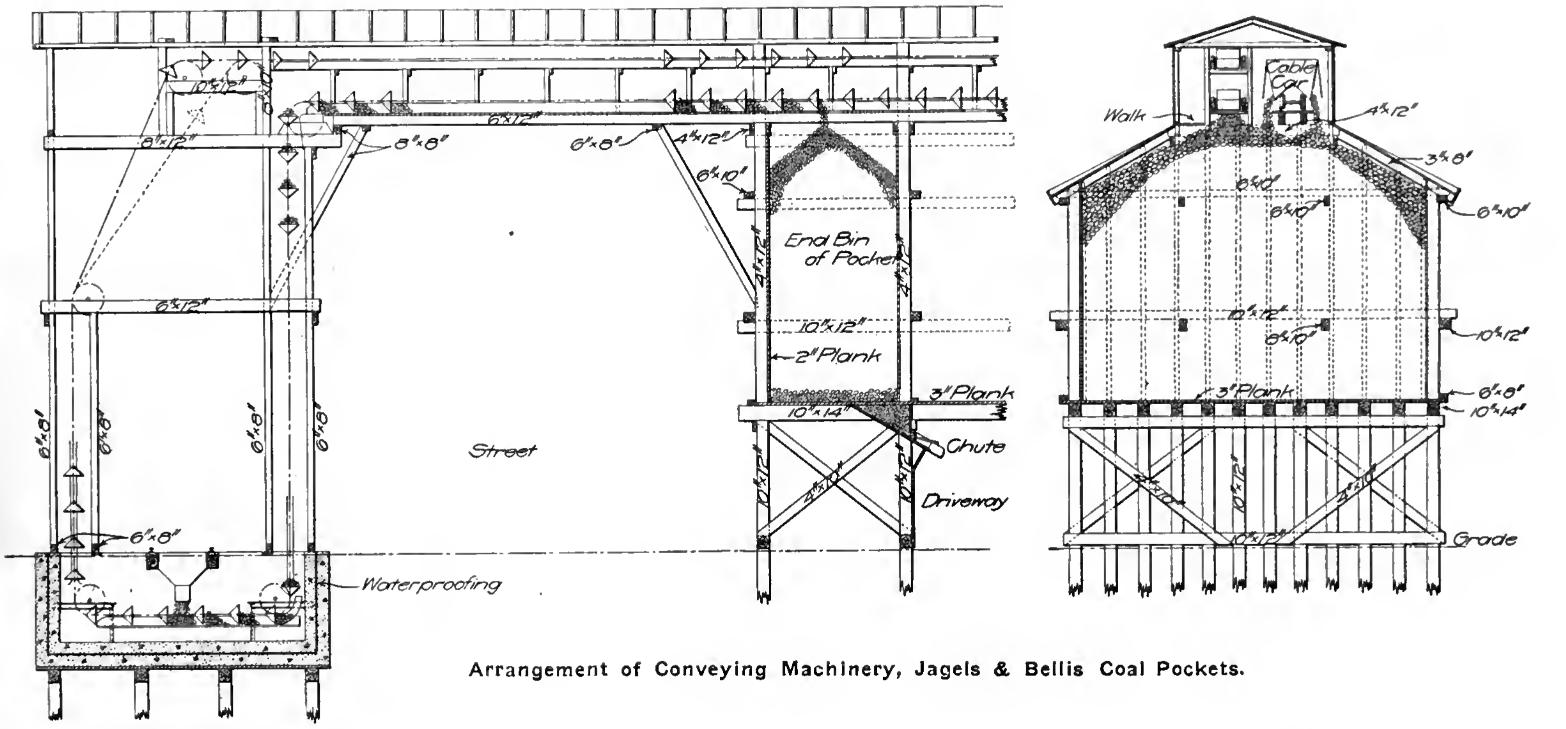
The pocket is built of long leaf yellow pine, the foundations being spruce piles driven to such a depth as to secure a penetration of not more than 2½ in. under the last five blows of a 2,000-lb. hammer having an effective fall of 10 ft. Rows of posts under the pocket and supporting the floorbeams are spaced 12 ft. apart, thus providing alternately for a 12-ft. driveway and a 12-ft. space for storage of dust from the delivery chutes. These chutes are so arranged that about 90 per cent. of the coal may be drawn from the bins and delivered to the trucks without shoveling.

The pocket is 145 ft. in length and 31 ft. in width, with a depth for 21 ft. of coal in the bins, thus giving a capacity of approximately 3,000 tons if the coal is trimmed by hand or 2,700 tons without trimming. The floor is elevated 12 ft. from the ground so that the trucks may be driven underneath and there loaded. Eleven bins are provided for storage of the commercial sizes of anthracite, no bituminous coal being handled through the pocket.

At the southern end of the pocket is a public roadway, beyond which is the siding for delivering coal cars, and at this siding are located the elevator towers and also a small engine and winch used for moving cars along the tracks. The illustration shows a view of the tower and operation of the elevator.

The elevator is arranged to take coal from a steel trough under the track hopper and carry it horizontally to the end of the track pit, then vertically to a level with the top of the bins, and from this point horizontally over the street and to the north end of the pocket, with provision for discharging into any of the various bins as it passes along. Buckets are V-shaped, 24-in. long, 20 in. wide and 10 in. deep, and are spaced every 36 in., being bolted between two strands of chain composed of steel links of 18-in. pitch with a pin connection for the links. Four-inch rollers are provided on the pins, the rollers being so constructed that they may be automatically oiled by a suspended oiler while the machine is in motion.

The trough along which the coal passes on the horizontal run is made of No. 10 gauge steel and is provided with a discharge gate at the center of each bin, the gates being operated by a rack and pinion connected to an 18-in. handwheel. In order to avoid the breakage due to coal falling from the trough to the bottom of the bins, break preventors are provided under each discharge gate. These are so constructed that the coal is retarded in its fall, striking baffle plates so arranged that the greatest vertical drop for the coal is 2 ft.



Arrangement of Conveying Machinery, Jagels & Bellis Coal Pockets.

At the north end of the pocket is a machinery room in which is located a 25-h.-p. direct-current 500-volt motor which runs at the speed of 1,100 r. p. m. The motor is geared down to the head-shaft of the elevator, the head-shaft being fitted with an equalizing gear to prevent the uneven motion of the buckets, which would otherwise result from having an 18-in. pitch chain. The elevator speed is 90 ft. per minute and the capacity is 60 tons per hour.

As the height of the tide rendered it necessary to make the track pit at the foot of the elevator waterproof, it was constructed in the following manner: Piles to support the weight of the pit were first driven, after which sheet piling of 2-in. plank was driven to a depth of 12 ft. and the earth excavated. A sump hole was also excavated adjacent to the pit, and a pump installed to keep down the water during construction. The piles were then cut off and capped with 12 x 12-in. yellow pine over which a 3-in. plank floor was laid, after which the outer walls

and floor were constructed of concrete 12 in. thick. When this had hardened, the inner forms were removed and all holes pointed up, after which waterproofing was applied, consisting of six layers of single-ply tar roofing felt, each layer as placed being coated with coal tar pitch, applied hot. The inner concrete walls and floor were then constructed, these being of the same thickness as the outer walls. This pit has been found thoroughly satisfactory and absolutely watertight.

Delivery chutes and gates, for loading the trucks, are made of sheet steel, each chute being provided with a screen 2 ft. wide and 3 ft. long over which the coal passes as it is discharged to the trucks. The size of mesh used in these screens for the various sizes of coal is as follows:

Pea, 3/16 in.; chestnut, 1/4 in.; stove, 3/8 in., and egg, 1/2 in. The chutes will discharge at the rate of one ton per minute, if the gates are fully opened. Dust and small coal which passes through the screens are taken away at intervals and resized at the screen pocket which is located at the bulkhead.

The hoisting tower, at the northerly end of the plant, is also constructed of yellow pine, the lower part being formed into a bin with a capacity of about 300 tons, for the storage of bituminous coal. Bituminous coal is also stored on the ground under the trestle which connects the hoisting tower and pocket. The tower is 22 ft. square and 75 ft. high, with foundations of concrete, which rest partly on the crib and partly on piles.

Equipped with a one-ton clam-shell bucket which is operated by a 10 x 12-in. double-cylinder steam engine, the tower is capable of handling 60 tons of coal per hour. All coal hoisted by the bucket is discharged into the receiving hopper at the head of the hoist and on a level with the engineer's platform, so that the engineer may, at all times, see the bucket. On this level are also located the engine and the boiler.

When anthracite coal is being hoisted, the receiving hopper discharges into an auxiliary hopper on the level below and from this the coal is loaded into cable cars which run through the pocket and discharge to the bins.

Bituminous coal may be taken from the receiving hopper and by-passed through a chute to the storage bin below, or it may be passed through a crusher between the receiving and auxiliary hoppers, then into the auxiliary hopper and be conveyed to the Public Service Corporation's power-house by means of the cable cars.

In order to secure a uniform and satisfactory feed to the crusher, an apron feeder is located under the receiving hopper. The feeder is 24 in. wide and about 4 ft. long, running at a speed of 30 ft. per minute. The head shaft is geared to a countershaft, and this in turn driven from the line shaft. A tight and loose pulley on the belt drive provides for stopping the feeder when it is desired to handle coal without passing through the crusher.

The crusher is of the two-roll type with removable teeth fitted to 18 x 24-in. rolls, and is operated at a speed of 180 r. p. m., being driven from the line shaft by means of a 10-in. double leather belt. The belt pulley on the line shaft is fitted with a clutch so that the crusher may be cut out when desired.

Starting from a point under the auxiliary hopper and passing over the bins of the pocket, then over the bridge and to the power-house of the Public Service Corporation, is a car system of the shuttle type consisting of one-ton, steel, side-dump cars on a narrow-gauge track.

Three pulleys on the line shaft, the outer ones tight and the center one loose, are connected by two belts to a jack shaft on which are three similar pulleys. One of these belts is crossed and the other open, so that by means of a belt shifter the jack shaft may be caused to revolve in either direction, thus reversing the motion of the cable and cars.

Cars are automatically dumped over the bins so that when the tower is in operation, it requires an engineer to hoist coal and his assistant to load the cars and operate the belt shifter. Power for the feeder, crusher and car system is furnished by a 30 h.-p. 500-volt direct-current motor at a speed of 975 r. p. m. The motor is geared to the line shaft in the tower and is on same level as tracks of the car system.

At the north end of the plant, near the hoisting tower and on the bulkhead line, is a screen pocket 12 ft. wide, 30 ft. long and having a depth of 15 ft. in the bins, which are elevated from the driveways similar to the arrangement for the storage pocket.

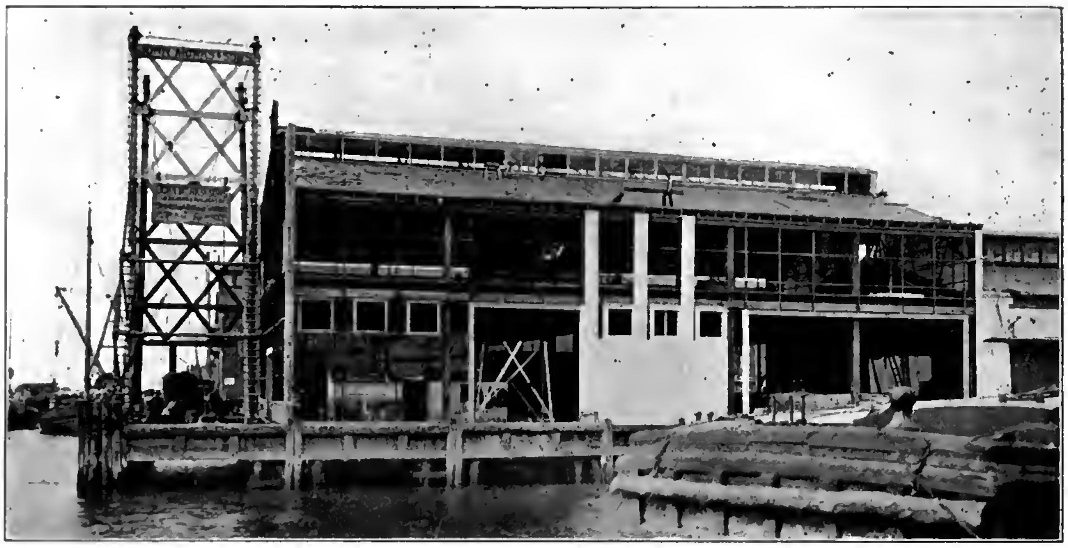
Small coal and dust which has passed through the screens of the chutes under the pocket is carted to the screen-house and there discharged into a small pit. From this point it is handled and sized automatically, being hoisted by a centrifugal discharge bucket elevator, with 5 x 7-in. malleable iron buckets, to a revolving screen 42 in. in diameter and 8 ft. long. The screen is mounted on trunnion bearings and covered with wire cloth, the mesh of the various sections being such as to size for dust, buckwheat and pea; chestnut and any other larger sizes pasing out over the end of the screen. Each size, as it is separated by the screen, is discharged into its proper bin from which it may be loaded to the trucks for delivery. Both screen and elevator are driven by a 7½ h.-p. motor.

THE EFFECT OF COMPRESSED AIR on health has lately been under investigation by two English engineers, who submitted themselves to some heavy pressures during the tests. A steel chamber was built, according to "The Engineer," in which the pressure was frequently raised to 75 lb. per square inch, without serious effect on the experimenters. Other tests showed that it is possible for a man to endure a pressure of 92 lb. per square inch without unpleasant results, provided that, first, at least twenty minutes are allowed for taking off each 15 lb. of pressure, the decompression being at a uniform rate; and, secondly, that the capillary circulation in every part of the body is maintained by muscular action during decompression. The only inconvenience under the pressure noted was a little temporary neuralgic pain in the arms. The studies further led to the belief that the longer the exposure, the longer and more uniform should be the decompression.

Reconstructing a New York Pier Shed.

The river end of the shed occupied by the Clyde Steamship Line on Pier 36, North River, New York, has recently been replaced by a modern steel structure of about the same width and about 10½ ft. higher. The new structure, about 114 ft. long and 73 ft. wide, is seated on the old wooden pier and has six transverse bents designed in accordance with recent practice for the construction of steel pier sheds. Each bent is about 32 ft. high to the eaves, and 54 ft. high over all, including the monitor, 5 ft. high. It is two stories high with the second floor 20 ft. above the deck of the pier and nearly 10 ft. in the clear below the lower chords of the roof trusses. The second floor is carried by a plate girder 6 ft. deep in each bent and both girders and roof trusses are supported entirely by the wall columns, leaving the interior of the shed unobstructed by intermediate columns.

Each bent is made with two 12 x 12-in. I-shape wall columns and a riveted triangular roof truss with a span of 73 ft. out to out and a center depth of 13 ft. 9⅜ in. The trusses are field



Traveler Revolved 90 Degrees and Stored on End of Reconstructed Pier.

riveted through vertical flange angles to the tops of the columns and are knee-braced with pairs of angles shop riveted to the lower chord gusset plates at the first panel points. The end panel is reinforced by a pair of angles back to back, inclined to the horizontal, which connects the gusset plates at panel points and materially stiffens the truss there. The 12-in. web plate of the 6 x 12-in. T-shape top chord is wide enough to provide connections with all the web members of the truss except at the center and ends where it is spliced to wide gusset plates. Pairs of angles are used for the bottom chord and single 2½ x 2½-in. angles are used for all of the web members, except at the center and quarter points of the span where pairs of 3 x 3½-in. angles are used to make a star shape cross-section.

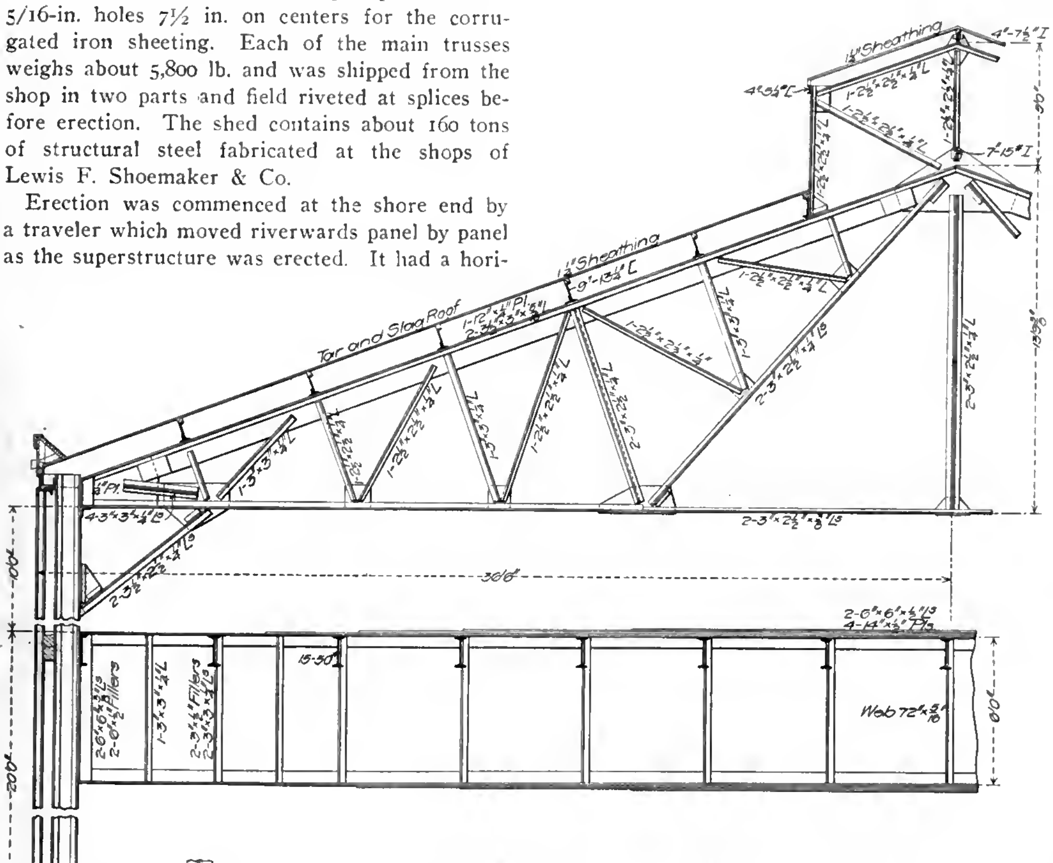
There are 12 lines of 9 x 13¼ lb. purlin channels on the main roof and three lines of 4-in. beam and channel purlins on the monitor frame 11 ft. 4½ in. apart which are supported on the main trusses and intermediately by the purlins. The purlins are secured to the rafters by short angle iron clips and have 2 x 2-in. nailing strips on their top flanges to receive the 1¼-in. sheathing boards covered with 5-ply of tar and slag roofing. The roof boards are finished at the eaves with a vertical fascia board and an inclined gutter board over which the water-proofing is flashed up to make an eaves trough. Vertical 4-in. I-beams are furred out 4 in. beyond the outer faces of the columns to provide frames for the large doors about 18 ft. square which occupy 3 of the panels in each side of the building. The

other two alternate panels have windows in the upper part and are sway-braced with 7/8-in. diagonal rods corresponding to the two sets of lateral rods in the same panels of the roof trusses.

The floor beams have web plates 5/16-in. thick and duplicate top and bottom flanges each made with a pair of full length 6 x 6 x ½-in. angles and four 14 x ½-in. cover plates from 26 ft. to 56 ft. long. The web is divided into 5-ft. panels by pairs of 3 x 3-in. vertical angles to the upper ends of which are field riveted the webs of 15-in. 50-lb. I-beam stringers with the top flanges bearing against the top flanges of the floor beams. Nailing strips on top of the stringers support the double plank floor clear of the rivet heads in the floor beam flange.

The end and side walls have 4-in. I-beam studs from 5½ to 7½ ft. apart and 2 x 2 ¼-in. horizontal angles from 4 to 4½ ft. apart punched with 5/16-in. holes 7½ in. on centers for the corrugated iron sheeting. Each of the main trusses weighs about 5,800 lb. and was shipped from the shop in two parts and field riveted at splices before erection. The shed contains about 160 tons of structural steel fabricated at the shops of Lewis F. Shoemaker & Co.

Erection was commenced at the shore end by a traveler which moved riverwards panel by panel as the superstructure was erected. It had a horizontal platform made with longitudinal and transverse sills braced to a pair of vertical masts about 65 ft. high and 20 ft. apart which were braced together with horizontal struts and triple intersection diagonals. Each mast had a 60-ft. 10-ton boom with which the columns of each bent were simultaneously erected. The columns remained supported by the booms until the floor girder was hoisted by tackles suspended from the masts direct, and set in position and connected to them, after which the booms were released and erected, the longitudinal stringers bracing the incompleted bent to the last finished bent. Finally the booms erected the roof truss and held it in position until connected to the columns and braced by the purlins which were hoisted by hand. A total force of 26 men including two gangs of riveters were required to operate the traveler and assemble and connect the steelwork. After erecting the last bent the traveler was revolved 90 deg. around a vertical axis and was left standing on the outer end of the pier as shown in the engraving until it was convenient to move it bodily on a lighter for the erection of another pier shed. The pier was designed and erected by John Monks & Sons, Mr. John W. Ripley, chief engineer of the structural department.



Half Cross Section of Reconstructed Pier Shed.

The Mechanical Plant for the Construction of the Tauern Tunnel in Austria.

In 1901 the Austrian State Railroads began the construction of three new lines which were planned to strengthen the commercial position of Austria and secure for the city of Triest, on the Adriatic Sea, a larger share of that part of the export trade of Austria, Germany and Italy, which now goes mainly by way of Hamburg, Genoa and Venice. The new lines connect the heart of Austria by short hauls with Triest and with the connection to the German railroads, and while facilitating passenger traffic from Germany and all parts of Austria to the famous health and scenic resorts, will also have a deep influence upon the freight traffic, since they shorten the distance from Triest to Salzburg by 43 per cent., the distance from Triest to Munich, 28 per cent., from Triest to Leipzig, 20 per cent., and from Triest to Berlin 17 per cent.

The standards on all three lines are very high and require much heavy cutting, long bridges and viaducts and quite a number of tunnels. Much of their total distance lies in mountainous country. One of the lines, that from Klagenfurt to Triest has no less than 32 tunnels, one of which, the Karawanken Tunnel, is 26,166 ft. or about 5 miles long, and another, the Wocheiner Tunnel, is 20,796 ft. or about 4 miles long. The second line running north from Selztal has a tunnel 15,648 ft. long and the last of the new roads, the Tauern Bahn, has the longest tunnel, 27,970 ft. or about 5 1/3 miles. The mechanical plant described was used at the last mentioned tunnel.

The first two of the new lines, and practically all of the work on the last line, with the exception of the Tauern Tunnel, were completed by the first of this year. The Tauern Tunnel, however, was not finally cut through until last July and at the present time the finishing touches are being put upon it. The remainder of the Tauern line has been in operation since September, 1905, and the entire line will be in use on the completion of the tunnel. The latter lies in the Tauern Mountains in Tyrol, a few miles south of the famous watering place, Bad Gastein.

The tunnel was driven simultaneously from both portals, at Boeckstein on the north, and Mallnitz on the south. The work was started first in 1901 at the north portal, the beginning at the south portal being purposely left over to the following year. The original mechanical installation at the north portal consisted of two ventilating fans driven by a 120-h.-p. water turbine and two Brandt twin reciprocating high pressure pumps, for furnishing water to the hydraulically-operated rock drills, driven by a 200-h.-p. water turbine. The machine shop, a blacksmith shop for caring for both hand and machine drills and an electric lighting plant completed the installation. All of the machinery was driven by water power, the total developed approximating 350 h.-p.

The ventilating fans have a diameter of 59 in. and a capacity of about 40,000 cu. ft. of air per minute. The turbine driving the high pressure pumps for supplying water to the drills makes 200 r. p. m., and transmits its power to the reciprocating pumps through gearing engaging on a crank shaft. The water is put under a pressure of 1,500 lb. per square inch and is led into the tunnel through a 3-in. pipe which is reduced to a 2-in. pipe near the face of the work. From the latter it is delivered to the drills through a flexible pressure hose.

The Brandt drills make from 5 to 10 r. p. m., and have a total pressure on the drill rod of 26,000 lb. In the exceptionally hard rock encountered in the work the daily progress was about 17 ft. in 24 hr., and the maximum progress about 24 ft. in the same time.

The final installation of the plant just referred to was not completed until September, 1903, and the work had scarcely been taken up in full force when a bad flood in the valley ruined part of the dam of the water power system, carried away some of the supports of the high pressure water pipe so that in places distances as great as 262 ft. remained suspended between supports, and flooded the power plant. The stream, which originally had crossed over the tunnel but which had been confined in an artificial channel, returned to its bed and broke through the roof of the tunnel with a flow of approximately 140 cu. ft. per second. The damage, however, was quickly repaired and the work again taken up with full force.

The entire original installation of machinery was of a temporary character, it being intended to add to it as the demands became greater. The building, however, in which the equipment was housed had been designed to take care of the entire final plant. It was the intention to make the increase in the equipment toward the end of 1904 and at the same time to let out the work by contract, but various circumstances caused the delay of both until December, 1905. A contract was then let to Redlich Bros. & Berger for the entire excavation of the remainder of the tunnel at both portals. As a result of this delay in increasing the size of the plant, the original installation, which had been designed to last but two years, had to be used for over three years, and an investigation was accordingly made to learn what steps should be taken to make it last until the tunnel was finally completed. In this investigation advantage was taken of the studies upon the ventilating equipment which had been made at the Wocheiner Tunnel. The figures showed that the original plant could pull through until the load on it was lessened by the new installation and then continue to give service till the tunnel was completed by substituting larger pipes in the ventilating system and reducing somewhat the rate of drilling and the lighting during the winter

of 1905. The theoretical result of this investigation was fully borne out by experience, for though the original plant was heavily overworked, it kept the excavation moving until the new plant was installed.

Previous to the installation of the new equipment a zone of soft rock was encountered, which not only delayed the work considerably, but made it dangerous. Through this section the only timbering found necessary in the tunnel was used.

In increasing the size of the plant it was determined in as far as possible to use the machinery from the three large tunnels which had already been completed on the other new lines. At the same time the equipment was so planned and arranged as to give the most economical results and reduce operating expenses. Similar plans were made at the same time for the installation at the south portal of the tunnel, the machinery here, too, being all second-hand, such repairs and changes being made as were necessary to secure satisfactory and economical operation.

It was estimated that about 19,500 ft. of the tunnel would be driven from the north side and the figures derived from the earlier experience at the same tunnel showed that three more groups of two centrifugal fans each and large ducts up to 31 in. in diameter were necessary. The two new sets were arranged so as to be driven either by water power or by three-phase current motors, the turbines being used in the summer when there was plenty of water, and the motors in the winter. This required the installation of a steam plant, the generator for supplying the ventilating motors being driven by a 300-h.-p. steam engine. Coincident with the installation of the new machines, changes were made so that great flexibility was secured in operating the plant. The fans were arranged so that all could be made to discharge directly into the ducts leading into the tunnel, or could be connected in series so as successively to raise the air pressure.

On account of the already large demands upon the water supply for power, drinking water, and the hydraulic drills, electric drills were adopted for the increase in the driving equipment, instead of Brandt hydraulic drills. For this purpose a steam engine driving a 2,000-volt three-phase current generator was installed in the plant at the tunnel portal and a high tension line strung in the tunnel to a point where a static transformer, which stepped down the current to 250 volts, was installed. The electric drills were first tried on the hardest rock encountered in the small heading and when using about 6 h.-p. were able to advance the heading about 7 ft. per day of 24 hr. This rate did not compare favorably with the progress of the Brandt hydraulic drills which operated in the broader bottom heading, but the difference in the two was not great when the fact that the hydraulic drills used about 20 times the power of the electric drills was figured into the problem. In order further to guard against failure of power during the winter months when water is apt to be scarce, the pumps for supplying the Brandt drills were equipped with a reserve steam engine of 200 h.-p.

The drinking water for the installation was secured from springs in a small creek and stored in a reservoir 377 ft. above the level of the mechanical plant at the north portal. This elevation was sufficient to force the water as far as needed in the tunnel without pumping.

Hauling in the tunnel was done by three types of locomotives. In the finished full section near the portal an ordinary steam locomotive was used, and operated as far into the tunnel as was allowable without seriously fouling the air. Beyond this point and stretching close up to the work in progress electric locomotives were used, the current being supplied from a generator driven by a 200-h.-p. engine. In the heading and the part of the tunnel where work was in progress the hauling was done by small benzine locomotives.

The current for electric lighting was first supplied by a small generator driven by a 20-h.-p. turbine, but as the work progressed another generator, also turbine-driven, was added. These two not proving sufficient toward the end of the work, an additional machine was belted to one of the steam engines that was carrying only a light load. Both arc and incandescent lamps were used.

The entire new equipment was obtained from the dismantled plants used in driving the tunnels on the other new lines.

Installation at the South Portal.—The plant at the south portal, at Mallnitz, was essentially different from the one at the north portal, and much more simple. About 1,500 h.-p. was available in a stream close to the portal and the construction of the necessary work for utilizing it was begun 1904. The dam, canal, and the forebay are entirely built of concrete. From the forebay the 36-in. flanged pipe, 870 ft. long, leads the water to the power house. There are two turbines, each of 615 h.-p. driving 512 KVA. generators. The turbines are of the Pelton type with high pressure oil governors. The generators are direct connected 3-phase current machines, from which the current is transmitted at 6,000 volts over a line about four miles long. Connections are made to the main transmission line for driving an inclined railroad and an elevator up the mountain side. At the mouth of the tunnel the current is stepped down in a transformer room in the power house building.

The difference in conditions at the two portals caused an entirely different development of the ventilating system. There were two different ways of looking at the problem: if the fans were of as low pressure as possible in order to save in the amount of power used, correspondingly large ducts would be required in the tunnel, with the result that the tunnel profile would be restricted; whereas, on the other hand, space might be saved in the tunnel by using smaller ducts, but the amount of power used would naturally be larger. The limited amount of water power available on the north side prompted the use of the former of these two solutions, while on the south side where power was plentiful and cheap the second solution was considered the better. Moreover, the plant at the north portal had to supply fresh air for a length of tunnel of about 6 km., whereas that of the south portal supplied only 2½ km. At the north portal there are over 3,000 ft. of ducts with a diameter of 800 mm., and others of 750, 700 and 500 mm., while on the south side all of the ducts are 500 mm. in diameter.

Brandt hydraulically operated drills were used entirely on the south side of the tunnel. The pumps for supplying the water were driven by three-phase current motors, three in number, all of them being belted to one main shaft which drives the pumps through sets of gears. The haulage in the tunnel and from the south portal was done entirely with electric locomotives which together with the necessary generators, transformers and transmission line equipment, were brought over to the Tauern tunnel after the completion of the Karawanken Tunnel.

The increase in the size of the installation at the north portal was a difficult matter, and the method of making the change was worked out so as not to delay the work in the tunnel. The excavation was carried on by two shifts, each working 8 hr., the one during the day and the other during the night, leaving 4-hr. periods of rest between the two shifts. The change of the shifts, putting the night men on days and vice versa was done every second Sunday and the work was then allowed to lie idle for 24 hr., from Sunday morning to Monday morning. It was planned to make the necessary changes on one of these Sundays and to have the new installation in working order in time for the day shift Monday morning. The work consisted in tearing out part of the large ventilating duct, the removal of the concrete drains from the high pressure pumps, changing the position of the coolers for the ventilating system and the connections between the pressure pumps and the wells, the installation of the connections for the new fans and the various valves, the setting of the new machines and the changing of the positions of the old ones, and the installation of measuring instruments in the ventilating ducts. All of the work that it was possible to do before disturbing the old equipment was finished before the night shift left the tunnel at 6 o'clock Sunday morning. At that time the entire plant was shut down and the work of removing the old structure commenced, the order and method of so-doing being determined beforehand. The changes were made without accident and the new installation put under full load experimentally at 20 minutes before 4 o'clock on Monday morning, 20 minutes ahead of the time determined for the completion of the work.

The installations were described in a paper by Karl Brabbée before the Society of Austrian Engineers and Architects, from which these notes have been taken.

A Mine Draining Plant in England.

An unwatering plant that possessed some interesting features was installed last year at the Lindal Moor iron mines, near Ulverston, England. The mines were abandoned about four years ago, partly because the plant then in operation could not cope with the water, which at times rushed in at the maximum rate of 7,000 gal. per minute, the dry-weather flow being 4,000 gal. per minute. When pumping ceased the mines rapidly became flooded. The shafts available for pumping purposes were all so small as to make the plant design difficult. The plan adopted was to use electrically-driven, high-lift centrifugal pumps, so arranged that the motors and pumps could be lowered down the shafts as the water receded. A power plant consisting of three steam turbo-alternators was especially erected for the work near the top of the shafts, and supplied three-phase alternating current at 3,300 volts. The shafts at the Diamond pit were vertical, measuring 6 ft. square, and in them two pumping outfits were installed, capable of raising 1,000 gal. per minute against a total head of 680 ft., the motors having an output of 315 h.p. at 1,480 r.p.m. The pumps were three-stage, and the entire apparatus was enclosed in a structural iron frame. The weight of each set, including the suspension cable, electric cable and its column of water was 22 tons. At the Berkune pit, the shafts, which were also vertical, measured 5 ft. 3 in. by 3 ft. 5 in., and the pumps were of the five-stage type, each delivering a maximum of 1,000 gal. per minute against a head of 540 ft. The Lowfield shafts were inclined at an angle of 43°, the pumps in them each designed to deliver 4,000 gal. per minute against a head of 395 ft. To permit rapid operation some of the pumps were arranged so that only some of the impellers were used while the heads were low, and thus discharged nearly 200 per cent. of their normal output. The pumps worked in series when necessary to overcome the high heads. The equipment was described in "Engineering," from which these notes have been taken.

The Hydro-Electric Development in the St. Mary's River at Sault Ste. Marie, Mich.

The Edison Sault Electric Co., of Sault Ste. Marie, Mich., a lessee of water rights from the Chandler-Dunbar Water Power Co., of that place, has recently placed in service a low-head hydro-electric generating station built in the rapids at the head of the St. Mary's River. The latter is the outlet of Lake Superior, and forms the international boundary between Canada and the United States. The development is on the American side, immediately off-shore from the government ship canal and two locks, and about 2,000 ft. downstream from the international railroad bridge over the river. The rapids in the river introduce a fall of about 20 ft. from the railroad bridge to a point 1,800 ft. below the power station, their total length being about three-quarters of a mile. Under present conditions the development renders 16 to 17 ft. of this head normally available, while 3 to 4 ft. additional head could be secured by the acquisition of additional rights below the station. The entire flow of water over the American side of the rapids, with the exception of the small quantity required to supply the two government locks can be utilized for power development.

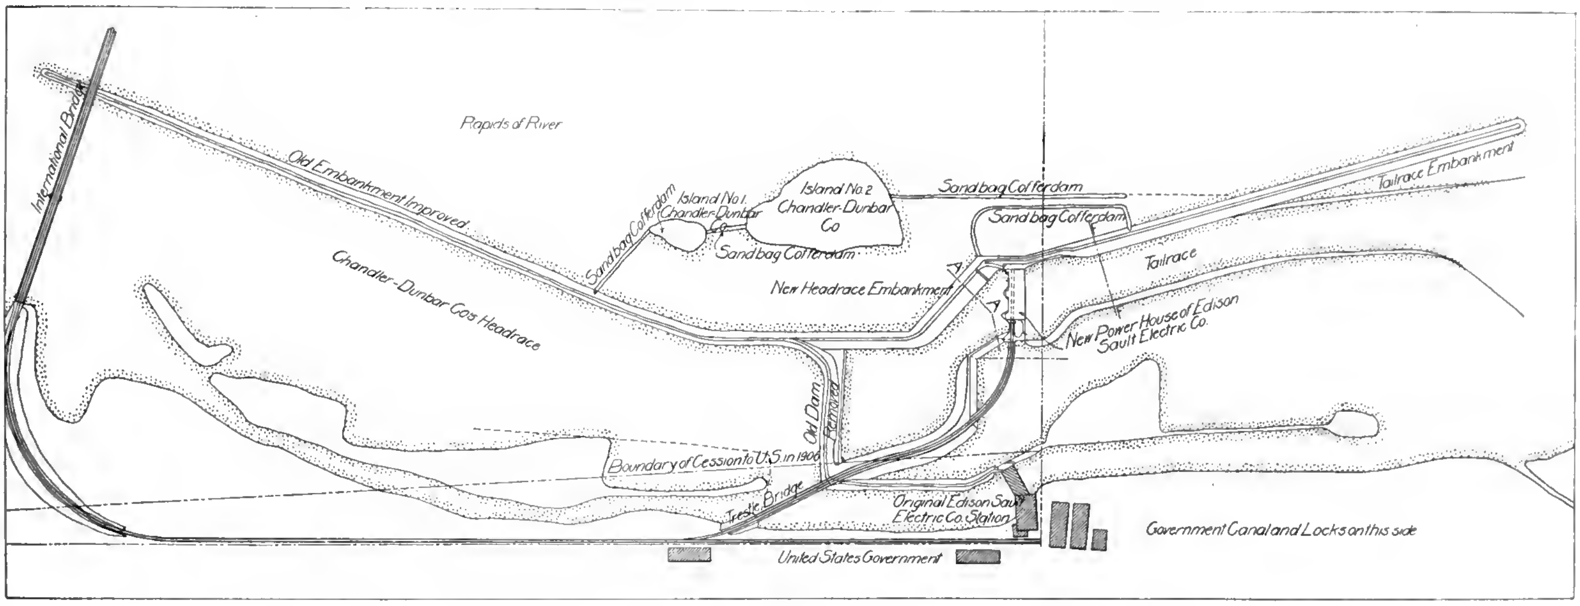
The power company has an existing hydro-electric station 300 ft. in-shore from the new station. The equipment of this original station is antiquated, and as the land on which the latter is situated was recently ceded to the government by the company, the old station is to be abandoned. The government contemplates the widening of the ship canal and the construction of a large new lock on this recently acquired land and on other land immediately downstream from it. The in-shore end of the new power house is 250 ft. from the boundary line of the government land, the original intention being to build a paper mill on this intermediate site. As the canal and lock works may eventually be still farther extended toward the river, however, this strip of land will not be developed. In fact, to provide for possible further extensions of navigation facilities, the owners desired to construct the power house the width of one canal lock further from shore, but the necessary permission, though approved by the United States Engineers, was overruled by the Department of Justice on account of a pending suit brought by the Lake Superior Corporation in the name of the United States, this suit being conducted by the attorneys of the Lake Superior Corporation. The suit has been decided by both the United States District Court and the United States Court of Appeals in favor of the Chandler-Dunbar Co., so it is now contemplated that the power house may be built out to the international boundary line, about 1,350 ft. beyond the existing off-shore end. The present installation has therefore been designed on the basis that the ultimate station will have wheel capacity sufficient to utilize practically the entire flow of the American side of the rapids, and an equal waste-weir capacity, available when the wheels are shut down.

A head-race, about half a mile in length, was provided for the original station by constructing an embankment down-stream from the international bridge, and 250 to 400 ft. from the existing shore line. The general location of this head-race, as well as its relation to the new works, is shown in the accompanying general plan of the latter. This original embankment was built with the expectation that an off-shore development would eventually be undertaken, and a dam was accordingly built across the head-race 400 ft. above the old station, with a narrower head-race continued to that station from the dam. This dam has been removed and a forebay for the new station provided by extending the head-race between two embankments as shown in the accompanying general plan of the development.

The original head-race embankment was a rock, gravel, clay and sand fill, which has been raised and strengthened with material from the excavation for the station building and for the tail-race leading from the latter. The new embankments which form the forebay of the station are also earth and rock fills, protected with dry stone walls, and adjacent to the building with a 12-in. face of concrete. A tail-race is extended about 1,100 ft. downstream from the station building. This race was built partly in excavation and partly between two embankments. The embankment on the river side of it is a rock, gravel, clay and sand fill similar to the original embankment of the head-race, which has stood for 15 years and is practically water tight. Various sections of these different embankments are shown in one of the accompanying illustrations.

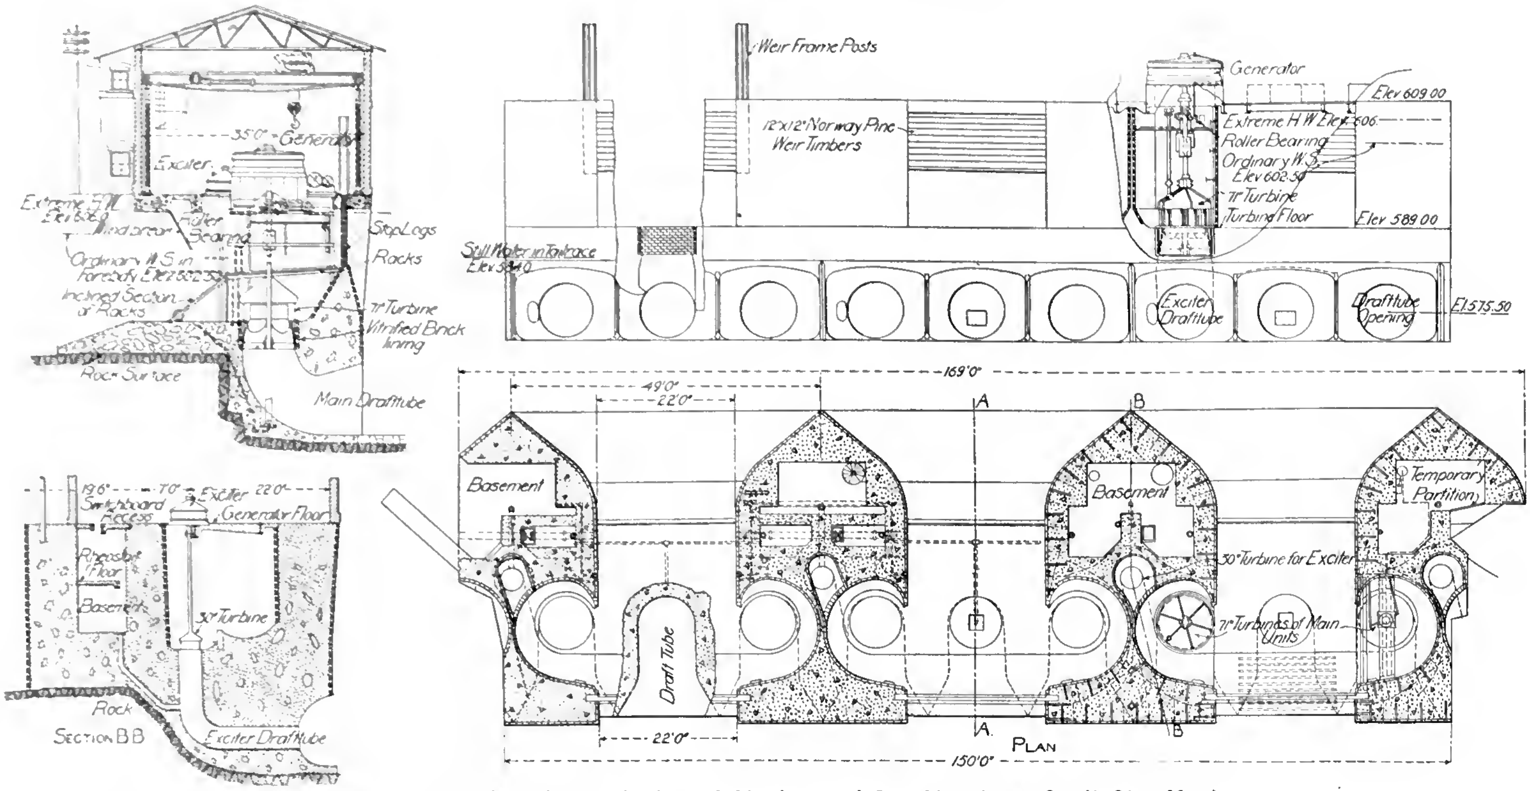
Bed rock at the site is overlaid by 8 to 10 ft. of gravel and boulder deposits, with intervening layers of clay. In general, the embankments were built on this bed of gravel and boulders, although on the forebay side of the embankments the rock was stripped back 10 to 12 ft. from the face of the embankment slope. Where the 12-in. concrete facing was used, it was laid against dry stone walls and bonded into the latter with strips of ⅛x2-in. band iron. The head-race embankments ordinarily have a head of 18 ft. against them, but show practically no leakage. The normal head on the tail-race embankment varies from 4 to 6 ft. at the station building, to about 1 ft. at the downstream end.

The power station building has a monolithic concrete substructure, built on bed rock, and a brick superstructure. The portion of the substructure that has been completed is 49x169 ft. in plan, providing space for nine main water-wheel units. It is arranged, however, so it can readily be extended at either end. The brick superstructure has been erected over two-thirds of this substructure, that is, to cover the space for six main units. It is built with temporary ends, in order that it may also be extended in either direction. Two of the main units have already been placed in service, a third is being installed and the other three will be acquired as needed. These units each consist of a 60-cycle. 3-phase, revolving-field, 450-kw., 4,000-volt, General Electric umbrella-type generator, direct connected by a vertical shaft to a 71-in., 750-h.-p. special vertical Samson turbine, operating at 100 r.p.m. Each unit has four steady bearings, one each above and below the generator and above and below the turbine. A roller thrust bearing just below the generator is supported by an I-beam girder, and carries the entire vertical load of the revolving element and wheel. This roller bearing is fed with oil by gravity and has thus far proved very satisfactory in service. The upper steady bearings are also supplied with oil by gravity, the lower ones being of wood and submerged. For the middle wheel of each group of three, provision has been made for a hydraulic step bearing instead of the roller bearing, if found more desirable.



General Plan of the Water Power Development at Saulte Ste. Marie, Mich.

The arrangement of the main units is shown in the accompanying plan and cross-sectional elevations of the substructure. Three water wheels are supplied from each penstock opening that leads into the building from the forebay. These penstock openings are 22 ft. in the clear and have a free water surface at the top. The heavy concrete piers which separate the adjacent penstocks have cutwaters carefully molded to reduce the disturbance of approach to a minimum, while their bottoms are also sloped at the entrance to secure the same result. One main water wheel is placed on the center line of each penstock, with one of the other two wheels of each group of three in a pit in the pier on each side of the penstock. The sides of these pits are built to deliver the water to the whole periphery of the wheels in them with the smallest possible frictional loss of head. The draft tubes



Cross-Sections, Elevation and Plan of Station and Sub-Structure, Sault Ste. Marie.

are formed in the concrete, and are designed so the water is delivered quietly from the units. Either of the side units may be shut off from the balance of the penstock by stop planks across the entrance to its recess, while the whole penstock may be closed by a floating bulkhead across the opening.

Each three main units are provided with an exciter unit consisting of a 75-kw., direct-current, umbrella-type generator, direct connected to a 30-in. vertical Samson turbine. The water wheel for each exciter is in a separate pit in the pier on one side of the penstock for the group of which it is a part. This chamber is connected with one of the main wheel pits, and is supplied through the latter with water from the penstock. In order to reduce the friction head, the pit for the wheel of each exciter unit is carefully located in reference to the chamber for the wheel of the main unit, and its sides are molded so the water is delivered to the wheel with little loss of head.

Although the low speed of the wheels necessitated larger-sized units than are usual, the arrangement of the wheels more than compensates for the increase in the width of the building that otherwise would have been occasioned. Furthermore, it permitted a rigid requirement of the government for waste openings to be met readily. This requirement stipulated that provisions must be made to pass through the building at such time as the wheels in any penstock are shut down the same quantity of water that would be carried over a section of the river of the width of the penstock. This was accomplished by building in the upper part of the downstream side of the substructure, a wasteway opening for each penstock, the openings being closed normally with 12x12-in. stop logs.

Each wasteway opening is 22 ft. in width, the same as the penstock opening. The lower edge is a weir, with its crest at such an elevation above the bottom of the penstock that when the opening is unobstructed the discharge over the weir will be equal to that of 49 linear ft. of river cross-section, 49 ft. being the distance between the center lines of the penstock piers. A groove for the stop logs is built into the concrete at each end of the opening. The stop logs are handled by a 15-ton motor-driven traveling crane, carried, in the superstructure, by a runway on steel columns. In order that the waste weirs could be conveniently placed in the sides of the substructure, and the stop logs closing them still be accessible to the crane, the downstream face of the substructure was built on a slight outward batter, so the floor of the superstructure cantilevers over that face.

A rack for intercepting and diverting from the wheels all floating and frazil ice and other debris is placed across each penstock. The lower section of this rack makes an angle of about 45 deg. with the horizontal, and extends from the bottom of the penstock to above the level of the top of the wheel casing. The top section of the rack is nearly horizontal and extends over the casing of the middle wheel, from the top of the inclined section to the waste weir. A vertical rack is placed across the entrances to the side wheel pits, above the inclined rack, to protect the wheels in these pits. By opening the upper part of the waste weir a strong current can be created near the surface of the water, which it is expected, will, to a very considerable extent, carry with it through the center of the penstock, the floating ice and prevent the stoppage of the side wheels, and the closing of the racks below.

The water wheels are each regulated by a Type D Lombard governor mounted on the floor over the wheel pit. Each governor is driven by a bevel gear on the shaft of the revolving element of the unit which it controls. The gate shaft of the water wheels is operated by the governor through a wire-cable rope drive.

The upstream ends of the piers between the penstocks are hollow, and provide basement space for oil storage, rheostats and a toilet. A spiral

Station Building from Downstream Side.

iron stairway leads down into each of these small basements, which are drained by 8-in. pipes connected to the draft tubes of the exciter units. The rheostats are placed on mezzanine galleries in order to protect them from possible dampness in the bottom of the basements.

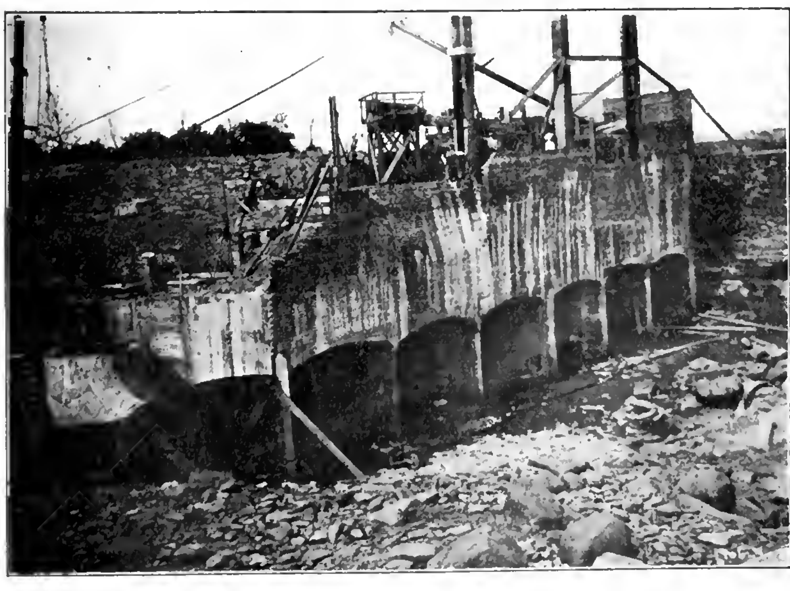
A four-panel switchboard in a wire tower recess on the upstream side of the building is provided for each group of three generators and their exciter. Lightning arresters and static discharges are placed in each wire tower, from which transmission lines lead out of the station. Current is transmitted at 4,000 volts and is stepped down to 220 volts for commercial lighting and is transformed to 500 volts direct current for power.

Construction.—The construction of the development was all handled under considerable hazard, and parts of it with serious difficulties. The sites of the forebay, the station building and the tail race were all covered with water from 2 to 6 ft. deep, which was flowing at a velocity of from 7 to 15 miles an hour. Two islands, that occur off-shore and just upstream from the station building, broke the force of the current over the rapids, so heavy sand-bag cofferdams could be built from the existing head-race embankment to these islands, and downstream from the latter, to a point well below the station building. The fall of the river was sufficient to enable all of the site, except about 850 ft. of the 1,100-ft. tail-race embankment, to be unwatered, and the construction handled in the dry. Such water as leaked through the cofferdams was removed by electrically-operated centrifugal pumps. The excavation of the tail-race was also carried on in the dry, as the construction of the embankment on the river side of it was advanced.

The spoil from the tail-race excavation was largely sand, clay, gravel and boulders, while the excavation for the power house was nearly all in rock. Practically all the material taken from these excavations was used in strengthening the existing head-race embankments, and in building the new embankments for both the head and tail-races. It was moved in 1½-yd. cars running on 24-in. gauge tracks laid from the excavations up to the grade of the embankments. These cars were handled by home-made electric locomotives, which operated with great satisfaction in doing this work, and also in delivering construction materials to the building. Each locomotive consisted simply of a four-wheel truck carrying a 30-h.-p. Northern motor, equipped with an ordinary street-car controller and the necessary starting resistances. Power was obtained from an overhead trolley wire supplied with direct current at 500 volts from the existing power station. The motor was designed to operate at 450 r.p.m., but it was geared to both axles of the truck with sprocket wheels and chains which reduced the speed to satisfactory limits. As thus equipped, the locomotive could readily haul five loaded 1½-yd. cars up a 6½ per cent. grade. It could also handle a train of cars, either on a grade or on the level, with considerable speed, thus enabling a large output to be maintained. One of the chief features in favor of it, however, was that it only weighed about three tons, so no heavy concentrated loads were brought on the tracks. The latter were used at first, in fact, with the cars drawn by horses. They had 20-lb. rails and 4x6-in. ties, which permitted them to be shifted readily, and required very little work to put them in running shape after being shifted. The trolley wire brackets were carried on overhanging arms on uprights fastened to the end of long ties, so the wire was moved with the track, without difficulty.

The concrete in the substructure of the station building was made in two different mixtures, depending on the location; one, in the proportion of 1 part cement, 2½ parts sand and 5 parts broken stone, and the other 1:3:6 of cement, sand and stone. In places where massive concrete was required, boulders up to the size of an ordinary bucket were imbedded in the concrete. Alpena Portland cement, river sand and crushed stone from the excavation for the station building, mixed with an equal quantity of crushed drift boulders, were employed.

An electrically-driven Smith mixer was erected in a tower close to the site, where it could be supplied with materials conveniently. The sand was brought to the lower end of the head-race site in barges, from which it was delivered to the mixer in dump cars hauled by one of the electric locomotives. The stone from the excavation was broken in an electrically-driven crusher set up at the work, and was delivered to the mixer in cars. The cars were hoisted by



Views of Tailrace End of Draft Tubes during Construction.

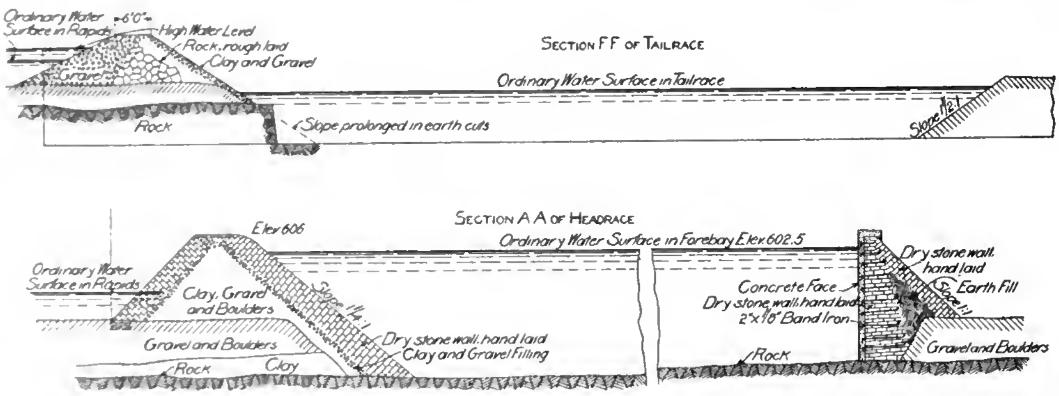
an elevator to a platform around the charging hoppers over the mixer. The latter discharged into side-tip buckets handled by derricks directly to place, or to stationary hoppers which supplied chutes leading down into the work.

Customary wooden forms for the concrete were almost entirely replaced by a single course of paving brick placed as a veneer to the concrete. The brick were laid in cement mortar and were built up to conform to the outlines of the concrete by using templates. The thin brick walls were carried up about 3 ft. ahead of the concrete, thus giving the mortar time to set before any load was brought on them. The brickwork was tied into the concrete with iron rods, placed at various intervals on different parts of the work, depending on the conditions; where tension might occur during construction it was reinforced by two strands of ⅛-in. telegraph wire laid in every fourth joint. It was found the brick forms handled in this manner were much cheaper and more satisfactory than wooden forms. The saving in their favor was particularly great in connection with the intricate curves and surface on the piers and in the wheel pits. One of the accompanying views of the draft tubes under construction shows relatively how the brick was carried up ahead of the concrete work.

Owing to the shape of the draft tubes the forms for them were first built up entirely in wood. The curves and the varying cross sections of these tubes made this form work very difficult and expensive in places, but the forms were built so as to be of service for further extensions. The centering for the forms was made of 2x12-in. plank carefully cut to templates; these centers were lagged with ½x2-in tongue and grooved flooring, cut and dressed to produce the warped surfaces of the draft tubes. After the first of the latter had been built with forms made in this manner it was found that equally good results could be secured at much less expense by replacing portions of the wooden lagging with wire-screen cloth covered with heavy canvass. Accordingly, the balance of the main draft tubes and those for the exciters were built with forms partly covered in that way.

The construction of the tail-race embankment was the most hazardous part of the whole project, so far as construction is concerned. The water over the site of the embankment was from 5 to 6 ft. deep and had a current of at least 15 miles an hour in places. Notwithstanding these conditions, the embankment was completed without much difficulty. This embankment is a continuation of the outer embankment of the forebay, so the track used on the latter could be extended out on it as the work advanced. The largest stones and boulders from the excavation were first delivered in the dump cars and dropped over the end of the track until the force of the stream was broken. Many of these stones and boulders, having 1 cu. yd. or more of volume, were carried away before the desired results could be obtained. As fast as the current was reduced sufficiently, smaller stones were brought out and dumped, and finally the rear or tail-race side was finished off with gravel and sand. The embankment has a minimum width of 6 ft.; the slope on the tail-race side was made 1½ to 1, and that on the river side, 2 to 1. Although little clay was used for this embankment, it is practically water tight, and after having been in place for a year and a half shows no evidence of weakness.

Mr. Alex. Dow, of Detroit, Mich., is president and general manager of the Edison Sault Electric Co. The other officers are all of Sault Ste. Marie and are as follows: Mr. Wm. Chandler, vice-president; Mr. D. B. South, secretary; Mr. S. G. Carlton, treasurer, and Mr. S. E. Peel, superintendent. Gardner S. Williams, of Ann Arbor, Mich., professor of civil engineering at the University of Michigan, as consulting engineer to the company, prepared the plans for the development and supervised the execution. Mr. Arthur Adams was resident engineer in charge for Professor Williams. The masonry construction, the excavation and the embankments were handled on a percentage basis by the MacArthur Bros. Co., of Chicago. The hydraulic apparatus, which embraces several special features designed for this plant by Professor Williams, was built by James Leffel & Co., of Springfield, Ohio, and the electrical equipment by the General Electric Co. The Standard Roller Bearing Co., of Philadelphia, furnished the roller bearings on the generators. All of the equipment and apparatus was installed by the employes of the Edison Sault Electric Co., working under the direction of the engineer.



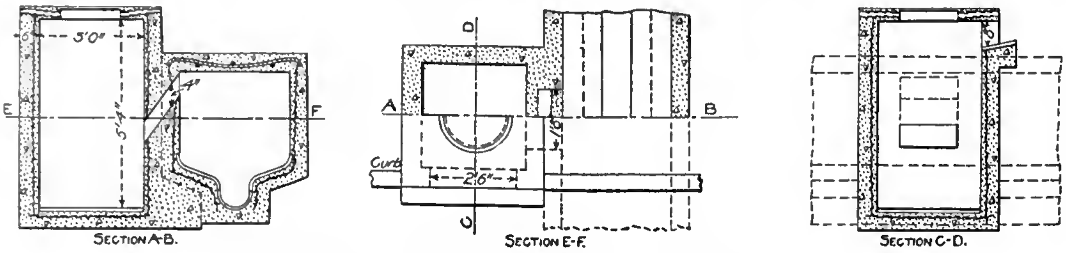
Sections of Headrace and Tailrace Channels, Sault Ste. Marie.

A Steam Motor Car has recently been put in service and others are being built by the Intercolonial Railway of Canada. In general appearance these cars resemble the combination passenger and baggage cars often seen in this country but the space reserved for baggage in such cars in this motor car is occupied by a locomotive boiler and coal bunkers. The locomotive is four-wheeled, and its wheels take the place of the regular passenger car truck at one end of the car. The car is 66 ft. long over the end sills and has a seating capacity for 52 persons. The locomotive is rated at about 200 h.-p. and is designed to give a speed of 25 miles per hour on a 1 per cent. grade. The cars are arranged to run either end first. Besides the boiler room and the main passenger section there is a baggage room and a smoking compartment.

Reinforced Concrete Sewers in Staten Island.

The Borough of Richmond, of the City of New York, includes all of Staten Island, which has a triangular form, with a maximum width and length of 7 and 14 miles, respectively. Its area is about 57¼ square miles. The island is hilly inland, but the shore land slopes back gradually for some distance, and is in many cases only a few feet above the elevation of mean high water. The hills are, in general, wooded or overgrown with brush and practically unsettled, but around the shore there are many villages. The total population is about 77,000. For many years the increase of population on the island has been very slow, but since the island became a borough of New York a more rapid increase has been noted, and it is considered probable that eventually the greater part will be well built up. The sewers of the borough are being designed, therefore, to meet the expected future conditions.

About 35 sewerage districts have been laid out, covering the entire island, but some of these districts are as yet only tentatively fixed. The districting has, of course, been determined by the topography; in general, it is expected that one main trunk sewer will serve as an outlet for each district. In some districts there are old separate sewers, and these, when in good condition, have been preserved, but the new sewers are all designed on the combined system. Up to the present time four main trunk sewers have been completed and two more are now under construction. Of these, three are interesting, on account of the somewhat unusual sections necessitated by the slight difference in elevation between the general ground level near the outlet and mean high water level, and the fact that the law requires all house sewage to be discharged beyond the pier-head line. Though a detailed topographical map of the borough, which will serve as a basis for designing street and sewerage systems, is being prepared, by methods described in The Engineering Record of July 20, 1907, this work is still in an incomplete state, and in designing the sewers it is necessary in many cases to make surveys to determine the most advantageous street grades and elevations of inlets and manhole tops as well as to fix the sewer grades.

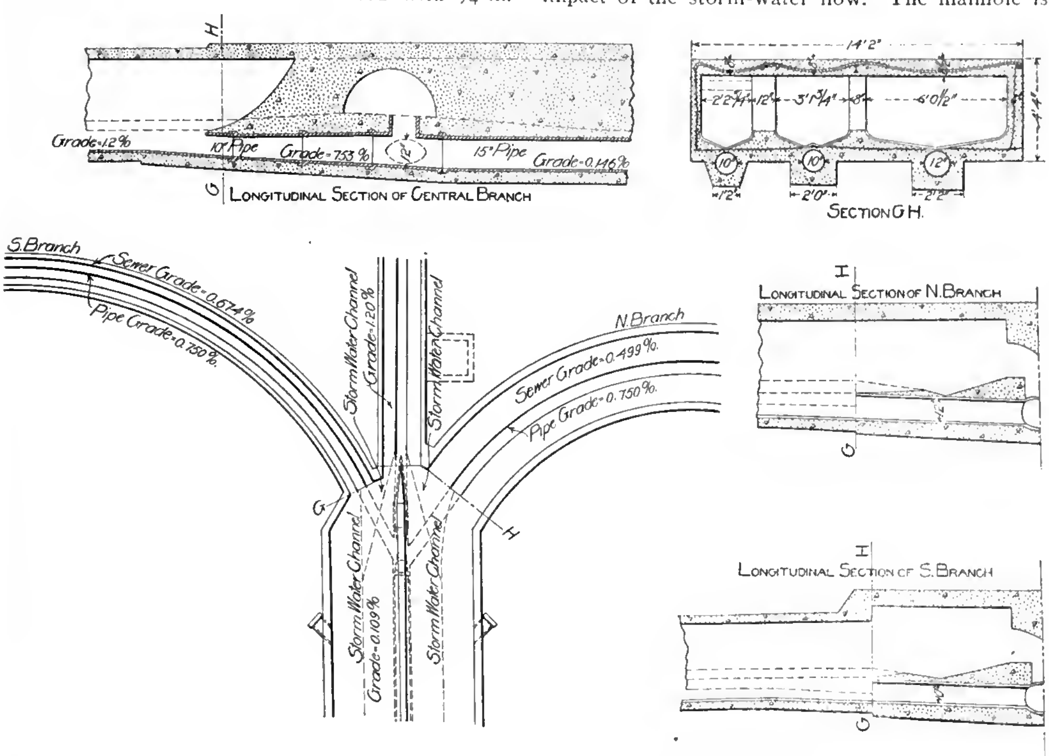


Catch-Basin for Flat-Top Sewers in Staten Island.

In order to avoid the expense of carrying the heavy construction of the main trunk sewers out to the pier-head line the expedient has been generally adopted of discharging the storm-water flow at the bulkhead line and carrying the dry-weather flow out the required distance through a cast-iron pipe supported on piles braced for rigidity. Where the difference in elevation between mean high water and the ground level requires a flat-top section, the invert is generally made nearly flat, also, except that in the center a depressed channel is provided for the dry-weather flow. The grade of the storm-water overflow is arranged so that sewage will not enter it, except during rainy weather, when the sewage will be so diluted as to become inoffensive.

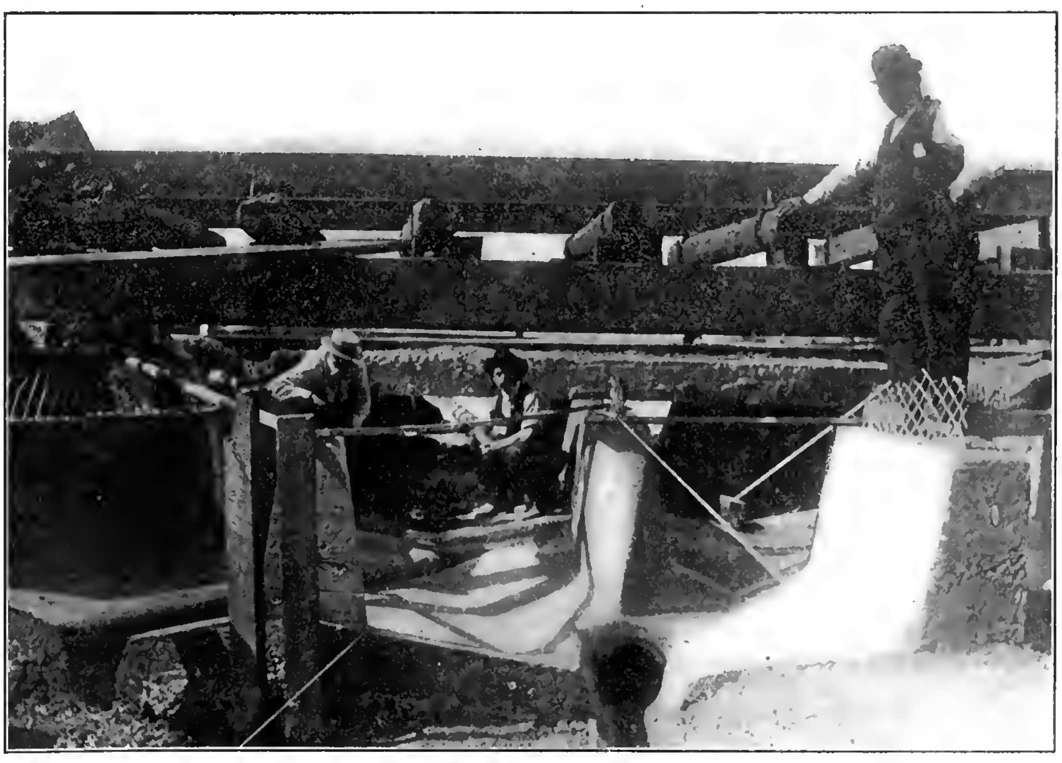
Trunk Sewer for District 6 A.—The trunk sewer for Sewer District 6 A, in the Fort Wadsworth section of the Borough, covering an area of about 366 acres, is now under construction.

The outlet end of the main sewer is at the bulkhead line, or at Sta. 5+10, according to the survey; from this point to Sta. 8 the sewer has, except for a few feet at the outlet end, in general a semi-circular invert 6½ ft. in diameter, lined with vitrified brick, and a flat reinforced concrete slab roof, the under surface of which is 2 ft. 8 in. above the springing line of the inverted arch. The side walls are vertical and are reinforced with No. 10 expanded metal, as indicated on an accompanying cross section. The roof slab is 8 in. thick and is reinforced with ¾-in. "old style" Johnson bars, both transversely and longitudinally, the former being placed 6 in. on centers and the latter 18 in. on centers. Over the top and on one side of this section of the sewer there is practically no covering material, the land being in general below the level of the roof slab. The sewer is close to the property line, and filling material cannot be placed on the property side; a covering of earth is to be placed on the top of the sewer and the street graded up, and to retain this in place the free wall on the property side has been carried up 8 in. above the top of the roof slab to form a curb. The flat-top section is laid on a grade of 0.823 per cent.



Junction at Upper End of Outlet Sewer, District 2A.

At Sta. 8 there is a reducer and the sewer changes to a circular section, 6 ft. 4 in. in diameter. This section continues to Sta. 15 on a grade of 0.881 per cent., the cover in this distance ranging from 0 to about 13 ft. At Sta. 15 there is a junction of two egg-shaped sewers, 4 ft. 6 in. by 6 ft. 9 in. and 3 ft. 10 in. by 5 ft. 9 in. These enter the circular outlet sewer on curves of 34 ft. and 36 ft. radii, respectively, and extend at right angles to the line of the outlet sewer in opposite directions. Just beyond this junction the 4 ft. 6 in. by 6 ft. 9 in. sewer enters a drop manhole, which was designed to reduce the steep grade and consequent excessive velocity of flow. These branches run back into the district to collect the flow from vitrified pipe and small reinforced concrete laterals. In design these egg-shaped sewers present no unusual features; the invert is in all cases lined with vitrified brick; in smaller sizes 1-3 split vitrified pipe forms the lowest part of the invert. The arch ring in all sizes is reinforced with No. 10 expanded metal. House connections are provided on all branches, placed about 20 ft. on centers on each side of the sewer.



Junction of Sewers above Outlet, District 17 A, Staten Island.

The drop manhole is built of brick and concrete, as shown in an accompanying cross-section, and is 24 ft. deep from top to bottom. The difference in elevation between the entering and leaving inverts is 8½ ft. A 20-in. cast-iron bypass pipe, arranged as shown in the drawing, is provided to handle the dry-weather flow, which is thus led quietly from one sewer to the other without the spattering which would prevail if the bypass was not provided. The flow through the bypass also forms a water cushion at the bottom of the manhole and breaks the heavy impact of the storm-water flow. The manhole is designed so that when the sewers are flowing two-thirds full or more a whirlpool will be formed in the vertical shaft, thus protecting the walls of the latter from the rush of incoming water. The bottom of the manhole is paved with trap rock blocks and has a sharp slope, as shown, to insure a good initial velocity of flow. The regular manholes, which are placed at changes of grade and at intervals of about 200 ft., where the grade is uniform, are built of concrete up to the level of the springing line of the sewer arch and above that point of brick.

To carry the dry weather flow the required distance from the end of the main sewer about 220 ft. of 20-in. cast-iron pipe is provided. Beginning at a point 22 ft. above the end of the main sewer the form of the invert is changed from semi-circular to a form designed to fit and enclose the circular end of the cast-iron pipe. This change is made in a distance of about 15 ft. The cast-iron pipe extends into the main sewer 7 ft. The pipe is carried 14 ft. beyond the end of the large sewer on a concrete apron, which consists of a 20-in. concrete slab reinforced near its upper and lower surfaces with expanded metal and carried by side and end walls, which enclose the supporting material and extend down 5¼ ft. below the top of the apron.

Beyond the apron the pipe is supported by pile bents 12 ft. on centers, two piles to a bent 2½ ft. on centers. Transverse caps, 10x12 in., slightly cut to fit the pipes, support the latter, which are securely strapped in place with galvanized iron bands. Guard pile bents are placed midway between the supporting bents, the piles of these bents being 4½ ft. on centers transversely and securely braced, both longitudinally and transversely.

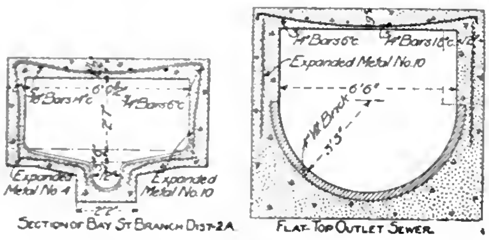
All the excavation for this sewer is being done by hand, but the methods of handling the spoil vary somewhat. For the greater part of the outlet sewer the depth of the trench required was in general only a little more than the depth of the sewer. The spoil in this stretch was thrown out by hand and but little sheeting was required. The 3 ft. 10 in. by 5 ft. 9 in. branch, however, for about 700 ft. is 19 to 25 ft. below the street. The construction of this part of the sewer is rendered particularly difficult by the unstable character of the clayey soil and the presence of a double-track street car line in the street. Where the work is in progress the cars are operated over a single track, the other having been taken up to make room for the trench. Two-by-ten-in. plain plank sheeting in 14-ft. lengths is used, two lengths being necessary to reach the bottom of the trench. Waling pieces are placed about 5 ft. on centers and are heavily braced to withstand the excessive pressure due to the passage of street cars and the weight of the earth. The sheeting is driven with a 100-lb

McKiernan steam driver. The ground water which seeps into the trench is carried away by two lines of 4-in. drain tile, one line of each side of the main sewer. These drain lines are extended as the work progresses and reach from the present point of construction to the outlet of the main sewer.

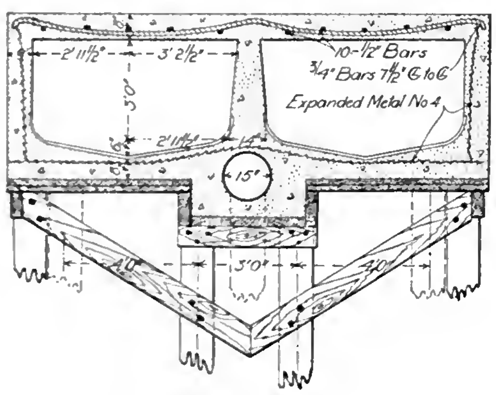
The spoil is shoveled into Hayward buckets, which are hoisted by a cableway and delivered over the completed sewer as back-fill. The cableway, which is 300 ft. long, was supplied by the Carson Trenching Machine Co. It is operated with a Lidgerwood engine and boiler mounted on a four-wheel truck platform, which also carries the A-frame headtower. The truck wheels run on plank runways.

The concrete, which is a 1:2:5 mixture of Phœnix Portland cement, Cow Bay sand and crushed trap rock, is mixed by hand on a platform spanning the trench and is delivered to place in buckets.

For the egg-shaped sewer now under construction wooden forms of the usual type are used for the invert and steel centers, supplied by the Blaw Collapsible Steel Centering Co., are used for the arch ring. The steel centers are greased slightly with linseed oil to prevent the adhesion of the concrete, and a very smooth surface has been secured by their use. They are drawn in 25-ft. sections, made up of ten 2½ lengths.



Sections of Staten Island Sewers.

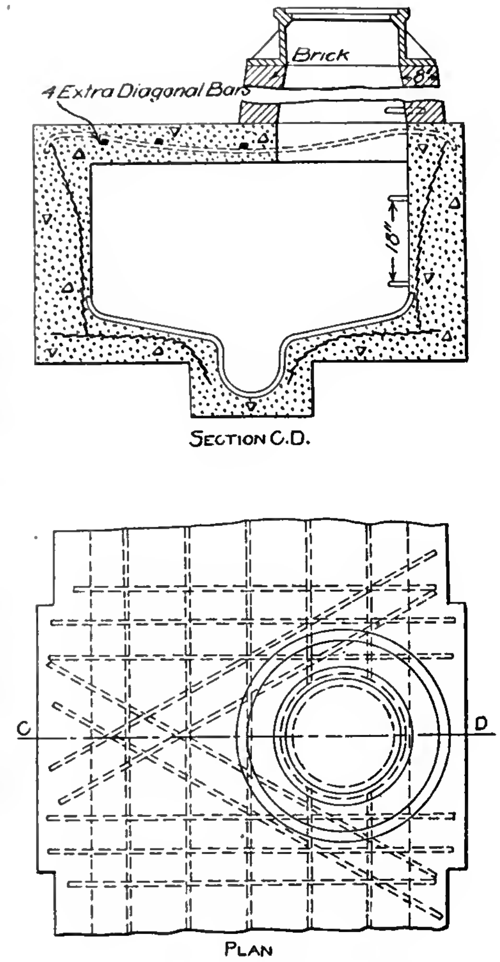


Outlet Sewer, District 2 A.

Trunk Sewer for District 2 A.—District 2 A, in the Tompkinsville section of the island, comprises about 155 acres. A great part of this area is very hilly, so much so indeed that 11 drop manholes are required in 1,500 ft. of sewer, the grade of the sewer being designed to limit the velocity of flow to 12 ft. per second when flowing full. On the other hand, Bay street, an important street in this district, paralleling the water front, is very low, being for some distance only 5 to 9 ft. above mean high water.

At the junction of Elizabeth and Bay streets two main branch sewers coming from opposite directions in Bay street meet another branch coming down from the hills in Elizabeth street, and the three join and are carried on in Elizabeth street to the bulkhead line, a distance of about 600 ft., by the main outlet sewer. Each branch sewer has a flat-top section, with vertical sides, and the invert sides slope gently toward the center, where a depressed channel is provided to carry the dry-weather flow. The section of the larger branch sewer in Bay street, which is shown in an accompanying illustration, is typical of the section of the other branches, the approximate sizes of which are shown in the section GH, taken at the junction point.

The outlet sewer has a twin-branch flat-top section and a 15-in. pipe conduit for the dry-weather flow. The storm-water section of each branch is 5 ft. 11 in. wide and about 3 ft. high, though both width and height vary slightly, as is shown in the cross section. The roof slab is reinforced both transversely and longitudinally with steel bars of the sizes and spacing indicated. The outside walls and floor are reinforced with expanded metal. The inverts are surfaced with a 1-in. coat of artificial stone, composed of equal parts of cement and trap rock screenings, applied and troweled to a smooth surface as soon as the rough work has set sufficiently to allow it. Pile foundations of the form shown are provided throughout the whole length of the outlet sewer.



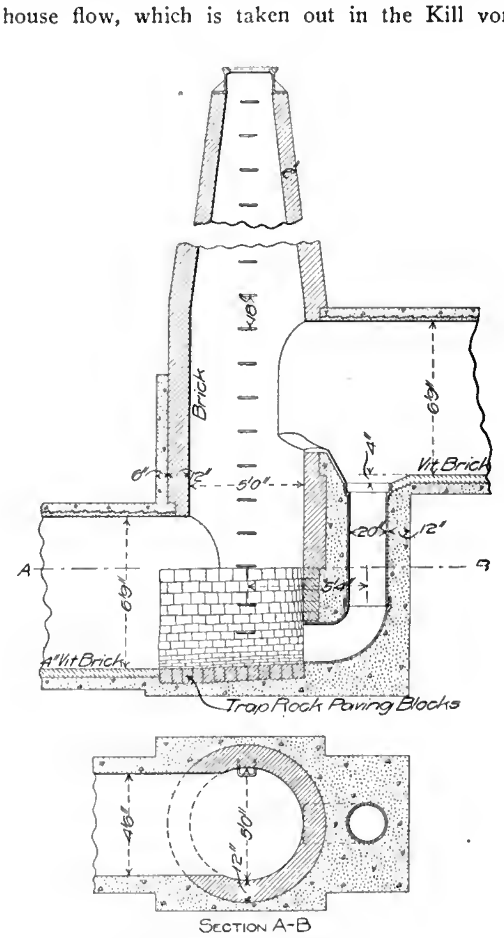
Manhole on Flat-Top Sewer.

About 300 ft. from the bulkhead line the sewer is crossed nearly at right angles by the double-track line of the Staten Island Rapid Transit R. R. The top of the roof slab is about 16 in. below the base of the rails, and the sewer is designed to carry the weight of the tracks and the live loads on them. The thickness of the roof slab is increased to 14 in., and it is reinforced transversely with ⅞-in. bars, 6 in. center to center, and longitudinally with ¾-in. bars placed in the same relative position as the longitudinal bars in the section illustrated. The thickness of the side walls is also increased. Batter piles are placed on the north side of the sewer under the east-bound track and on the south side of the sewer under the west-bound track to resist the thrust due to braking trains on the track.

The dry-weather flow will be carried from the end of the main sewer to a point 439 ft. beyond by a 16-in. cast-iron pipe line, supported on piles in the same manner as has been described in connection with the trunk sewer for District 6 A.

Owing to the low level of the main outlet section of this sewer a large part of the construction work has to be carried on during periods of low tide. The excavation was made by hand, the trench being made wide enough so that sheeting was not required. The piles were driven with considerable difficulty, owing to the presence of a large amount of old cribbing and riprap; the penetration, for the same reason, varied greatly, the maximum and minimum being about 42 and 12 ft., respectively. But little concrete has been placed as yet in connection with this work; Pennsylvania Portland cement is used with sand and trap rock in the same proportions as for the Fort Wadsworth sewer.

Trunk Sewer for District 17 A.—District 17 A, in the Elm Park section of the Borough, is served by three sewers, which are brought to a junction just above the outlet, to collect the house flow, which is taken out in the Kill von Kull by a 12-in. cast-iron pipe, supported on piles in the usual manner. The three main branch sewers are of the flat-top and depressed-channel type, very similar to those under construction in Tompkinsville, and the junction is much like the one to be built at Elizabeth and Bay streets.



Drop Manhole, District 6 A.

The outlet is of the twin-branch flat-top sort, each branch being about 2½x6 ft. It is crossed just below the junction point by a double-track street car line. The cover at this point is practically zero, and the rails are embedded in the rail-top of the sewer, so that the rail heads only 5 in. above the top of the slab. The outlet was constructed without interrupting traffic on the car lines.

The depressed channels of the sewers in this section are lined with sections of vitrified half pipe. This proved an aid to construction, for the pipe, with its bedding of concrete, was laid a little way ahead of the rest of the work all the time and served to drain the trench. The forms used were wooden, of the usual type. Building paper was laid over the top of the flat-top forms to give a smooth finish; this made it possible to use rough lumber and still secure satisfactory results. Phœnix and Atlas cement was used and Johnson "new style" bars. The concrete was mixed by hand.

To meet the same conditions that necessitate

flat-top sewers special catch basins and manholes have been designed. The manholes are built in general of brick, and the basins of concrete reinforced with expanded metal. Illustrations showing sections of a manhole and basin are given.

The engineering work for construction in the Borough of Richmond is under the general direction of Mr. Louis L. Tribus, Commissioner of Public Works and consulting engineer, and Mr. Theodor S. Oxholm, engineer in charge. Mr. L. W. Freeman, assistant engineer, has direct supervision of sewer work. The designs for the sewers described were prepared by Mr. Victor H. Richelt, assistant engineer. Messrs. Joseph Johnson's Sons, P. Hart & Sons and James Conley are the contractors for the sewers in Districts 6 A, 2 A and 17 A, respectively.

Foreshore Improvements at the Chalk Cliffs, England.

Foreshore improvements have been completed at Brighton, England, to check the erosion of the local chalk cliffs. The cliffs are 75 to 125 ft. high and have been cut back during the past eleven years at the rate of about a yard per year, according to "The Engineer," London. A highway and several public buildings on the cliffs were endangered in consequence. The foreshore consists of practically bare chalk, but there was apparently plenty of traveling material and a good supply of sand just below low-water mark. Accordingly it was decided to erect a series of groins perpendicular to the face of the cliff and extending to the low-water line to intercept the moving shingle and cause the formation of a protective covering over the chalk. They are made of 16-in. square columns between which are 6-in. concrete slabs. The columns are 5½ ft. on centers for the first 200 ft. from the face of the cliff and 7 ft. for the remainder of the distance to the low-water line. Their clear height above the chalk increases from 2½ ft. near the low-water mark to 8 ft. near the cliff. Grooves are formed in them to receive the slabs which are dropped into place and grouted fast. The slabs are formed in units 1 ft. high and not more than two or three units are placed at first; as the shore builds up more will be added. The columns are set in holes in the chalk and where necessary 10x10-in. concrete struts are built for additional support. Messrs. Owens & Case, of Westminster, are the engineers for the work.

THE COAL PRODUCTION in Pennsylvania in 1906 was 200,575,617 short tons, of which 71,282,411 tons was anthracite. This is an increase of 2.3 per cent. over the production in 1905. In mining this coal, there were 557 men killed and 1,212 injured in the anthracite mines, and 477 killed and 1,160 injured in the bituminous mines. In both classes of mines the major cause of accident was falling of the roofs. The State produced 48.4 per cent. of the total coal mined in the country during the year. These figures are furnished by the United States Geological Survey, which states that the rapid growth in the production of bituminous coal during recent years compared with that of anthracite forms one of the most interesting features in the statistics of coal mining. From 1876 to 1880 the average production of soft coal in Pennsylvania was 1.41 times that of anthracite, while from 1901 to 1905 the bituminous production was 4.08 times that of the other. In explanation of this change it is stated that for a number of years anthracite has been practically eliminated as a fuel for manufacturing purposes, and has been used almost entirely for domestic purposes in Eastern states. And now, even for domestic purposes, coke and gas are competing more and more with anthracite in the larger cities and towns.

Tests of Gasoline Engines Using Alcohol.

A brief mention has already been made in these pages of the elaborate tests made by Prof. C. E. Lucke and Mr. S. M. Woodward to determine the behavior of internal combustion engines using both gasoline and alcohol as fuel. The report is a profusely illustrated pamphlet of nearly a hundred pages, giving the details of many tests with eight engines of different types. The information regarding the tests themselves is too complex in its nature to be given satisfactorily in abstract, but some of the general statements in the report and the authors' summary of their conclusions are as follows:

The objects of this investigation may be put under two heads:

First, to determine whether gasoline and kerosene engines can run on alcohol as fuel. This involved the manipulation in making the engines run on alcohol, the measurement of the maximum powers of the engines when using alcohol and other fuels and last the relative consumptions of the different fuels.

Second, to determine the improvements desirable in engines manufactured especially for alcohol.

The engines used were: No. 1, a 15-h.p., 2-cylinder, vertical, 4-cycle gasoline engine; No. 2, a 6-h.p., horizontal, 4-cycle gasoline engine; No. 3 a 6-h.p., horizontal, 4-cycle gasoline engine; No. 4, a 6-h.p., vertical, 4-cycle gasoline engine; No. 5, a 6-h.p., horizontal, 2-cycle kerosene engine; No. 6, a 40-h.p., 4-cylinder automobile gasoline engine; No. 7, a 40-h.p., 4-cylinder automobile gasoline engine; No. 8, a 2-h.p., vertical, 2-cycle marine gasoline engine. The last three, of course, were high-speed engines.

Gasoline and kerosene are most easily examined by their specific gravities but since each is a mixture of numerous lighter and heavier oils, a constant density is not a guarantee that the composition may not change sufficiently to affect the action of the fuel in an engine.

Commercially pure grain or ethyl alcohol is sensibly pure except for the water which may be mixed with it. In this country alcohol is described according to its strength by stating the percentage of absolutely pure alcohol, by volume, which exists in the mixture of alcohol and water. Thus, 90 per cent. alcohol means that if the alcohol present could be separated absolutely pure, its volume would be 90 per cent. of the volume of the actual mixture of alcohol and water.

In France the strength of alcohol is described as in this country, but on the other hand, in Germany the strength is always expressed as percentage of alcohol present by weight.

In the statistics relating to alcohol, issued by the Commissioner of Internal Revenue, quantities are stated in "proof" gallons. A proof gallon contains 50 per cent. alcohol by volume, the remainder of the mixture being water; hence, a quantity of alcohol when stated in proof gallons is expressed by a number just twice as large as it would be if stated in gallons of 100 per cent. alcohol.

The denatured alcohol which may be used in engines in the United States must be prepared as follows, according to the regulations of the Commissioner of Internal Revenue: To 100 volumes of ethyl or grain alcohol of a strength not less than 90 per cent. there must be added either 10 volumes of methyl or wood alcohol and one-half of 1 volume of benzine or 2 volumes of methyl alcohol and one-half of 1 volume of pyridin bases. The substances added to the grain alcohol will probably not be of uniform quality, and hence there will be some variability in the properties of the denatured alcohol which will affect its use as a fuel.

The heat of combustion of the various petroleum oils varies between 19,000 and 21,000 B.t.u. per pound and 20,000 is used as an average value. The experimental value for pure alcohol is about 12,700 B.t.u. per pound.

By the formula for ethyl alcohol, C_2H_5OH, its molecular weight is 46. For the complete combustion of 1 molecule of alcohol the 2 atoms of carbon require 4 atoms of oxygen to form carbon dioxide and the 6 atoms of hydrogen require 2 atoms of oxygen, in addition to the 1 atom present, to form steam, thus making 6 atoms of oxygen in all to be supplied. The weight of the 6 atoms is $6 \times 16 = 96$. Hence complete combustion of 1 lb. of C_2H_5OH requires $96 \div 46 = 2.086$ pounds of oxygen. In 1 lb. of pure dry air there is 0.230 lb. of oxygen, so that the combustion of 1 pound of C_2H_5OH requires $2.086 \div 0.230 = 9.06$ lb. of air, or about 119 cu. ft. of pure air at a temperature of 60° and at sea level. If the alcohol contains water, 1 pound of the alcohol-water mixture requires less air than that stated. If the air is moist, 1 pound of it contains slightly less than 0.230 lb. of oxygen and hence more air would be required. In an actual engine the amount of air is proportioned to the amount of vapor, not by any exact measurement of either, but by trial to secure either the best results in maximum power or in minimum fuel consumption.

As with all substances which liquefy at ordinary temperatures, there is a definite limit to the amount of alcohol vapor which can exist in a cubic foot of space at any given temperature. Assuming the laws for perfect gases to hold, at any given constant temperature the weight of alcohol vapor present in a cubic foot of space is proportional to its vapor pressure and is usually measured or represented by this vapor pressure.

The vapor pressure of saturation increases rapidly with the temperature, and the values as determined by experiment for alcohol and some other substances at various temperatures are given in Table 1.

When different gases or vapors exist simultaneously in the same space, if they have no chemical action on each other, each one acts by itself just as though no other gas were present. But it is to be noted that in such a case the pressure as measured by a barometer column or pressure gauge would be the sum of the separate pressures due to the air and due to the alcohol vapor. If moisture were present it probably would have some effect on the alcohol-vapor pressure, because water and alcohol have a certain affinity for each other.

TABLE 1. VAPOR PRESSURE OF SATURATION FOR VARIOUS LIQUIDS, IN MILLIMETERS OF MERCURY.

Temperature. °C.	Temperature. °F.	Pure Ethyl Alcohol.	Pure Methyl Alcohol.	Water.	Gasoline.
0	32	12	30	5	99
5	41	17	40	7	115
10	50	24	54	9	133
15	59	32	71	13	154
20	68	44	94	17	179
25	77	59	123	24	210
30	86	78	159	32	251
35	95	103	204	42	301
40	104	134	259	55	360
45	113	172	327	71	422
50	122	220	409	92	493
55	131	279	508	117	561
60	140	350	624	149	648
65	149	437	761	187	739

Since alcohol, as used commercially, is always mixed with some proportion of water, a combustible mixture formed by the vaporization of such alcohol may become saturated with water vapor before it is saturated with alcohol and this may retard the complete vaporization of the alcohol. Such a state is more likely to occur if the air originally contains a considerable amount of water vapor—that is, if the relative humidity is high. In such a case a temperature higher than 72° would be necessary to maintain the required amount of alcohol vapor in the mixture.

In order that alcohol may change from a liquid

to a vapor, it must receive a large amount of heat either from the air with which it mixes or from the metal parts of the carbureter with which it comes in contact. The hotter these parts the more quickly the alcohol can absorb the requisite amount of heat. But if the air is too hot there is danger that the mixture of air and alcohol vapor produced may be too rich in alcohol and some of the vapor must remain unburned. Still, if the air be moist, or the alcohol contain water, or the time allowed for vaporization be too short, the temperature of the air must be higher than 72° to form a proper explosive mixture.

Air at any temperature will take up some alcohol vapor, and the higher the temperature the quicker it will take up the amount necessary for the best explosive mixture. In the case of incomplete vaporization, some of the fuel may be carried along as spray, which may or may not be vaporized in the cylinder on the compression stroke. If not, it certainly will be vaporized after the explosion of the rest. It would seem desirable, therefore, to heat considerably the air supplied to an alcohol carbureter. But too much heating of the air will bring about a bad effect on the engine, because it will make the charge hotter at the end of compression, and thus decrease the weight of the charge in the cylinder. The horsepower of the engine, other things being equal, will be decreased in direct proportion as the density of the charge is lowered by this heating, so that heating of the air before carbureting is good for complete vaporization, but bad if carried too far in its effect on power reduction.

The following general conclusions are drawn as a result of the investigations reported in detail above:

(1) Any gasoline engine of the ordinary types can be run on alcohol fuel without any material change in the construction of the engine. The only difficulties likely to be encountered are in starting and in supplying a sufficient quantity of fuel, a quantity which must be considerably greater than the quantity of gasoline required.

(2) When an engine is run on alcohol its operation is less noisy than when run on gasoline, its maximum power is usually materially higher than it is on gasoline and there is no danger of any injurious hammering with alcohol such as may occur with gasoline.

(3) For air-cooled automobile engines alcohol seems to be especially adapted as a fuel, since the temperature of the engine cylinder may rise much higher before auto-ignition takes place than is possible with gasoline fuel; and if auto-ignition of the alcohol fuel does occur, no injurious hammering can result.

(4) The consumption of fuel in pounds per brake horsepower, whether the fuel is gasoline or alcohol, depends chiefly upon the horsepower at which the engine is being run and upon the setting of the fuel supply valve. It is easily possible for the fuel consumption per horsepower-hour to be increased to double the best value, either by running the engine on a load below its full power or by a poor setting of the fuel supply valve.

(5) These investigations also showed that the fuel consumption was affected by the time of ignition, by the speed, and by the initial compression of the fuel charge. No tests were made to determine the maximum possible change in fuel consumption that could be produced by changing the time of ignition, but when near the best fuel consumption it was shown to be important to have an early ignition. So far as tested the alcohol fuel consumption was better at low than at high speeds. So far as investigated, increasing the initial compression from 70 to 125 lb. produced only a very slight improvement in the consumption of alcohol.

(6) It is probable that for any given engine the fuel consumption is also affected by the quantity and temperature of cooling water used and the nature of the cooling system, by the type of ignition apparatus, by the quantity and quality of lubricating oil, by the temperature and humidity of the atmosphere, and by the initial temperature of the fuel.

(7) It seems probable that all well-constructed engines of the same size will have approximately the same fuel consumption when working under the most advantageous conditions.

(8) With any good small stationary engine as small a fuel consumption as 0.70 lb. of gasoline, or 1.16 lb. of alcohol per brake horse-power-hour may reasonably be expected under favorable conditions. These values correspond to 0.118 and 0.170 gal. respectively, or 0.95 pint of gasoline and 1.36 pints of alcohol. Based on the high calorific values of 21,120 B. t. u. per pound of gasoline and 11,880 per pound of alcohol, these consumptions represent thermal efficiencies of 17.2 per cent. for gasoline and 18.5 per cent. for alcohol.

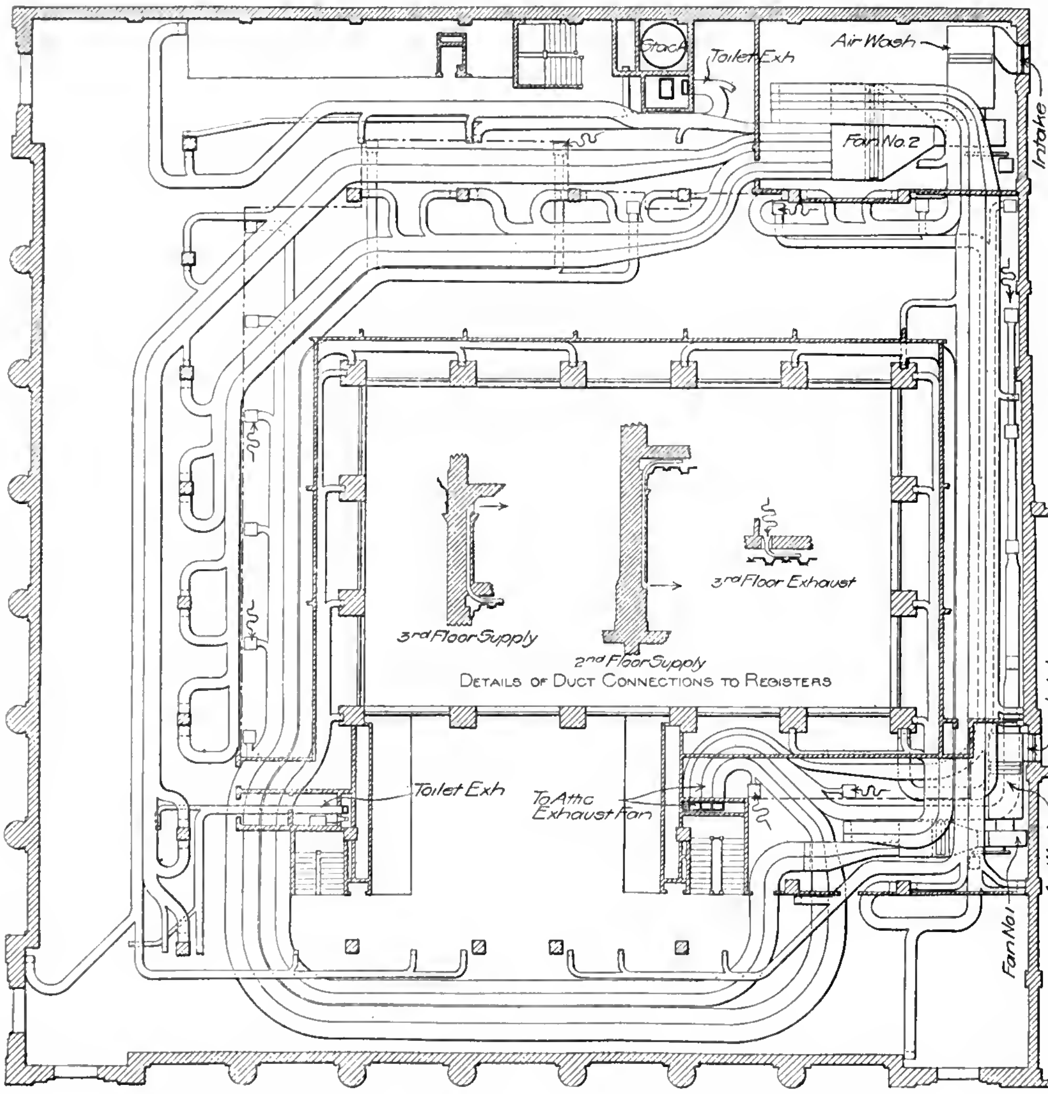
But calculated on the basis of the low calorific values of 19,660 B. t. u. per pound for gasoline and 10,620 for alcohol, the thermal efficiencies become 18.5 for the former fuel and 20.7 for alcohol. The ratio of the high calorific values used above is, gasoline to alcohol, 1.78. The corresponding ratio of the low calorific values is 1.85. The ratio of the consumptions mentioned above is, alcohol to gasoline, 1.66 by weight, or 1.44 by volume.

THE HIGH COSTS OF OPERATION at Poplar, England, near London, are reported to be the cause of the coming removal to Scotstown, in the Clyde Valley, Scotland, of the large shipbuilding and engineering works of Yarrow & Co.

Heating and Ventilating the Commercial National Bank Building—Part II.

Ventilation.—Mechanical ventilation has been provided for the lower floors of this building to a considerable extent, in addition to the usual exhaust ventilation from toilet rooms, the extensive banking offices and safety deposit department of the Commercial National Bank being fitted for both fresh air supply and exhaust ventilation, while separate ventilating systems are installed for the basement and sub-basement storage and auxiliary rooms, the engine room, the boiler and pump room, and for hot blast in the building entrances in winter weather. For this service seven fresh air supply fan systems have been installed, having an aggregate capacity of 142,330 cu. ft. per minute and three exhaust fans of an aggregate capacity of 41,515 cu. ft. per minute. An interesting feature of the ventilating installation is the use of air-washing systems for all fresh air supplies, except that to the engine and boiler and pump rooms, allowing air intake connections at low levels through the side walls of the building without unpleasant results from the dirt and dust that would otherwise be obtained from this source. Ventilation is effected by admission of fresh air at points in or near the ceilings of the rooms supplied, while foul air is exhausted through registers at or near the floor line, and the air supply is tempered automatically by thermostatic control. Both tempering and reheating coils are used with the supplies having air wash systems and tempering coils only for the two systems fitted with cheese-cloth filters.

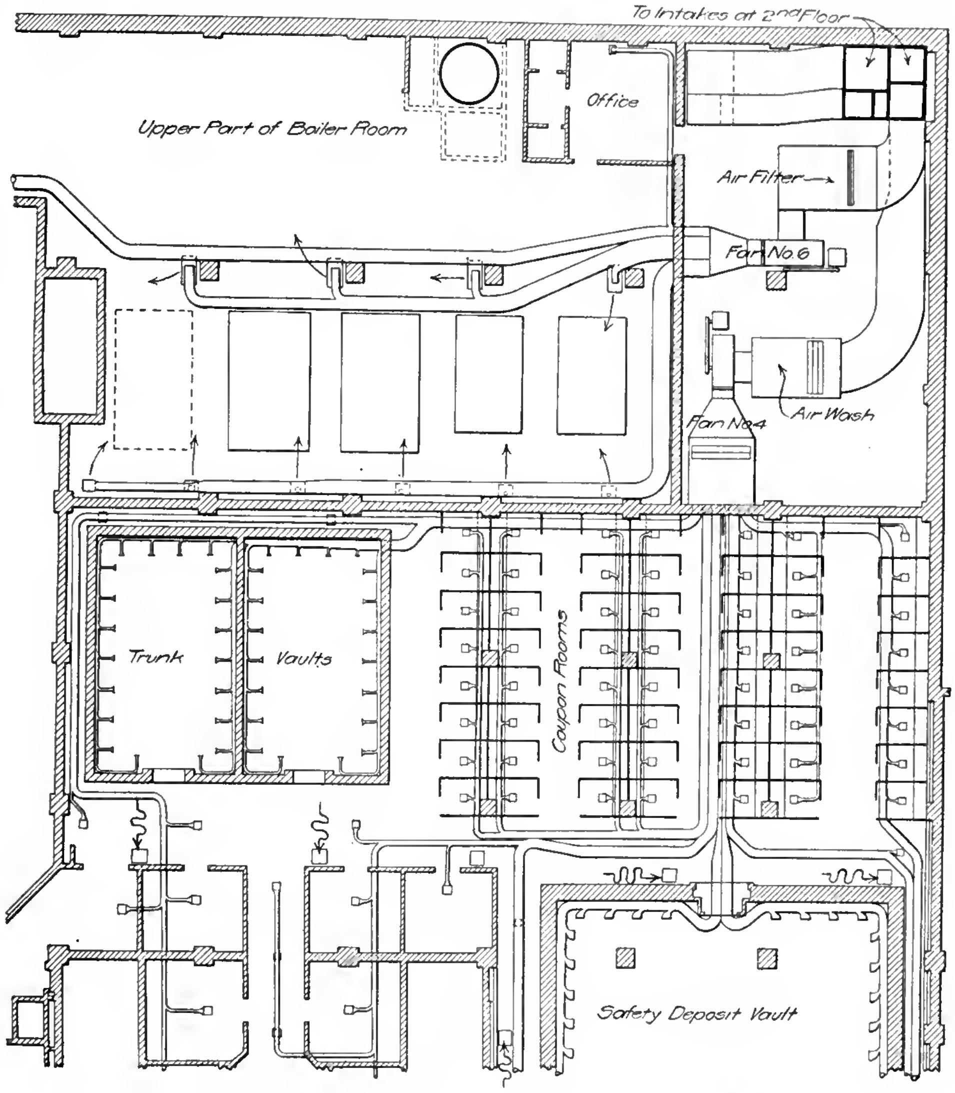
The ventilating services in the different parts of the building are sub-divided and separately operated so that each is entirely independent of



Ventilation of the Bank Division, Commercial National Bank Building.

the other at all times. The banking division which occupies the second floor, the mezzanine and the third floor is supplied with fresh air by two fan equipments, one for the second floor and mezzanine, and the other for the third floor, both of which are located in enclosures at the east side of the third floor convenient to direct intakes through the outside walls to open court spaces. The safety deposit department, which occupies a large portion of the basement, is ventilated by an independent fan equipment located at the northeast corner of the basement with an extensive system of distribution ducts extending principally to the confined spaces and small coupon rooms in the basement, while the street entrances are served by hot blast equipment in the sub-basement for use in winter weather. The remaining spaces in the basement and sub-basement, such as store rooms, printing office, etc., as well as also the engine room and the boiler and pump rooms have each independent fresh air supply systems, although owing to proximity to steam using machinery, no tempering coils are installed in the fan intakes, and cheese-cloth filters only are used for cleansing the air supply. All exhaust ventilation is operated by fan equipments in the attic, separate systems being installed for exhaust from the safety deposit department, the third story of the bank division, and from the toilet rooms and janitor's closets on all of the upper floors. The use of separate systems, prevents the communication of odors from the mechanical plant or toilets to other parts of the building.

The principal dimensions of the ventilating equipment installed are presented, together with capacities of the fans and of heating coils, in the accompanying table. Each separate system has an extensive amount of distributing duct work, the arrangement of which and the location of outlets are well shown in the accompanying floor plans of the building. System No. 1, supplying the third story of the bank division, delivers air into a corridor surrounding the upper portion of the court space underneath the skylight covering the main bank floor area, delivery being made through 16 registers on the inner sides of building columns at this level. System No. 2, which is confined to the second story and mezzanine of the bank division, delivers air through four registers to the mezzanine gallery, through 10 outlets in the president's, directors' and other private offices and through 41 openings to the main banking division. The arrangement of these supply registers is such as to thoroughly distribute the air delivered, and these systems were designed to change the air approximately three times per hour in the banking division.



Ventilation of the Safety Deposit Department in Basement.

Provisions for exhaust ventilation from this division are made upon the third story level only, in the floor of which there are distributed 18 exhaust registers, 20 in. square, each designed to remove 700 cu. ft. of air per minute; these registers are installed in the outer portions of this floor level where partitions prevent free communication with the large central court space of the main banking division.

In the safety deposit department a somewhat greater proportion of supply is provided for, owing to the more confined spaces ventilated. Here is a safety deposit vault approximately 45 ft. square, to which 1,690 cu. ft. is supplied per minute through 26 register openings, two trunk vaults, 18 x 32 ft. in size each, each of which receives 910 cu. ft. per minute through seven outlets, 56 coupon rooms with separate supplies, which receive in the aggregate over 10,000 ft. of air per minute, and a number of committee and office rooms, which with the main corridor, receive the remaining 3,600 cu. ft. of the supply. The exhaust ventilation provided for from this division is, as will be noticed from the table, somewhat in excess of that for supply, there being a large number of exhaust registers distributed in the floors of the main room, the corridors between the coupon rooms and offices, the committee rooms, offices and toilet rooms. They are so distributed in the relation to the supply register outlet as to effect a positive circulation in all parts. It is to be noted that there are no exhaust vent connections to the vault, circulation being had only at such times of the day when the main vault doors are open. The exhaust fan equipment for this division is, like that for the third floor of the banking division, located in the attic to which duct connections are made through the sub-basement and a 36x42-in. flue extending up the pipe shaft to the attic space alongside of the smoke-stack enclosure. The proportions for supply and exhaust are such as to cause a complete change of air about four times per hour in this department.

Of the remaining systems, that for the main floor entrances was installed solely for the supply of hot blast at the outside entrances in severe winter weather for the purpose of diffusing with the cold air admitted and preventing cold drafts through the corridors. This system is necessarily simple, having a double duct connection to the main entrance to the building from Adams St. and a single duct to the Clark St. entrance. In the Clark St. entrance there are two registers delivering 3,000 cu. ft. per minute, and in the main Adams St. entrance, eight registers having a capacity of 12,000 cu. ft. per minute. These capacities were selected arbitrarily in view of the expected usage of the different entrances and the tempering of the cold drafts admitted thereby. The basement and sub-basement system, No. 5, is the smallest equipment installed, and supplies a printing shop, about 75 ft. sq. in the front corner of the basement with about 3,500 cu. ft. per minute, distributed through ten register outlets, while the remainder goes to a number of store rooms, locker rooms, etc., in the sub-basement, for the employees of the building. The engine room and boiler and pump room systems are each large equipments, intended solely for the supply of cold fresh air to the heated machinery sections and have extensive

systems of distributing duct work for diffusing the air thoroughly through these rooms. These systems are each proportioned to change the air in the rooms served about ten times per hour for the comfort of the workmen, the outlets being distributed alongside of building columns and along the side walls on either side, as indicated in the plan drawing. A considerable amount of exhaust is effected from these rooms by the boiler furnaces and also by the pipe shaft and enclosure around the steel smoke-stack which rises to a hooded outlet at the roof.

The remaining system, No. 10, serves to exhaust foul air from the toilet rooms on practically all floors of the building. In the lower floors numerous toilet and locker rooms are ventilated from the sub-basement to the second floor mezzanine, above which there is only a janitor's closet and a small men's toilet served on each of the floors, excepting the eleventh story in which the large public toilet rooms of the building are located. For the latter service extensive gathering duct connections are installed, there being an exhaust register located in the rear of each of the toilet enclosures of the extensive groups. This system exhausts about half of its capacity from the toilets below the fourth floor, and over 2,600 ft. per minute from the eleventh floor toilet rooms, while on the other upper office floors, there are uniformly two vent registers to each floor, one exhausting from a janitor's closet and the other from a small men's toilet, and in a number of cases connections to private toilets in special office suites, each of which draws at the rate of 50 cu. ft. per minute.

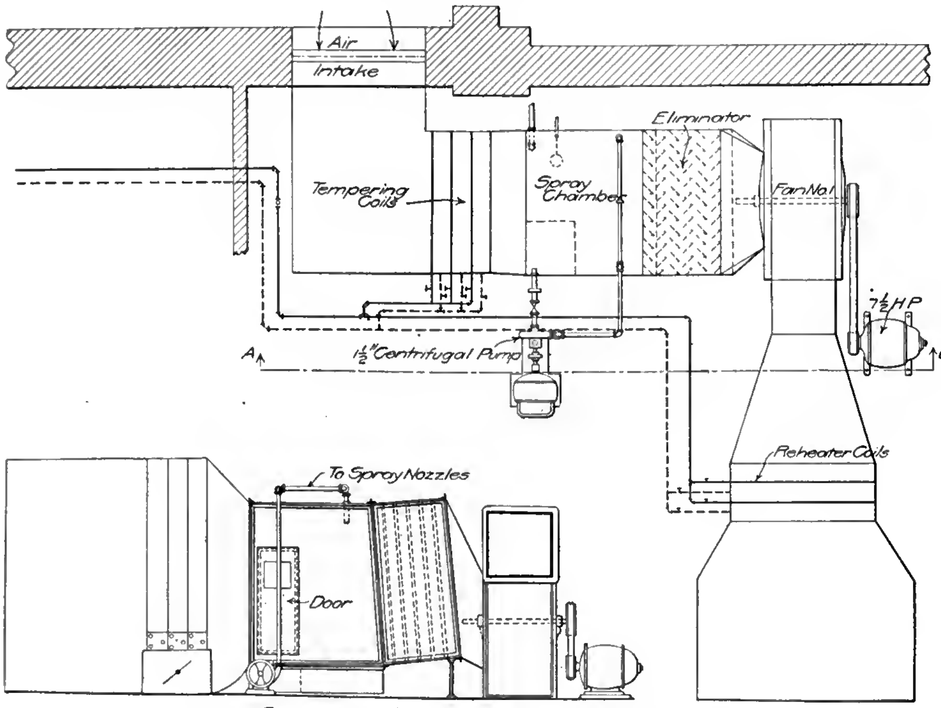
The fan equipments for these ventilating systems are, as above stated, located in three separate groups, those for the banking division fresh air supply on the east side of the third floor, the remaining fresh air supply fans in the sub-surface floors, and the exhaust equipment in the attic above the eighteenth floor. This arrangement of the fresh air supply apparatus was due in part to the use of the air wash systems which renders the locations independent of consideration as to points of intake of outside air. The two fans on the third floor have intake through ordinary windows opening into open courts at the rear of the building, while those located in the sub-surface floors have intake through ducts carried up to special screened intake openings at the rear corner of the building on the second floor level. In all five equipments fitted with air washing systems, there is in the intake connection a tempering coil for the purpose of preheating the incoming air sufficiently in extreme winter weather to prevent freezing of the spray of the air wash, after which the air is passed to the spray chamber. The air washing apparatus is of the Acme type, furnished by Thomas & Smith, Chicago, which has been previously described in these columns, and consists, in each case, of the spray chamber in which the air passes through an unbroken sheet of water spray and between the latter and the fan intake, a separator or eliminator, for preventing entrained water being carried along in drops into the fan intake. The spray chamber is an enlargement over the intake duct so as to greatly reduce the velocity of the incoming air, and in it are mounted on a pipe framework spray nozzles so placed as to effectively distribute the spray; the nozzles used are the Thomas No. 6 bar lock, circular spoon brass nozzles which are fitted for easily freeing themselves in case they are clogged by obstructions coming through the water piping. The eliminator consists of a series of narrow vertical baffle plates with hooked edges which are so placed as to cause the passing air to take a tortuous path and, as the entire eliminator chamber is inclined slightly upward toward the fan the moisture from the passing air is arrested by the baffle plates and forced downward toward the base of the chamber, where it drains back into the catch basin underneath. The water for the spray is used over and over continuously for a number of days at a time, being recirculated for this purpose by a motor-driven centrifugal pump. The catch basins all have service water supply connections with float valve control to maintain the water level against evaporation by the passing air and all pump suctions have double strainers to prevent obstruction of the piping. The principal details of one of the air washing equipments is shown in the accompanying illustration of the third story system, No. 1.

The fans, which were furnished by the B. F. Sturtevant Co., are of the centrifugal exhauster type with top horizontal discharge casings, and are all belt driven by slow-speed electric motors, operated from the power circuits of the building, which motors were supplied, together with those operating the circulating pumps of the air wash systems, by the Western Electric Co., Chicago. A feature of the duct connections to the fans is the use of canvas boots at the delivery outlets to prevent communication of vibration from the fan casings to the duct work. The boots consist of sleeves of No. 6 duck, 2 ft. in length, well sized and painted, bolted air-tight between the fan outlet and the reheater casing or duct line. The duct work systems are well fitted with dampers, tight closing dampers being installed in all of the intake connections near the outer walls and also for by-passing all heater coils for the purpose of reducing the temperature of the air delivered. At all branches in the duct lines, there are installed adjustable air splits which may be adjusted from outside of the duct to control the amount of air passing in the branches. The duct lines are fitted with cleaning holes, 10 in. square, located at all curves and at all branch connections to main duct lines. The ducts are of galvanized iron construction, heavily braced when greater than 256 sq. in. in cross section and are built of No. 22 gauge metal for lines of 4 sq. ft. area and larger, and of No. 24 gauge for smaller lines. Covering is applied to the duct lines only on the engine room and boiler and pump room systems, and between the intakes and tempering coils of the remaining fresh air supply systems, the covering being of ½-in. asbestos air cell blocks, lapped and canvas covered. The engine room and boiler and pump rooms system filters consist of screens of 1/16-in. mesh wire netting mounted on iron frames over which the cheese-cloth is tightly stretched, each screen being arranged to slide on rollers in independent grooves so that they may be easily removed for cleaning.

The heating stacks installed in all of the fresh air supply systems except those for the engine room and boiler and pump rooms, are of the cast-iron base type, installed in amounts of lineal feet of 1-in. pipe, indicated in the accompanying table, and were furnished by the American Blower Co., Detroit, Mich. Both tempering and reheating coils are installed in from 2 to 4 sections to enable adjustments of the heating surface to be made in accordance with the requirements of the rooms supplied, and all are fitted with by-pass dampers under thermostatic control for securing the desired temperature of delivery. The temperature controlling apparatus for the fresh air supply systems, which together with that for the control of the direct radiation, was supplied by the Johnson Service Co., is especially designed to maintain the temperature of the air delivered at 70° under all conditions. The control is, in the case of the fresh air supply systems, applied to the by-pass dampers underneath the coils while for the direct radiation, thermostats in the rooms controlled operate motor valves on the steam supply connections to the radiators.

The banking quarters of the building are equipped with a complete system of wiring for call bells, telephones, watchmen's service, telegraph, clocks, etc. A pneumatic tube system for transmission of documents, telegrams, etc., between the various departments was also installed by the Lamson Consolidated Store Service Co. The plumbing and sewerage was installed by M. J. Corboy, and that portion of the drainage below street sewer level is disposed of by a duplicate pneumatic ejector system installed by the Shone Co. Foundations for all machinery were installed by H. A. Bishop & Co., Chicago. The electrical equipment, including generating apparatus, was installed by the Brennan Electric Construction Co., of Chicago, and the elevator equipment by the Otis Elevator Co. The refrigerating plant which is installed for cooling water for the drinking fountains in the hallways is of the absorption type built by the Carbondale Machine Co., Carbondale, Pa. A vacuum sweeping system has also been installed by the Vacuum Cleaner Co.

The ventilating equipment was designed by the architects of the building, D. H. Burnham & Co., of Chicago, under the direction of Mr.



SECTION A-B

Typical Air Washing Equipment, Commercial National Bank Building.

John D. Small, chief mechanical engineer. Thomas & Smith, Chicago, were contractors for the heating and ventilating systems.

A Long Rope Tramway.

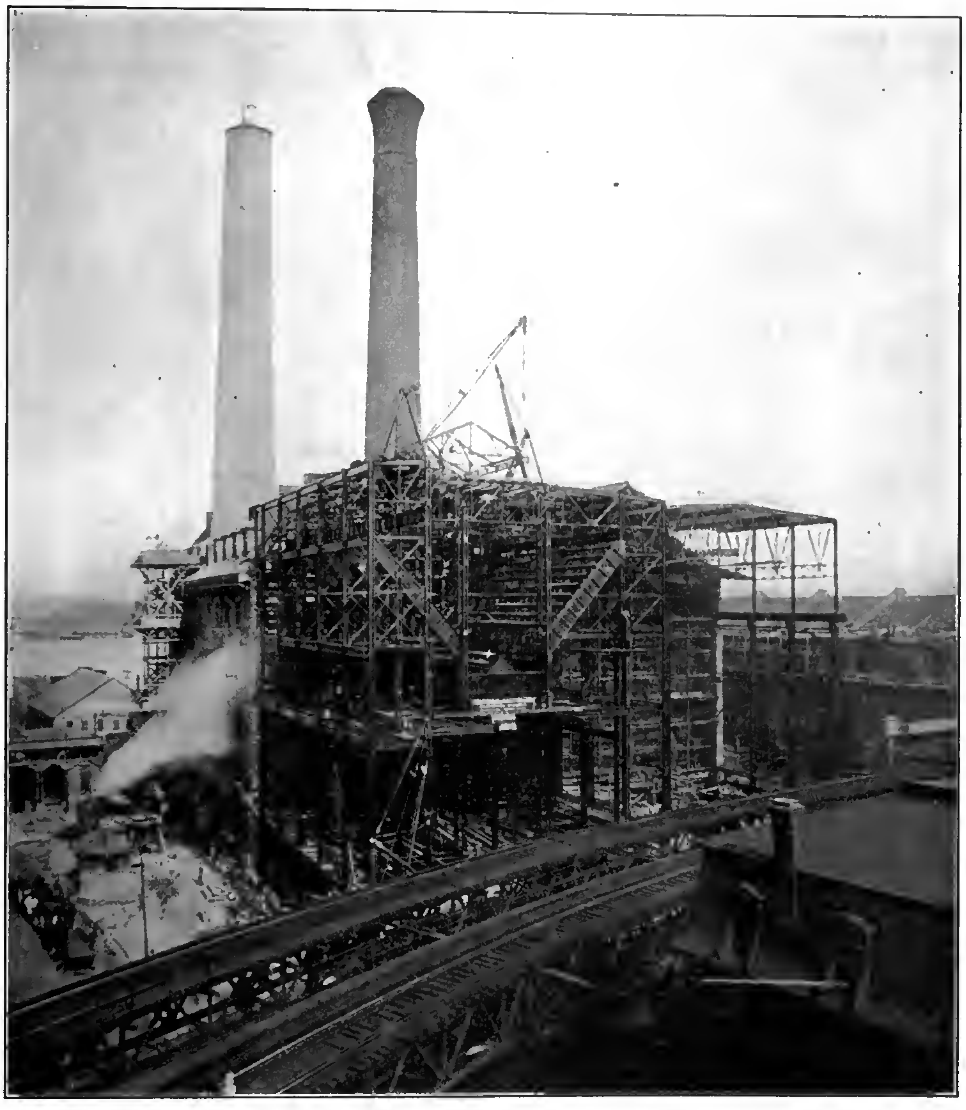
A rope tramway 4 km. long and overcoming a difference in elevation of 1,819 m. has been supplied by Ceretti & Tanfani to the Italian military authorities for building a fortress in the Italian Alps. The line starts at Cesana, where the power and loading station is placed. The first section is 1,230 m. long and runs to a station 484 m. above the lower terminal. Between these two stations are several intermediate supporting stations, the maximum distance between them being 400 m. The tramway cable for loaded buckets on this section of the line is a steel rope 24 mm. in diameter, and that for empty buckets is 18 mm. From the second main station there is a span 1,250 m. long, rising 750 m. to the third main station, from which the third section, 1,350 m. long, rises 585 m. higher to the upper terminal station. The tramway cables for the two upper spans are 28 mm. in diameter for the loaded cars and 24 mm. for the empty cars. The cars are hauled by a steel rope 20 mm. in diameter driven at a speed of 1½ to 2 m. per second by hydraulic power. The cars or buckets attached to the hauling rope are spaced 480 m. apart and each of them is rated with a carrying capacity of 400 kg. The tramway is in continuous operation, requiring 55 h.-p. and handles about 144 tons daily. It is stated to have cost about $60,000.

A Freight Movement of 8,630 cars in 24 hrs. is reported as having passed Lewistown Junction on the Pennsylvania R. R. on Sept. 29.

Erecting a Heavy Steel Building with Jinniwinks.

The Boston Elevated Ry. Co. has recently experienced a shortage of power and retained the Stone & Webster Engineering Corporation to investigate their power plants. The report recommended present relief by extensions aggregating about 12,000 kw. for the power stations at Lincoln Wharf, Boston; at Sullivan Square, Charlestown, and at Harvard Square, Cambridge.

The principal power station, at Lincoln Wharf was illustrated and described in The Engineering Record of August 17, 1901. It has a massive steel framework 92 ft. high from foundation line to top of main columns and consists of a one-story engine house 67 ft. 8 in. wide, and a parallel and adjacent boiler house 82 ft. 8 in. wide and three stories in height below the coal bunkers. The engine house has only two longitudinal rows of columns, one of which is on a center line between the two houses and serves for the boiler house also. In the boiler house there are six longitudinal lines of columns, including the one common to the engine house and in the engine house there are only two lines including the same common columns. All of the columns are arranged in transverse bents 17 ft. 7½ in. apart except at the outer end and form three 20-ft. center aisles and two side aisles about 10 ft. and 12 ft. wide in the boiler house and leave a single unobstructed floor space of the full width of the engine house. The coal bunkers 60 ft. wide, extend the full length of the building, and are nearly 60 ft. high from the foundation line to the bottom of the bin. They are made with horizontal transverse bottom girders 20 ft. long and inclined side girders about 35 ft. long over all supporting lines of longitudinal I-beams and tied together at the foot by horizontal eye-bars and at the top by the roof trusses, both passing through the bin. The roof trusses are riveted lattice girders about 6 ft. deep and 60 ft. long for the boiler house and 16 ft. deep and 67 ft. long for the engine house.



Erecting Lincoln Wharf Power House Extension.

In order to increase the boiler capacity it has been found necessary to extend one end of the building with a full width addition occupying a trapezoidal area 150 ft. 4 in. wide by 118 ft. 2 in. long on the long side, and 59 ft. 1½ in. long on the short side, including four regular transverse bents of framework and three special bents at the oblique end. The design was the same as that of the original structure except that it was made somewhat heavier to provide for increased loads, but the erection methods were different and are of interest on account of their simplicity and economy, and of the rapidity and successful results obtained by them.

It was at first intended to erect the new superstructure entirely with overhead movable derricks. Accordingly two steel jinnywink derricks were erected on the roof of the old part of the building and commenced operations by unloading the material from trucks and erecting it complete for the first panel, after which they moved forward on the steel work and erected the next two panels in the same manner.

As the building is situated in a congested part of the city where the street traffic is heavy and cannot be obstructed or interrupted, and as the sidewalk and elevated railroad structures come close to the building lines, it was impracticable to store any materials outside of the building or even to have trucks standing long there while being unloaded. It was therefore necessary to handle the steel work as fast as it was received, and in order to permit the rapid erection demanded by the rush order, it was also necessary to store material in advance of erection inside the building lines.

A guyed steel derrick with an 80-ft. mast and a 70-ft. boom was set up near the middle of the lower floors so as to command practically the entire area of the building and unloaded the bulk of the material. It also erected the columns, beams and girders up to and including the economizer floor on which it stored the material for the upper part of the structure.

Above the economizer floor the structure was erected by the jinniwink derricks moved forward on the completed panels and erecting the members of the framework from the bottom upward exactly as viaducts are erected by overhead travelers. After the completion of the boiler house, a 100-ft., 10-ton steel boom with a special Chicago foot block was set at the foot of one of the intermediate columns in the side wall of the boiler house near the middle of the extension so as to command practically the entire area and height of the engine house, and with it the engine house framework, consisting merely of the one row of wall columns and the roof trusses and connecting members, was erected.

The foot block was made with two 12-in. channels 15 in. long, with their webs 6 in. apart and their flanges turned inwards and riveted to two 12x¾-in. cover plates. The channel webs were punched for four 1-in. horizontal bolts through 12x12-in. horizontal timbers fitted between the projecting edges of the cover plates and forming the cantilever girder anchored to the steel framework of the building and supporting the boom beyond the outer face of the column which was utilized for its derrick mast. The cover plates were bored in the center for a 3-in. vertical pin with a 24-in. grip the upper end of which has a solid collar and engaged a cast-iron knuckle block with eccentric lugs bored to receive the 2½-in. horizontal boom pivot pin.

The jinniwink derrick had steel sills seated

on loose track timbers laid on the upper tier of beams and girders in the boiler house and were readily advanced by pushing forward by hand. The minimum erection gang of six men operating each jinnywink being sufficient for this purpose. The lead lines of their tackles were taken around snatch blocks to the capstan heads of two double-drum American Hoist & Derrick Co.'s engines located on the ground on opposite sides of the building.

The jinniwinks were simply small movable steel derricks of 7 tons capacity, weighing about 3,000 lb. each. The framework consisted essentially of a transverse and a longitudinal horizontal sill forming a T-shape base supporting two inclined shear legs in a vertical plane and one inclined back leg, with a 40-ft. boom pivoted at the intersection of the sills. Most of the members of the framework were made with pairs of 8-in. channels, back to back, latticed, and a second, shorter, transverse sill was attached to the extremity of one of the T-pieces to enable the jinniwink to be moved across open spaces between girders. The length, width and height of the framework were about 20, 12 and 16 ft. respectively.

Neither the guyed derricks or the 100-ft. boom were moved during erection, the latter being arranged to utilize one of the columns of the building for a mast. The field rivets were driven by Chicago Pneumatic hammers operated by air from an Ingersoll-Sergeant compressor. The work was very efficiently executed by a force which, when all six riveting gangs were at work with the erectors, numbered only about 40 men.

The building weighed about 900 tons and the contract for it and for the other two power house extensions was awarded Feb. 15, 1907. It provided that the shipment of steel from the shops must be commenced May 1st, erection commenced May 15th, and the erection of the framework so far advanced that the wall columns should be finished, riveted and painted in readiness for the construction of the wall masonry by July 1st. A bonus was offered for the completion of this work 15 days sooner than contract limit and another and larger bonus was offered for its completion 30 days in advance of contract time. The 30 days bonus was earned with two days to spare for the Lincoln Wharf Power House and with about two weeks to spare for each of the other power houses.

The work was designed and its construction carried on under the direction of the Stone & Webster Engineer Corporation. The contract for the steelwork was awarded to L. F. Shoemaker & Co. The structural steelwork was fabricated at their Schuylkill Bridge Works plant and the erection was directed by Mr. L. D. Rights, contracting manager.

An Automatic Ore-Weighing Machine, said to be the largest yet constructed, has been shipped from England by Messrs. Samuel Denison & Son, Ltd., to the Canadian Northern Ontario Ry. Co., for use at the Parry Sound coal depot of that line. The capacity of the machine is 800 tons per hour. The ore is delivered to a special belt conveyor, 36 in. wide, which travels at a speed of 600 ft. per minute. A continuous weighing apparatus operates in conjunction with the conveyor and a recording indicator shows the total net weight of ore handled in any predetermined period, the tare being deducted automatically. The weighing apparatus operates once every four seconds. The return run of the conveyor belt drives the recording mechanism and controls the weighing, so that slipping on the driving wheel and changes of speed of the belt travel do not affect the accuracy of the results, which, according to "The Engineer," are correct within one-half of one per cent. The English Board of Trade has sanctioned the use of these machines.

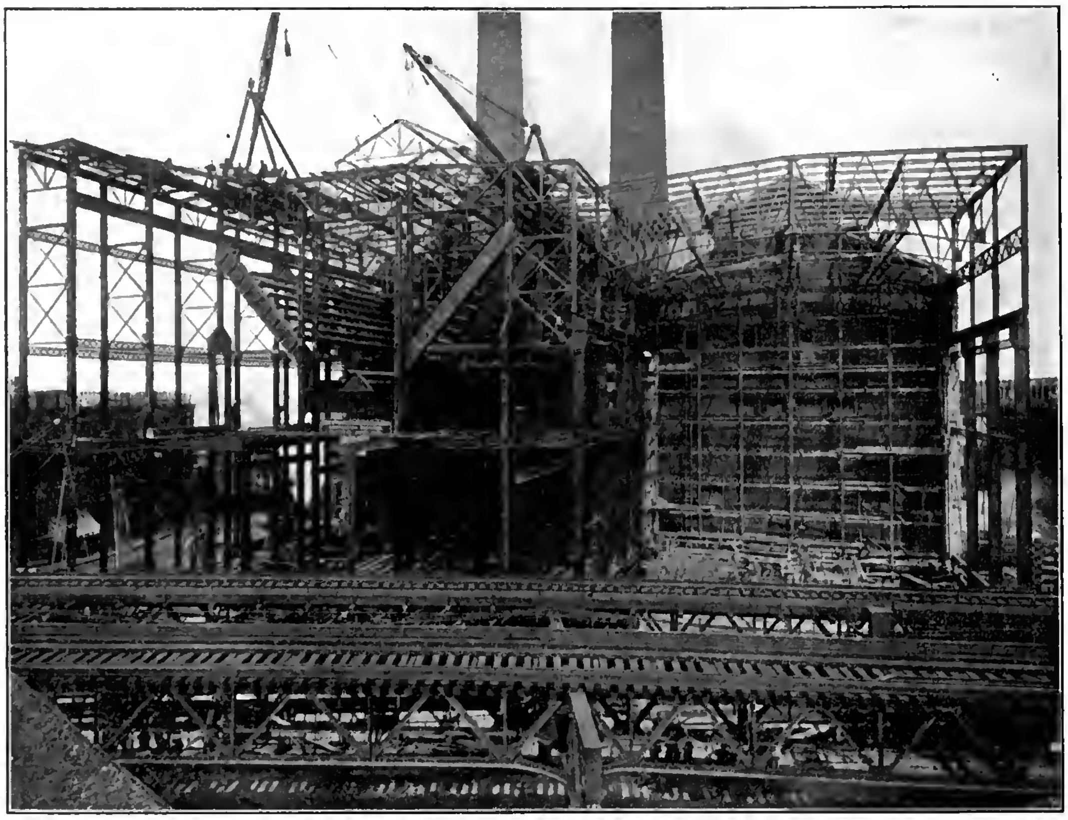
The Bracing of Trenches and Tunnels.

The sheathing and bracing of trenches and tunnels in dry and water-bearing materials were treated under the general subject of bracing in a paper on October 16, before the American Society of Civil Engineers. The paper, which was by Mr. J. C. Meem, was entitled, "The Bracing of Trenches and Tunnels, with Practical Formulas for Earth Pressures," and was printed in the Society's "Proceedings," Vol. xxxiii, p. 599. The following abstract gives the main points of the theoretical considerations of the paper.

The term "sheeting" is taken by Mr. Meem to mean that class of sheathing which is set in or driven coincidentally with the excavation. That class of sheathing which is driven ahead of the excavation or beyond its final limits, is referred to as "sheet piling." The general question of earth pressure, in connection with its action on sheeting and bracing, Mr. Meem believes has never been developed so as to reconcile the theoretical with the practical conditions, and he develops a practical basis for effecting an approximate reconciliation between the actual conditions of stability of earth and the theoretical formulas or resultants arising therefrom.

In all his experience, Mr. Meem has used the diagram, Fig. 1, for calculations of earth pressure, whether applied to retaining walls or to sheeting and bracing. If $B\ C$ be the line of the sheeting, and $D\ C$ the natural slope of the earth, b being the angle of repose, then the mass of earth causing pressure against the line, $B\ C$, is contained within the triangle, $D\ B\ C$. The weight of the earth in this triangle rests on $D\ C$, and its thrust is transmitted to $B\ C$, not through the toe of each layer at the foot of its slope line, but by the arching effect of this earth between the lines, $B\ C$ and $D\ C$. For purposes of calculation, it is probably not far from correct to assume that a line, $A\ C$, bisecting this triangle, $D\ C\ B$, measures with $B\ C$ an area equivalent to the weight transmitted as thrust against this line, $B\ C$. Also, it is true that the center of pressure against $B\ C$ is where a perpendicular from the center of gravity of the triangle, $A\ B\ C$, meets this line.

This assumption is going contrary to the general theory, which assumes that earth pressure acts along the line of rupture and parallel with that line, and is therefore greatest at the toe, but this theory is not borne out in actual practice, and all closely-sheeted, well-braced trenches invariably show a heavier pressure at the top than at the bottom. Any attempt to assume a theoretical condition which is contrary to this fact must be of little value to engineers in making practical calculations. Many retaining walls have been built from designs based on this theory; and Mr. Meem believes that it makes little difference, practically, which form of reasoning is applied to retaining walls. It does, however, make a vast difference which form of reasoning is applied to a braced trench, or to a concrete wall reinforced horizontally; and, while Mr. Meem does not contradict this theory, if based entirely on a theoretical condition of frictionless material, he does advise against its use in ordinary practice.



Jinniwink Derricks in Final Position on Boiler House Roof.

In other words, if it be assumed that $D\ C$ is a solid plane, and that the triangle, $D\ C\ B$, is filled entirely with particles which are absolutely without friction, and therefore the weight of one upon the other transmits accumulatively the weight of all entirely and directly to the bottom, then the truth of the theory noted above cannot be controverted. Such a condition, however, does not exist, and earth pressures and aqueous pressures are not similar; for, in dealing with ordinary materials, it is impossible to proceed with any practical calculations without taking into account the frictional resistance of these materials and their arching effects, which render it virtually impossible to consider their action as in any way allied to hydrostatic action. For instance, Mr. Meem has repeatedly observed where trenches have been sheeted from B to E, Fig. 1, and the excavation has been continued below E without sheeting, that cutting excavations have been made in loams, clays or moist sands back along the line, $E\ M$, by the use of light poling-boards driven in under the toe of the sheeting at E, without disturbing the stability of the mass above. If this sheeting had been so poorly put in as to cause the stability of the mass to be disturbed, it would have manifested itself by the continual dropping of masses of ma-

terial from above, rather than as a constant pressure, as would have been the case had the material been full of water or absolutely frictionless. And, if any small holes should be left between these poling-boards in absolutely dry sand, it would "bleed" in through these orifices just as the sand runs into an hour-glass, until the hole had gone to the top of the excavation, but at no time would there be observed any continuous pressure which could be defined in any way as equal to the entire weight of the sand from the bottom to the top over the unsheeted area.

It may be, as Mr. Meem has frequently observed, that the lower part of a trench may be left unsheeted, as from E to C, and for a considerable distance longitudinally in clays and moist sands, without disturbing the stability of the face, E C, and yet more or less heavy pressure may be observed in the bracing above. This can only be explained on the theory of the arching effect of the material above, one buttress of the arch being B E, and the other D C. If this be correct, there can be no doubt of the action being wedge-like, with the center of pressure opposite the center of gravity. Any engineer who has had to do with excavations must be aware of the fact that pressures are frequently developed in the top braces and rangers while men are excavating with impunity beyond the limits of

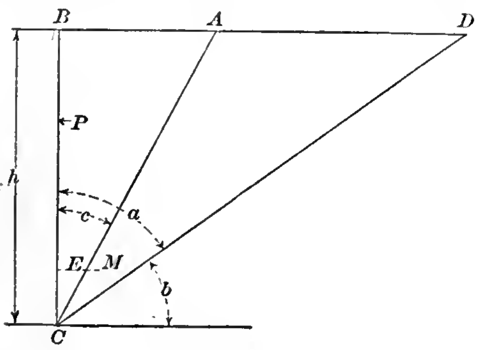


Figure 1.

the sheeting at the bottom of the trench. It is possible, also, at any time to cut or remove the bottom sheeting (except in dry sand) for a considerable percentage of the vertical distance from the bottom, and for indefinite lengths, without interfering with the stability of the bank above, provided the sheeting is removed without jarring. Any practical man, however, will admit that it would be suicidal to remove any one of the braces near the top of the excavation, particularly after the ground had stood for any considerable time.

The practical application of the foregoing will now be shown, and the formula be demonstrated. Let b (in Fig. 1) = the angle of repose, $a = 90° - b$, $c = a/2$, h = height = B C, and w = weight of 1 cu. ft. of earth.

Then, the area of $A\ C\ B = h \times h \tan. c \div 2$, and the weight of the mass of earth causing pressure on $B\ C = w\ h^2 \tan. c \div 2$.

The resultant pressure of this mass would occur at two-thirds of the height, or at P, in Fig. 1.

In the case of a well-sheeted and braced bank, there would be no overturning moment, but there would be a thrust, represented by the general tendency of the triangle, A B C, to slide along the line, A C, and therefore move out and exert pressure in a horizontal direction.

To understand this more clearly, it might be well to assume that the lines, B C A and D C A, are blocks of ice which are held in place along the line, D C, by their weight impinging on this line, and on the line, B C, by a rigid strut bearing against that line at P. If the pressure at P be slightly released, the whole triangle, B D C, will slide along D C and assume a new position. If, again, A B C be taken as a solid wedge bearing against a solid block, A C, and the wedge be forced down, then, in order that it may be resisted most effectually at any one point, this resistance should be placed at P. Or, in a word, Mr. Meem believes that the action of earth pressure in properly braced trenches is more closely allied to that of a coherent solid than to that of an aqueous or frictionless mass.

Mr. Meem believes that there is a limit of depth beyond which it is not possible to brace a trench against the pressures which would be developed, and he believes that this limit could be defined by a simple practical calculation, depending, of course, upon the nature of the soil through which the trench was dug. For example, if a trench be sunk 20 ft. and stopped, the pressure developed at the 15-ft. level will not be excessive, whereas if it be continued to 60 ft. the bracing will have to be heavily reinforced at the same 15-ft. level; and, if the trench be carried down to an indefinite depth, no bracing would eventually be able to withstand the pressures at this same point, owing to what may here be described in a homely way as the "topheaviness" of the bank. Anyone who has had to do with deep trenches or tunnels, however, must realize that an exposed face of earth is under no more

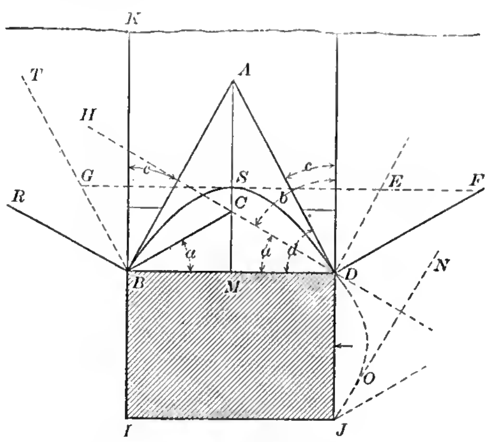

Figure 2.

pressure at the bottom of the deepest trench or tunnel than it is at the bottom of a shallow one.

As an illustration of this several of the bottom plates of a lined tunnel which had been driven at a depth of about 70 ft. by the shield method, were removed, exposing a face of moist sand. The latter was in as quiescent and undisturbed a state as though the exposure had been made only a few feet from the surface.

The danger in sheeting a trench arises mainly from three causes:

a.—In driving the sheeting carelessly and allowing slips to occur behind it; or, in the case of clayey soils, not properly guarding against voids which may occur behind the sheeting. The natural tendency of earth eventually to fill these voids causes slips, which develop not only the full pressures theoretically provided for, but frequently, by reason of the shock incidental to the velocity of slip, cause increased pressure to impinge against the sheeting and incidental bracing.

b.—In not fully tightening the braces by the use of wedges driven practically to refusal; and

c.—Because strata of quicksand may be uncovered in ordinary soil, thereby developing hydrostatic and unbalanced pressures on the sheeting and causing stresses not properly provided for.

There appears to be no controversy as to the generally accepted theory and formula in connection with bracing and sheeting and its relation to earth pressures in subaqueous or other soils so saturated as to be under hydrostatic pressure. If h equals the depth of saturated soil against a sheet pile and w is the weight of 1 cu. ft. of water, then the weight against a pile with a width of 1 ft. would be $w\ h^2 \div 2$, and the overturning moment $w\ h^3 \div 6$, taking the center of pressure at a point one-third above the base.

The next question taken up by Mr. Meem was earth pressures on tunnels or subterranean structures, where it is necessary to consider the other side of the pressure areas noted in the development of the formulas for pressures in open trenches.

Referring to Fig. 2, if it be assumed that B D J I is a tunnel (the area of which will be taken as a square, in order to simplify the assumptions), and that H D or D F is the natural slope of the earth above this tunnel then a = the angle of repose, b = the complement of the angle of repose, and $c = b \div 2$.

As a first assumption, it is unquestioned, of course, that all earth contained in the triangle, B C D, necessarily presses directly on the roof of the tunnel. And if the assumptions made at the beginning of this paper are true for open trenches, then it is also true that all the earth contained in the triangle, A C D, bears directly upon the line, C D, and therefore all this weight likewise is transmitted to the tunnel and all the pressure of the earth in the triangle, A D L, goes to the line, L D, arching itself somewhere below the triangle, B A D, in a curve approximating the line, B S D, so that, in a well-braced tunnel, the only pressure on the roof would be that due to the weight of the material below this line. In order to be consistent and carry out the line of reasoning in the original assumption, however, provision must be made for the pressures of all the material in the triangle, B A D. No pressure beyond the lines, B A and A D, can be transmitted to the tunnel unless the ground contains water in such quantities as to make the pressure hydrostatic. Of course, if the tunnel is a subaqueous one, the pressure on the line, B D, for purposes of practical calculation, must be that due to the hydrostatic head of the water measured by its depth to the line, B D, and by the width of the tunnel opening.

Returning again to earth pressures free from excess of water, it is found, of course, that the larger the angle, a, the greater is the resultant pressure upon the tunnel. It is possible that some may argue from this that the greatest pressure will occur in clayey soil where the earth stands vertically. This supposition, however, is erroneous, because, any soil which will stand vertically and continue to stand vertically under any circumstances must be considered in the same way as solid rock, and cannot be properly classed as material for which bracing is necessary. As a matter of fact, however, clays are treacherous soils for tunneling, and frequently develop pressures by squeezing or sliding horizontally, for which it is difficult to provide.

If, now, it be assumed that the square, B K L D, is made up entirely of blocks of ice (or frictionless solids) having an angle of repose of 90 deg., the full weight of this material would have to be provided for in bracing across the tunnel roof, B D. If, on the other hand, a material, such as dry sand, be considered, in which the angle of repose is very flat, the arching effect of this material comes more greatly into play by reason of its tendency to slide along the angle of repose, and therefore, the condition of least pressure that can come upon a tunnel in dry ground is where the angle of repose of the superimposed material is least, always providing the material is held by close sheeting. In a word, then, the greater the angle of repose the greater the pressure to be provided for, and this leads to the conclusion that dry sand of a small angle of repose would prove the best material for tunneling if it were possible to sheet and brace the roof absolutely without disturbing its equilibrium. In practice, however, it is, of course, impracticable to drive a tunnel through sand of any kind without having some movement of ma-

terial, and the dryer the sand, the more likely it is to run through any opening in the sheeting.

Here, again, it may be of interest to note that if a frictionless material could be imagined, resting in a trough made by the prolongation of the lines, *R B* and *D F*, measuring the angles of repose, allowance would probably have to be made for the full pressure of the weight of all the material contained within the prolongation of the lines of rupture, *B T* and *D E*. Assuming a case where a tunnel is so close to the surface that the arching effect is lost, for instance, if in Fig. 1 the surface of the ground be taken at *G E F*, it is probable that there would be obtained not only the full pressure of the ground directly above the opening, but an increase due to the lines of rupture, *B T* and *D E*. Therefore, Mr. Meem thinks it is always wise to discontinue tunnel operations when the surface of the ground intersects, or nearly intersects, the perpendicular line, *A M*; and it is within the reasonable limits of good practice to tunnel when the surface of the ground is fairly well above the point, *A*. It may also be of practical interest to note that any longitudinal trenching should always be avoided if possible over the line of a tunnel while it is being excavated owing to the consequent destruction of the key to the arching effect of the ground.

As to the actual pressure: Let l = the width of the tunnel; $A\ M = h = l \times \tan.\ d \div 2$.

Then the area, $B\ A\ D = l\ h \div 2$, and, assuming that a = 34 deg., then c = 28 deg. and d = 62 deg.; and the tangent of d = approximately 2; and l, of course, = h.

The area, $B\ A\ D$, therefore, becomes $l^2 \div 2$, and $w\ l^2 \div 2$ = the total weight per lineal foot of tunnel, where w = the weight of earth per cubic foot.

As to side pressures, the pressure against the sheeting, *D J*, continues along a line of rupture, *J N*, stopping at some indefinite point, which, for practical purposes, may be taken at *O*, and making the only actual pressure in closely-sheeted work approximately within a line measured by the curve, *D O J*. An excess allowance covering conditions of sheeting, ground, etc., in which judgment is a large factor, should be used in all calculations relating to the question of side bracing, to give a proper factor of safety in connection with this somewhat indeterminate quantity.

As to the question of shaft bracing, Fig. 3 is a cross-section of a square shaft of an area sufficiently small to give the surrounding earth a tendency to arch itself horizontally, it being very probable that such a shaft of reasonably small dimensions and driven as here shown will develop pressures somewhat as indicated by the circumscribed circle. It appears to be reasonably fair to assume that a circular shaft of not too large diameter, driven in dry ground or moist sand, will arch itself so that very little pressure is exerted on the bracing in excess of that originally developed in making the sheeting and bracing tight. This excess pressure is small and indeterminate in actual practice, and may be measured by the intersection of the lines of the arching effect in a horizontal plane and the lines of rupture in a vertical plane, and somewhat as shown in the vertical section in Fig. 3. This pressure varies, of course, in direct proportion to the care with which the sheeting was originally placed. In view of this, it is true, both practically and theoretically, that a small shaft may be driven to any depth without developing any greater pressures below than are found near the surface. As soon, however, as the shaft becomes so large that the horizontal arching effect is destroyed, the action of the pressures becomes the same as the bracing in an open trench, and therefore it would be impracticable to sink to any great depth a shaft the dimensions of which were such as to put it in the same category as trenches.

Mr. Meem showed a photograph of an underpinning pit sunk to a depth of about 18 ft. by the use of horizontal or well-diggers' sheeting. The bottom of this pit is at the level where ground water has been struck, and is there sheeted with interlocking steel sheet piling driven some 5 ft. into the ground to bring its toe well below the sub-grade of the adjoining excavation for which the underpinning is required. This pit can now be pumped out and excavated without danger of bringing in sand, and can then be filled with concrete to form a proper foundation for supporting underpinning timbers. Mr. Meem has personally supervised the work of sinking numbers of similar pits for different purposes, some to depths of 45 ft., without other bracing than the horizontal sheeting noted above, each set alternately bracing the other. It is also known that pits of this character, and not more than 5 ft. square, have been sunk by well-diggers to a much greater depth than those noted without using any bracing other than the sheeting of the character described above.

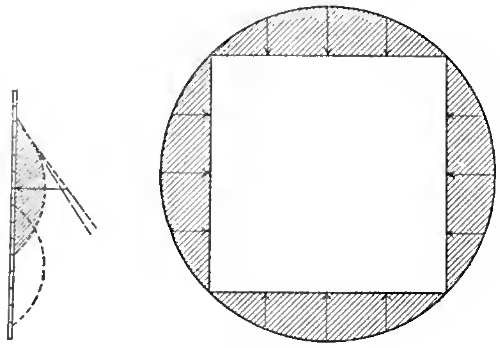

Figure 3.

Mr. Meem believes that the practice of lining circular manholes with masonry walls the thickness of which increases with the depth is not consistent with good designing, and that a circular shaft may be safely designed with a masonry wall which has the same thickness at an indefinite depth as it has near the surface.

The remainder of Mr. Meem's paper illustrated and discussed a few general types and methods of sheeting and bracing, including subway work near the surface and various types of tunnel work.

In closing, Mr. Meem stated that he had written the paper for two main reasons: First, he believes that the subject of bracing and its relation to earth pressures is not properly provided for in the ordinary data and formulas and he hopes, either in this paper or in the resultant discussion, that the question may be established beyond controversy, and on a basis which will be of practical value to engineers and contractors. Second, Mr. Meem believes that insufficient consideration is given to the subject of bracing by engineers in general, it being ordinarily deemed sufficient to leave this question to more or less intelligent foremen; and, while it is not intended to impeach in any way the intelligence of any foreman, it is thought that the subject is one requiring more engineering consideration than is ordinarily given to it.

The Concrete Ties which were placed in the track of the Chicago & Alton R. R., near Lockport, in 1905, are stated to be wearing well, although subject to a heavy traffic. The ties are of the type designed by Mr. G. H. Kimball, of Detroit, and consist of blocks of concrete 3 ft. long, 7 in. high and 9 in. wide. Two of these blocks are connected by a pair of 3-in. channels so as to form a tie of dumb-bell appearance. The rails are carried on top of the concrete blocks by pieces of hardwood, bolted to the concrete and receiving the regular rail spikes.

Book Notes.

A little book which will be helpful to railway surveyors is Messrs. E. F. Hauch and P. D. Rice's "Tables of Quantities for Preliminary Estimates," a title that is a bit misleading, for nearly all the contents relate to a single method of calculating the volume of an embankment. The method followed by the authors is based on a cross-section triangle having for its sides the slopes of the embankment, and for its base the natural transverse slope of the ground. In the tables these slopes are ¼:1, ½:1, ¾:1, 1:1, 1¼:1 and 1½:1. From the area of this triangle was deducted that of the isosceles triangle having for its base the roadbed width, and the remainder was multiplied by 100/27 to give the results in the tables. The tables were checked by a method explained in the book. The roadbeds for which tables are given have widths of 12, 14, 16, 18, 20, 22, 24, 26, 28, 30, 32 and 35 ft., and for each width and side slope the volume of the section is given for center heights varying by 1 ft. from 1 to 50 ft. There are also tables of toe slopes, cubic yards in 100-ft. sections from the sum of the end areas, decimals of a mile expressed in feet, acreage for a 100-ft. right-of-way, equivalents of chains in feet and feet in decimals of a chain, and fractions of an inch in decimals of an inch and a foot. (New York, John Wiley & Sons, $1,25.)

An important contribution to the published information on industrial disturbances is the volume on "Strikes and Lockouts" forming the report of the U. S. Commissioner of Labor for 1906. It is a book of nearly a thousand pages giving the results of an investigation of this subject for 1901-1905 inclusive and summaries covering the period from 1881 to 1905 inclusive. In the 25-year period there were 36,757 strikes and 1,546 lockouts lasting more than one day. Strikes occurred in 181,407 establishments and lockouts in 18,547, making a total of 199,954 places affected in this way. The number of employes thrown out of work because of strikes was 8,703,824, and the number of those locked out was 825,610, making a total of 9,529,434 people, exclusive of those who were idle on account of shut-downs, which resulted in other industries than those in which these troubles were actually occurring. Of the 36,757 strikes, 69 per cent. were ordered by labor unions, and of the 181,407 establishments involved in strikes, 90 per cent. were included in strikes ordered by labor unions. The average length of a strike was 25.4 days. The employes succeeded in winning all their demands in 48 per cent. of the establishments, partly succeeded in 15 per cent. and failed to win anything in the remaining 37 per cent. Lockouts lasted 84.6 days on an average. They resulted wholly in favor of the employers in 57.2 per cent. of the establishments involved, were partly successful in 10.71 per cent. and failed in 32.09 per cent. The most common cause of strikes was a demand for more wages, which alone was at the bottom of 32 per cent. of these disturbances and was a partial cause of about 8 per cent. more. The cause next in importance was a demand for recognition of unions and union rules. Over half of the lockouts were caused by a refusal to recognize union demands. Over a quarter of all the strikes and over a third of all the establishments they affected were in the building trades. About 25 per cent. of the strikers were in Pennsylvania, 21 per cent. in New York, 13 per cent. in Illinois, 6 per cent. in Ohio, and 5 per cent. in Massachusetts. The volume contains a great mass of statistics on the subject, and also a large amount of information regarding strikes and lockouts in other countries. (Washington, Department of Commerce and Labor.)

The fifth edition of Mr. Edward Wegmann's "Design and Construction of Dams" has been thoroughly revised so that the new theories of the design of masonry dams and the many important recent structures of both standard and novel character are explained. This edition contains 93 more pages, 39 more plates and 45 more figures than appeared in the edition of 1904, and a considerable part of these additions give information not readily found elsewhere. The book has been regarded for so many years as one of the standard American engineering treatises that it is hardly necessary to give any long review of its contents, which cover all types of fixed and movable structures for impounding water. (New York, John Wiley & Sons, $6.00.)

Letters to the Editor.

Rock Tunneling Machines.

Sir: In the number of your paper for Oct. 19 I was very much interested in the article on the machine for tunneling in shale. I send you a photograph of a small section of the tunnel which the machine bored before it was removed. The total distance bored was about 2 ft. We all regretted very much the failure of the machine to carry out the work.

Yours truly,
H.

A Reinforced Tile Wall.

Sir: As bearing on the note in your paper of Oct. 12 concerning reinforced brickwork, I would call your attention to a test of a partition wall in the Criminal Court Building, Berlin, designed by me while chief engineer of the Lolat Concrete-Steel Construction Co. of that city. The belief that brickwork containing steel reinforcement was about as "monolithic" as reinforced concrete led me to propose such material about four years for some 170,000 sq. ft. of partitions. The wall built for a test consisted of two thin walls of porous brick or tile. Running lengthwise of the wall at four of the longitudinal joints were ⅜-in. rods, two rods being used to each of the three upper sets of reinforcement and four in the bottom set, which was in a joint close to the floor. The wall was tested by laying transverse I-beams across the top and suspending a platform from their ends on each side, and then loading the platforms. This wall was one of seven submitted in competition, and although it contained the smallest amount of steel it had the highest test load. In fact, it was impossible to cause any cracks or marked deflection by any load that could be applied.

Yours very truly,
O. Gottschalk.

Chicago, Oct. 18.

Restricting Competition on Local Work.

Sir: From investigations of the past records of public work, we are of the opinion that proposals for public work are not advertised in over 20 per cent. of the work let. The lack of this publicity causes little, if any, competition, and it permits a few local contractors to take work at high figures, and also permits illegal combinations between a few local contractors, resulting in the pooling of bids at the city's expense. In our work in something over 130 municipal plants, we have always adhered to the policy of advertising the work in some engineering and contracting papers. An investigation of Oklahoma and Indian Territory records show twelve waterworks plants installed in the last year, none of which were advertised except in the home paper, the work going to a combination of two or three contractors whose engineer withholds the publicity of the letting.

We are writing to suggest the advisability of a certain movement on the part of engineering and contracting papers to attempt to get legislation in the different States, compelling the advertisement of public work in engineering and contracting papers. This could especially well be taken up with the new State of Oklahoma, where laws will soon be made pertaining to public work. We believe, however, that similar legislation could be recommended and passed with slight opposition, and perhaps no opposition, for representatives from the cities would realize at once that this would result in saving much to the cities.

Knowing that you are interested in this matter, we would be pleased to receive your ideas and any suggestions you may have along this line.

Very truly yours,
Burns & McDonnell.

Kansas City, Oct. 22.

[The opinions of The Engineering Record on this subject have been stated at considerable length on several occasions, the last time on July 4, 1903. Assuming that a failure to advertise proposed work in journals of wide circulation is due only to a desire to restrict competition to local contractors, which is generally the case, it follows that such a plan simply results in throwing large contracts into the hands of people without resources for handling them. Local contractors of experience and business standing can underbid outside contractors on works up to the limit of their resources, and it is noteworthy that where large works must be done and outside firms are given the contracts they generally engage local sub-contractors and workmen and buy their supplies locally so far as practicable. It is far better for a community to advertise all large works and thus have them constructed by a company of experience and financial resources than to let the works to local parties who do not know how to carry them on and do not have the financial standing necessary to handle such extensive operations. Letting such works to local parties without outside competition is simply giving them a business education at the expense of the taxpayers without any good resulting to the city or citizens.—Editor.]

Cut by Tunneling Machine.

The Importance of Steffan and Boltzmann's Radiation Law.

Sir: In a forthcoming bulletin entitled "Study of Four Hundred Boiler Tests, with Deductions," the Steam Engineering Division of the United States Geological Survey treats of the lately developed and proven law of Steffan and Boltzmann regarding the total radiation of heat (including light) from a hot to a cold body.

It was formerly thought that the amount of heat radiated was proportional to the temperature difference. Inasmuch as former experimental work was done at low temperatures the error of this assumption was very small. But of late years, since interest has arisen in the quantitative investigation of high temperature furnaces, it has become important to think with the true law in mind. This law of Steffan and Boltzmann states that if two infinite plane surfaces are close together, or, better yet, if a ball is inside a hollow sphere, all surfaces being in all cases of the same material, in the same state of surface finish—this law states that the rate of heat radiation from the hotter to the cooler surface is:

Rate of radiation $= K\ (T_1^4 - T_2^4)$.

Where $K =$ a constant for any particular set of bodies and surfaces $T_1 =$ the absolute temperature of the hotter body, $T_2 =$ the absolute temperature of the colder body.

The above equation is equivalent to stating that each body radiates heat and receives heat by radiation; that the rate of radiation from each body is proportional to the fourth power of its absolute temperature; and therefore that the net amount of heat given up by the hotter body to the cooler one is proportional to the difference of the fourth powers of their absolute temperatures.

The above mentioned forthcoming bulletin giving a "Study of Four Hundred Boiler Tests, with Deductions," makes a number of applications of this law. Some similar applications are given below.

In a Heine water-tube boiler having the lower row of tubes over the furnace completely encased in clay tiles, excepting about 3 ft. at the rear end, over the combustion chamber, this exposed 3 ft. of tubes absorbs heat not only from convectional contact with the gases entering the boiler, but also from intense radiation from the white-hot combustion chamber walls and bottom.

The soot covering of the water tubes is of a different surface and finish from the surface of brick and slag constituting the combustion chamber walls and bottom; nevertheless, the above equation will hold approximately, and a couple of examples are given to show the enormous increase of this radiation factor with rise of combustion-chamber temperature.

Example 1.—Let the soot on the exterior of the water tubes have an average temperature of 1239° F.—a dull red heat. Adding 461° F. to get the absolute temperature, we have $T_2 =$ 1700°.

Assume the rear furnace temperature to be 2039° F., a rather poor condition of operation. Adding 461° to 2039° we have $T_1 = 2500$. Then, net heat received by tubes per second from furnace bottom and sides $= K\ (T_1^4 - T_2^4) = K\ (2500^4 - 1700^4) = K\ (30{,}710{,}400{,}000{,}000)$.

Example 2.—Let the average soot temperature be 1239° F. or 1700° F. absolute as before.

Then $T_2 = 1700°$. Assume that the average rear combustion-chamber temperature is only 500° higher than in Example 1; that is, 2539° F., a medium temperature; then $T_1 = 3000°$.

Then, net heat received by tubes per second from furnace bottom and sides $= K\ (3000^4 - 1700^4) = K\ (72{,}647{,}900{,}000{,}000)$.

Example 3.—Assume as before $T_2 = 1700°$ absolute and raise the furnace temperature another 500° F. to 3039°, which would be wall tempera-

ture in quite a hot furnace. Therefore, $T_1 = 3500°$.

Then, net heat received by tubes, etc. $= K (3500^4 - 1700^4) = K$ (141,710,400,000,000).

SUMMARY OF EXAMPLES.

Dropping the constant K and the last twelve figures of every answer, we have,

Furnace Temp.	Tube Temp.	Number to Which Net Radiation is Proportional.
2039° Fahr.	1239° Fahr.	31
2539	1239	73
3039	1239	142

The heat absorbed from radiation practically doubles with every 500° increase in combustion-chamber temperature.

As a matter of fact the temperature of the soot on the tubes rises a little as the furnace-wall temperature rises, and it is also a better radiator of heat than is the brick wall. Nevertheless the above examples are substantially correct.

The above calculations give no idea as to whether the percentage of heat received by a boiler from radiation is the larger or smaller portion of the whole. In the "Study" mentioned some numerical calculations are given, determined by two independent methods of approach. The results are probably right within 20 per cent.

It is evident, in the case of an ordinary multitubular boiler burning smokeless coal right under the boiler shell, that perhaps half of the heat enters the water from a radiation source. Even in water-tube boilers it may be about 20 per cent.

In locomotive boilers the firebox may sometimes absorb perhaps 30 to 50 per cent. of the total heat absorbed, most of this 30 to 50 per cent. being due to radiation.

The engineers of the Steam Engineering Division were recently much surprised at the magnitude of thermometric errors due to radiation when measuring the temperature of dry gases. If the bulb of a thermometer have a chance to "look out-doors" when in a hot chamber surrounded by a flowing stream of hot gas, it may read twenty or thirty degrees low at the moderate temperatures of 500 or 600° F.; nor does the "window" have to constitute a very large percentage of the chamber walls in which the bulb is situated. Two thermometers a little over an inch apart in the same long chamber, swept by the same stream of hot air, were found to read nearly 100° apart; a third one farther along, carefully closed in, read nearly as high as the first one. All the instruments were carefully calibrated and were repeatedly interchanged.

In superheated steam work such errors are very persistent. It is no easy matter to get the temperature of a flowing stream of superheated steam within 10° of the true temperature. It may be said that under such circumstances the thermometer bulbs are always colder than the steam; the only question is, how much? This fact alone will explain away many troubles engineers have had in working with superheated steam and other permanent gases.

In determining the temperature of flue gases in boiler practice the errors due to radiation of heat from the thermometer bulb are usually large. Unless the bulb is carefully protected from radiation by two or three concentric chambers around it, it is likely to read dozens of degrees low. A moment's reflection will make it evident that all surface ordinarily "visible" to the thermometer bulb is hundreds of degrees colder than the gases (and than the bulb). This is true of the brickwork, the adjacent water tubes and steam drums, the stack and the sky above.

The measurement of the temperature of a permanent gas is a high art.

WALTER T. RAY.

DIAGRAM FOR REINFORCED CONCRETE BEAMS.

SIR: In your issue of July 27 of this year you published an abstract of the report of the British Joint Committee on Reinforced Concrete, containing certain formulas recommended by that Committee for use in proportioning reinforced concrete structures. I am sending you herewith a diagram showing certain relations in those formulas, which may be of some interest to your readers.

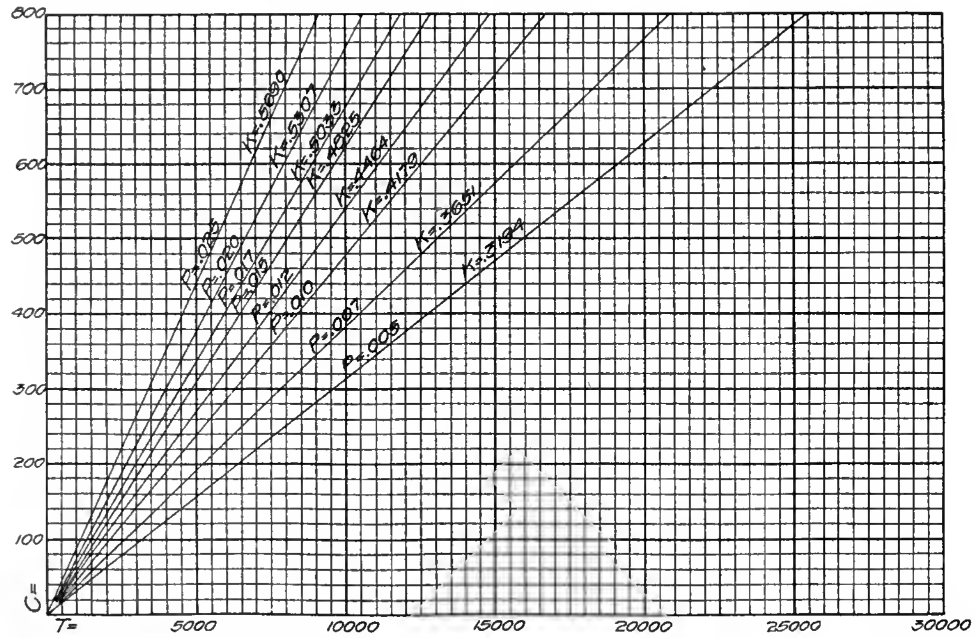

Diagram for Reinforced Concrete Beams.

In this diagram C is the compression in the extreme fiber of the beam, expressed in pounds per square inch; T is the tensile stress in the steel, expressed in pounds per square inch; P is the ratio of the area of steel to the area of concrete, and K is the ratio of the distance of the neutral axis below the extreme upper fiber to the distance of the center of gravity of the steel below the extreme upper fiber. The ratio of the coefficient of elasticity of steel to the coefficient of elasticity of concrete is assumed to be 15.

Yours very truly,

GEO. T. PRINCE.

A FORMULA FOR LATTICE BARS.

SIR: In your issue of October 12, Mr. Henry S. Prichard has a letter on stresses in the lattice bars of columns. I send herewith some notes on a formula that will give, I think, approximate results.

Let L be the length of the column in feet, A the area of its section, Q the section modulus for the axis Y Y in Fig. 1, r the least radius of gyration in inches, l the length of the column in inches, w the load per linear foot of the column as explained below, r' the radius of gyration for the axis Y Y in Fig. 1, and n the distance of the extreme fiber from the axis Y Y.

The New York law gives the following formula for the pressure in pounds per square inch, $15{,}200 - 58\ l/r$, or if l is in feet, $15{,}200 - 696\ L/r$. If L is very short then we can use 15,200 lb. per square inch, and under this assumption evidently $696\ L/r$ may be taken as the stress per square inch due to bending in the column. Calling this stress S',

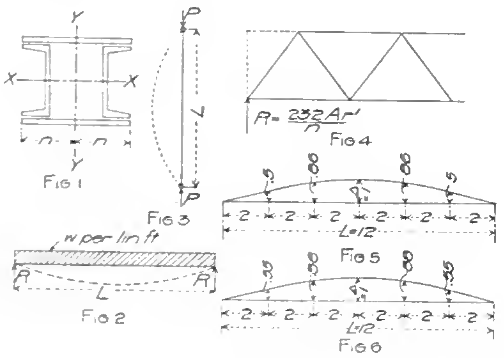
$$S' = 696\ L/r'.$$

If the column is put in a horizontal position and a load w per linear foot is applied, it would tend to take the shape shown by the dotted line in Fig. 2. If the column is pin-connected top and bottom and a load P is applied, it will take the shape shown by the dotted line in Fig. 3, or approximately the same curve shown in Fig. 2. Therefore we may assume that the bending in the column is the same as would be caused by an evenly distributed load as shown in Fig. 2. Then $w\ L^2/8$ is the bending moment in foot-pounds, or

$$12\ w\ L^2/8 = \text{Bending moment in in.-lb.}$$

But $m/Q = S''$

where S'' is the stress per square inch due to bending.



Lattice-Bar Diagrams.

Hence $12\ w\ L^2/8\ Q = S''$. But $Q = Ar'^2/n$ and therefore $S'' = 12\ wl^2/8\ Q \times n/Ar'^2 = 3\ wL^2n/Ar'^2$. But $S' = S''$, therefore $696\ L/r' = 3wL^2n/2Ar'^2$ and $w = 464\ Ar'/Ln$. Hence R in Fig. 2 is found from the expression $R = 464\ Ar'/Ln \times L/2$, and $R = 232\ Ar'/n$.

Having found the end reaction R it is easy to find the stress in a lattice bar by treating it the same as a lattice truss, see Fig. 4. If the column is fixed at both ends, the bending moment will be $wL^2/12$, which gives

$$R = 348\ Ar'/n.$$

A comparison of the two curves in Figs. 2 and 3 may now be made.

The curve shown in Fig. 3 is a sinusoid whose equation is $y = \Delta \sin n\ \pi\ (x/L)$. (See Merriman's "Mechanics of Materials," 1894 edition, p. 115). In the case considered $n = 1$, and if we assume $\Delta = 1$, the equation reduces to $y = \sin \pi\ (x/L)$. If we plot this curve, using 12 for L, we get the coordinates shown in Fig. 5.

Referring now to Fig. 2, we have a parabola, and if we plot this curve we get the coordinates shown in Fig. 6.

By comparing Figs. 5 and 6, we see that they are approximately the same. When Δ is very small, which is the case in columns, we can therefore safely say the two curves are alike.

Yours truly,

W. W., PEARSE.

NEW YORK, Oct. 19.

THE ENGINEERING RECORD
PUBLISHED WEEKLY BY THE
McGraw Publishing Company
James H. McGraw, Pres.; Curtis E. Whittlesey, Sec. and Treas.
MAIN OFFICES:
239 WEST 39TH STREET, NEW YORK.
BRANCH OFFICES:
CHICAGO: Old Colony Building.
PHILADELPHIA: Real Estate Trust Building.
CLEVELAND: Schofield Building.
SAN FRANCISCO: Atlas Building.
LONDON OFFICE: Hastings House, Norfolk St., Strand.

SUBSCRIPTION RATES.

United States, Cuba and Mexico..........$3.00 a year
Canada ....$4.50 a year
Foreign subscription.......................$6.00 a year
25 shillings. 25 marks. 31 francs.
Foreign subscriptions may be sent to our London office.

NOTICE TO ADVERTISERS.

Changes in advertisements intended for a particular issue should reach the office of THE ENGINEERING RECORD on Friday of the previous week. New advertisements can be received up to noon of Wednesday of the week of issue.

NOTICE TO SUBSCRIBERS.

REMITTANCES.—Remittances should be made by check, New York draft, or money order, in favor of THE ENGINEERING RECORD.

CHANGE OF ADDRESS.—The old address should be given as well as the new, and notice should be received a week in advance of the desired change.

BACK COPIES.—No copies of issues prior to July, 1906, are kept on sale, except in bound volumes.

DATE ON WRAPPER indicates the month at the end of which subscription expires. The sending of remittances for renewal prior to that date will be much appreciated by the publishers.

CLUB RATE.—In acknowledgment of assistance rendered by subscribers in the securing of new orders, a club rate of $2.50 per annum is quoted. This rate applies to subscriptions in clubs of two or more, at least half of the names in the club to be those of new subscribers.

Entered at the New York Post-Office as Second Class mail matter.

Of this issue of THE ENGINEERING RECORD 15,000 copies are printed. Total circulation for 1907 to date, 657,000 copies, an average of 14,600 copies per week.

TABLE OF LEADING ARTICLES.

The Denatured Alcohol Situation.

In the last issue of The Engineering Record the Department of Agriculture's recent tests of gasoline engines with alcohol as fuel were briefly described. In spite of the denatured alcohol law and the interest it excited, the results up to date have been inconsiderable so far as fuel uses are concerned. It is somewhat unfortunate that wood alcohol remains still the chief material used in the denaturing process, since when used in so large a proportion as 10 per cent. it is a considerable item of expense, while the pyridin bases employed if the amount of wood alcohol is reduced are not produced in material amount in this part of the world. This rather complicates the situation if one attempts to get alcohol from the cheapest present source, i. e., the refuse of cane sugar production. In the sugar producing countries alcohol can undoubtedly be made at a figure which would permit its importation and denaturing at a price which would put it into immediate competition with gasoline. It is therefore much to be desired that a more convenient and cheaper process for denaturing should be authorized if one can be found.

As regards the results obtained with alcohol in gasoline engines, they are upon the whole very encouraging. Of course there is no getting around the fact that gasoline has a higher thermal value than alcohol, gallon for gallon, in the ratio of nearly 3 to 2. Obviously alcohol must be obtainable at about two-thirds the price of gasoline to put it in full competition merely on the basis of fuel cost. With gasoline at the prices now current in this country such competition in the gross, as it were, is for the present unlikely. But nevertheless the use of alcohol should be encouraged as an automatic check on increase of price in gasoline. This substance being practically in the hands of a monopoly such a check is exceedingly important, lest the price should suddenly be put up, let us say to the much higher figure prevalent abroad. As regards net value for the purposes of its use, alcohol has a much better situation, especially as regards its employment in automobile engines. The gain in its use is two-fold; first, it gives somewhat greater power in an engine of given size; and, second, it burns far more cleanly. As regards the first count, one can therefore build a somewhat lighter and smaller engine for the same output. This is a distinct help for one of the prevalent vices in automobile design is excessive weight for the motive power carried. A heavy engine means heavy supports. Incidentally the lessened danger of auto ignition when using alcohol makes it easier to use air-cooled engines which still further lightens and simplifies the structure. Further the much cleaner combustion of alcohol lessens the danger of overheating and the chance of serious friction from the accumulation of soot in the cylinders. Gasoline is of complicated and variable composition and its tendency is to leave hard carbonaceous residues unless the combustion is exactly what it should be. And proper combustion in automobile operation is very difficult to maintain.

For these reasons there would seem to be a strong probability that the use of alcohol would tend to materially lessen repairs, an improvement which is very greatly to be desired. In spite of the fact that gasoline engines as now made can be used with alcohol the researches described last week make it pretty clear that some minor changes in carbureters and compression, and perhaps in ignition are desirable in an engine to be used exclusively with alcohol. It is to be hoped that some of the more enterprising automobile makers will take up the question and be prepared to furnish first class alcohol engines if desired. The gain in the abolition of the unpleasant odor of gasoline is a material one, too, especially in cities where many malodorous machines are now in use. If some of the large makers would thus take hold of the question and arrange to keep in stock denatured alcohol in the large centers, a considerable gain would be made. Even now Cuban alcohol could probably be denatured and imported at a figure that would not be at all prohibitive.

As regards the use of alcohol in ordinary stationary engines the possible gain is less. Such engines can be run under fairly uniform conditions of combustion, and a little extra weight is of small moment. With the introduction of small gas producers, too, giving less fuel cost even than gasoline, there will be a tendency to confine the use of stationary gasoline engines to very modest sizes so that they will become relatively less important. Still if the production of cheap alcohol once gets fairly under way there is a good chance that the price can be brought to a figure that will encourage its use, especially since in some parts of the country the transportation charges on gasoline are considerable, while alcohol may be of local manufacture. At all events the automobile side of the matter may easily rise to considerable importance, and it is earnestly to be hoped that the work will be rapidly pushed along.

Interpreting Power Plant Tests.

Whatever may be the object of a test of a commercial power plant, the interpretation of the results secured is unquestionably the most important part of the whole task. Too little emphasis has been laid in the past upon the analysis of test results, in comparison with the pains bestowed upon the test apparatus, its arrangement and readings. To secure consistent figures from a more or less complicated outfit of inter-related machinery during a service trial requires a high order of technical knowledge, but to dissect the detailed columns of test figures obtained in the field and marshal them in groups for or against a given policy in design, construction or operation, calls for the most experienced judgment of the trained engineer.

Without carefully obtained test data it is, of course, almost impossible to draw correct conclusions. No sensible engineer would minimize the need of accurate readings and full records of all unusual conditions arising during a test—and few tests are run off under commercial conditions without the presence of disturbing factors which a pure theorist would overlook in planning the work. To the outsider one day looks very much like another in a plant handling routine service, but the operating man inside the station walls realizes that even in such a uniform business as handling the morning and evening rush hour loads of a street railway system on two successive days in the same season of the year, contingencies and differences in hourly conditions are bound to keep him on the anxious seat until the peak load has been passed. Granting such points as this, however, does not for a moment lessen the responsibility of those who are to interpret the data secured.

The practice in some companies requires the testing engineer to submit comments upon his experiment data when presenting the figures to his executive officers. Such a course need not in any way vitiate the analysis of the figures which the higher officer may bring to bear, and in many cases it opens the way toward a much closer co-operation between the head of a department and his subordinates. It is easy for young engineers to fall into the error of assuming that everything needful has been done when a set of test data has been carefully tabulated. If heads of departments would more generally encourage the presentation of critical comments with their subordinates' test figures, even in minor investigations, there is no question that many valuable suggestions would thereby be placed on file, instead of overlooked or lost, as is too often the case. In matters like counting stores and checking up carload shipments figures speak for themselves; but in a power plant test a correct interpretation requires full knowledge of the conditions and arrangements obtaining at the time.

Among the sources of inaccurate deductions from test records are failure to separate different kinds of output in relation to the station load

as a whole, omission of instrument, tank and scale calibrations, and consequent calculation of costs without reference to the accuracy of the readings, absence of calorific determinations upon representative fuel samples, neglect of atmospheric and weather conditions in studying the results of chimney and blower performance and failure to appreciate the load factors and efficiencies of individual machines contrasted with the station as a whole. In order to interpret the results of an extensive test on a large plant it is very desirable to know what similar equipment may be expected to do and what it has done in other installations; and if the plant which has been tested is to be modified in arrangement or operating methods the hours of service of each important unit need to be studied quite as carefully as the possible sources of energy loss in the chain of events between the coal bunker and the bus bar. The condition of the apparatus with regard to repairs and depreciation, its performance at different seasons of the year under varied load conditions, the number of men on the operating shifts and their personal equations all need to be considered before any sweeping change in station design or methods of handling is carried into effect. It is a great mistake to make a hasty decision to modify a plant's equipment in the light of a single test taken by itself without relation to daily records of service. If a test shows the existence of unfavorable conditions it is far better to endeavor to improve the economy of the existing installation then to tear out important parts of it on the strength of a single test interpretation. Sweeping changes are better the result of both tests and corroborative operating experience.

The British Machinists' Agreement.

Few things have occurred of late in the manufacturing world so instructive as the agreement recently signed between the Engineering Employers' Federation and the representatives of the three leading machinists' trade unions in Great Britain. The history of this agreement is worth consideration. For some time prior to 1897 there was a dispute between employers and employees in the machinery industries of Great Britain over the eight-hour day. The unions had been fairly well organized long before that date, and consequently the fight they put up could be readily directed by central authorities. On the other hand the employers were without any association for a considerable time. Each man was striving to enforce his own ideas in his own way and as a result there was a long-drawn-out struggle disastrous for the machinery trade of the country. During that time the United States and Germany obtained a large amount of business which would naturally have gone to Great Britain, and neither men nor employers gained materially by the strife. A national trade union fighting against dissociated manufacturers has always a great advantage. The struggle can be confined to those places where the conditions are most favorable to the union and work can be continued in places where the union has little to gain, so that funds for the strike can be contributed by the men of one district to those of another. Owing to this former lack of agreement among employers, shop rules and methods differed widely in different parts of the country, and in consequence the cost of production of the same kind of output varied widely. The disturbances prior to the strike of 1897 brought this fact home to the manufacturers very vividly, and as a result the Engineering Employers' Federation was formed, which in 1898 successfully demanded and enforced practically uniform conditions in all parts of the kingdom.

When the Federation and the unions drew up their first agreement nine years ago, there still remained a very bitter feeling on the part of some of the representatives of both sides of the warring interests. Since the representatives have become better acquainted in the course of their duties in settling differences of opinion between employers and employees, a very much better feeling has arisen. The old days of the influential blatherskite have largely passed away, and at the same time a tremendous pressure has been put upon the employer who says he will be hanged if he will allow anybody to dictate how he shall treat his men. The trade unions have sent their best men to represent them in conferences with employers, and the latter have sent tactful representatives to these meetings. Both sides have been the gainers in consequence, and there is now a feeling of mutual respect between the two parties, which is a favorable sign of industrial tranquility and a better appreciation of the obligations of all concerned in the engineering trade. This is well shown in the new agreement between the two parties.

Under the terms of this agreement the members of the Federation agree not to interfere with the proper functions of the union and the latter agree not to interfere with the employers in the management of their business. This is a sort of general statement which has definite meaning only in the light of the subsequent clauses of the agreement. These are important on account of their explicit nature. For example, it is specifically provided that every employer may employ any man, and every workman may take employment with any employer, whether the workmen or the employer belongs or not to a trade union or to the Federation respectively. Furthermore the trade unions recommend all their members not to object to work with non-union workmen, and the Federation recommends all its members not to object to employ union workmen on the ground that they are members of a trade union. Moreover, no workman will be required, as a condition of employment, to make a declaration as to whether he belongs to a trade union or not.

The old source of controversy over piece work seems to be pretty well eliminated by the terms of the agreement. Employers and their men are entitled to work piece work under certain conditions. The first of these is that the prices to be paid shall be fixed by mutual agreement between the employer and the men who perform the work. The second condition is that each workman's daily pay is to be guaranteed irrespectively of his piece work service. The third condition is that overtime and night shift allowances are to be paid in addition to piece work prices on the same conditions as already prevail in each workshop for time work. As regards overtime, both the Federation and the unions agree that systematic overtime is to be deprecated as a method of production and that when overtime is necessary the following conditions should be observed so far as possible. No union workmen shall be required to work more than 32 hours overtime in any four weeks after full shop hours have been worked, allowance being made for time lost through sickness, absence with leave, or enforced idleness. On the other hand the agreement specifically states that overtime ought not to be restricted in cases of breakdown, repairs, alterations for employers or their customers, trial trips and repairs to ships, and cases where urgency or emergency enter.

The rating with respect to pay is one of the most important features of the agreement. Under its terms employers have the right to employ men at rates of wages mutually satisfactory to both parties. In fixing the rates of skilled workmen the employer is expected to pay attention to the prevailing rates in the district for fully trained and skilled men. The unions disclaim any right to interfere with the wages of the men other than their own members, but, under the agreement, have the right in their collective capacity to arrange the rate of wages at which their members may accept work. General alterations in the rate of wages in any district are to be negotiated between the employers' local association and the local representatives of the trade union or unions concerned. The agreement concerning apprentices is an unusually sensible one. It provides for no recognized proportion of apprentices to journeymen but authorizes the unions to bring forward for discussion the proportion of apprentices generally employed in the whole federated area. This means, probably, that where more apprentices are employed than customary, the union shall have the right of talking the matter over with the employers. The agreement further states that the apprentice shall be afforded facilities for acquiring a practical knowledge of the branch of trade he adopts and shall be encouraged to obtain a theoretical knowledge of it so far as circumstances permit. This is already the practice in a good many of the leading British works, where apprentices are required to attend evening classes and in some cases are rewarded by prizes for specially meritorious work. The agreement also specifically provides that employers have the right to select, train and employ those whom they consider best adapted to the various operations carried on in their workshops and to pay them according to their ability as workmen. The employers have full discretion under the agreement to appoint men they consider suitable to work all their machine tools and to determine the conditions under which they shall be worked.

The most important section of the agreement is probably that which provides for avoiding disputes. Many employers have an extreme dislike to receiving union representatives and in some places men are reluctant to go to their employers with a grievance lest they be discharged. In the new agreement just signed due weight has been given to these conditions. Deputations of workmen will be received by their employers by appointment for mutual discussion of any question in the settlement of which both parties are directly concerned, or it will be competent for an official of the trade unions to approach the local secretary of the employers' association with regard to any such question, or it shall be competent for either party to bring the question before a local conference to be held between the local association of employers and the local representatives of the trade unions. Local conferences are to be held within twelve working days from the receipt of the application by the secretary of the employers' association or of the trade union. Failing settlement at a local conference it shall be competent for either party to refer the matter to the executive board of the Federation and the central authority of the trade union concerned. The agreement provides that there shall be no stoppage of work, either partial or general, but work shall proceed under the current conditions until the procedure indicated has been carried through. The agreement specifies who shall be considered local officials of the union, and refuses to permit an employer who declines to employ trade-union men to sit in the central conferences composed of members of the executive board of the Federation and members of the central authority of the trade union, called to consider questions which the local conferences cannot decide.

The new agreement has two significant features. The first is the centralization of authority on the part of both employers and trade unions. The men who are intrusted to represent each party to such an agreement will naturally feel the weight of their responsibilities, and will be

less inclined to act hastily concerning controversies that may affect the entire industry in which they are interested throughout the kingdom. This centralization of authority is simply another indication of the tendency of the times and must be accepted as inevitable and probably as advantageous. The other important consideration to be observed is the added security given to the workmen on account of the Employers' Federation standing between him and any arbitrary and unreasonable employer. The day of the all-around mechanic has practically disappeared. A man may learn to run one or two tools, but that is about all. If he becomes a planer hand he will probably remain a planer hand for life, going from one shop to another and doing different kinds of work at them, but still working on a planer. As a result of this condition he cannot shift so readily from one employment to another as could the man who worked in the old-fashioned way. He naturally must seek some measure of protection and there is no way which furnishes such protection as the well-managed trade union. It is a fact of the deepest social significance, therefore, that the full recognition of the leading British trade unions engaged in the machinery industry, which is accorded by the agreement under consideration, has met with approval rather than criticism by the most conservative organs of the employers of such labor. Let us hope that all parties to this new agreement will live up to its spirit of fairness and mutual consideration, so that the British engineering trades may regain the strength and vigor they possessed ten years ago.

Engineering Education in France.

It has generally been understood that the system of education in the Polytechnic School and the School of Mines of France was a matter of great pride to French engineers. Accordingly it is surprising to learn that there is a feeling of considerable doubt among them of the advisability of the theoretical instruction in these institutions. The vice-director of the School of Mines at Paris, M. André Pelletas, is among those who recently have expressed a fear that the instruction was too much along the lines of higher mathematics. These views have been held for some time by engineers who have not had the advantage of a polytechnic education, but their recent confirmation by men who graduated from the great national schools and have since achieved distinction is attracting considerable attention. The Polytechnic School is the leading French technical institution, its graduates being ranked above those of the Central School of Arts and Manufacturers, where a more practical training is given. The graduate of the Polytechnic School has a certain distinction which helps him to obtain employment and tends to facilitate his advancement. The officials of the French railways are largely drawn from the ranks of the graduates of this school and most of the technical staff of the national government were educated at this institution, which, indeed, was established in 1794 to furnish specially trained men for government service.

The course of instruction at the Polytechnic School is largely mathematical, and the other portions of it are influenced considerably by the consideration that many of the students enter the army. The graduates of high standing have a large number of openings in the state service from which they may choose, while the men at the lower end of the class have to take what is left after their superiors have made their selection. The range of these positions is something astonishing. In the army, there is a choice between the artillery and engineering branches. In civil life there are situations in the state mining departments, the bureau of bridges and highways, on river and harbor improvements, in lighthouse construction and maintenance, in the supervision of state monoplies of tobacco, matches and powder, in the inspection and the technical and commercial administration of railways, in the postal and telegraph service, in naval architecture, on hydrographic surveys and in various other lines of work which it is hardly necessary to enumerate. In order to equip the polytechnic graduate for many of these positions it is necessary for him to attend a further course of study in some other school. His highly theoretical training has been so deficient in practical subjects that a three-year course at the Mining School is therefore essential. Some of the students at the Mining School do not attend the Polytechnic School before they take up the practical courses of the former, but they are not ranked so high as the Polytechnic graduates. At the Mining School they study various practical subjects and at the same time, however, have to review the higher mathematics which they learned at the first school. As a result of the long period of education and their army service, the average of the graduates of the Mining School who also studied at the Polytechnic School is about 28 years.

The critics of this system of education assert that a large part of the time spent at the schools is practically wasted. They believe that the graduates would be just as well educated in every sense of the term if they pursued advanced theoretical subjects to a far smaller degree. They also believe that a feeling of general distrust of the national technical educational system is arising. The managers and technical directors of many of the largest industrial works are drawn from the graduates of the schools named, and there seems to be a sort of understanding among them that the men promoted to the higher positions in their works should be other graduates of the same schools. Consequently a young man whose education has not included a course in the Polytechnic School, who has shown great ability in working up through any department of the industry with which he is connected, suddenly finds his advance to the highest positions blocked in favor by somebody who has shown by no means the same ability as himself.

It is interesting to notice that these severe criticisms of French engineering educational methods are not from those who have failed to achieve distinction but from eminent graduates of the schools themselves. If half of what they say is true, and certainly their standing warrants the acceptance of everything they assert as an accurate presentation of actual facts, then it is high time for a reform. The situation, in fact, resembles in many respects that in Great Britain some ten years ago, when the educational methods there were so severely shaken up by some of the leading scholars of Great Britian. The rumbling of that disturbance even echoed through the United States and The Engineering Record can bear witness to the fact that some three or four years ago the British mathematical reforms were the subject of widespread interest in the United States.

Notes and Comments.

MR. GEORGE WESTINGHOUSE has the sympathy and good wishes of all Americans who delight in good work well done. For the second time in his career financial troubles are interfering with some of the great enterprises he founded and has carried on. He met the first crisis successfully, and carried forward the many enterprises in which he was interested until at the present time there are thirty-one Westinghouse companies in this and other countries, having a total capital of $120,000,000 and an annual output estimated to be worth about $90,000,000. Some 38,000 men are employed by these companies in twenty-four factories, turning out products of every sort. The air brake which has made high-speed railway traffic possible, the introduction of automatic block signals to increase the safety of railway travel, the introduction of natural gas in the Pittsburg district, the development of electrical apparatus, particularly of alternating current apparatus, the development of steam and gas engines and many other things too numerous to mention, lie to his credit. All of these things have been pushed forward manifestly for some other purpose than personal gain. Any ordinary business man would have been satisfied with the success achieved in one of them, but the incentive of genius made it impossible for Mr. Westinghouse to withhold his hand from anything where he saw a chance to do good work. What he has done in the last few years has been of so much benefit to the world that there is every reason for anticipating more achievements by his compelling force. At the present time, while he is facing the difficulties of unsnarling the financial tangles of the affairs of some of his companies, he has the sympathy of all who appreciate in any degree what great contributions he has made to the nation's prosperity, and how much may still be expected from his creative genius.

A RAILROAD ANNOUNCEMENT which has attracted little attention during the period of financial strain just passed was that of the sale of the Port Chester and the Westchester roads to the New York, New Haven & Hartford Railroad Co. These electric projects attracted much attention a year or more ago. They were looked upon as the beginning of real rapid transit in the section immediately northeast of New York City. One of them, at least, was begun in good faith for the purpose of building up a suburban transportation business in Westchester County and the Borough of the Bronx. The absorption of both companies by the New Haven road puts an end to all prospect for the time being of any competition in passenger traffic in the district in question. Whether this clinching of a monopoly will be to the detriment or to the advantage of the people served remains to be seen, although this journal is of the opinion that advantage rather than disadvantage will result. Both of the proposed roads had a rather unsatisfactory termination near the end of the Lenox avenue subway, while the New Haven road will hardly be satisfied with any such crossroads terminal. Probably very few people know just what the New Haven company proposes to do, but it seems reasonably certain that such a great corporation will never be satisfied without its own station in the Borough of Manhattan, even if it has to build a great subway system to attain its purpose.

THE CURTAILING OF EXPENSES ordered by the Pennsylvania Railroad directors during the coming year is something which should occasion no surprise. That road has been spending money for a number of years with a lavish hand; in fact, some people have looked with apprehension upon the great expenditures that have been made. A large part of the work for which these great sums have been paid out is now practically complete, and a heavy reduction in construction expenses can be made without affecting traffic to any extent. In view of the present financial troubles and the prospect of tight money, which a year of presidential election always presents, there is manifestly every incentive of going slowly for the next few months. It is understood that those works which affect the public convenience in any direct way will be pushed along with the same vigor as in the past, but that undertakings mainly to the advantage of the company will be checked until the normal condition of affairs is again assured.

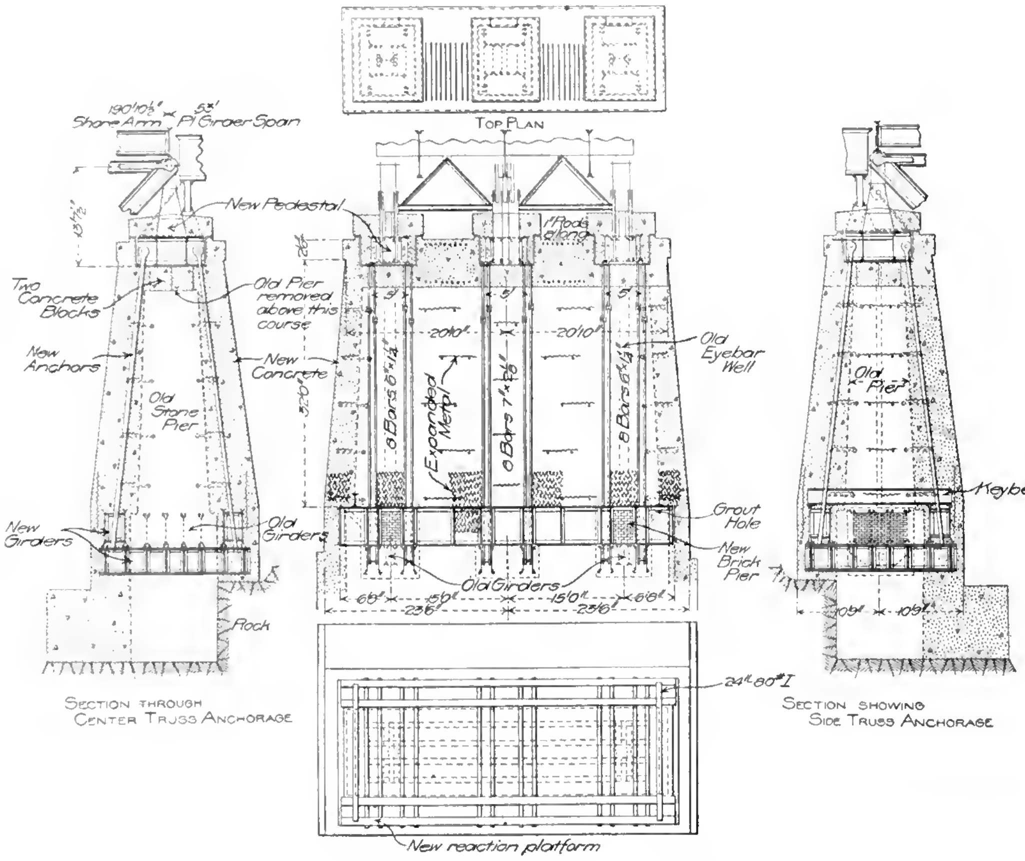
THE RECONSTRUCTION OF THE ANCHOR PIERS OF THE POUGHKEEPSIE BRIDGE.

The double track bridge over the Hudson River at Poughkeepsie was, when built, one of the first and most important long-span high railroad bridges in this country and was one of the first examples of cantilever erection. It has a total length of 6,747 ft. and a height of 212 ft. from the surface of the river to the base of rail. There are five main spans of 525 to 548 ft. lengths, besides high steel approach viaducts, with spans of 53 to 175 ft. The sub-structure is of ashlar masonry, with the river piers supported in deep water on very long footings. The superstructure is of steel and was proportioned for a live load on each track, consisting of two coupled locomotives, each with four 24,000-lb. axle loads, followed by a train load of 3,000 lb. per linear foot. After many years of constant use and hard service it was found that the bridge structure needed extensive reconstruction to endure the present heavier traffic and provide for a live load increased to 45,000 lb. on each locomotive axle and 3,600 lb. train load per lineal foot.

After a careful inspection and the study of alternate plans, it was decided to build additional columns in the viaduct towers, to provide new trusses and reinforce the existing trusses in the longer approach spans, to replace the short approach spans with new plate girders and to add a new line of center trusses between the old trusses of the main spans and new towers to support them. It was also necessary to make extensive alteration in the masonry and to provide entirely new and increased anchorage for the ends of the anchor-arm trusses. A general outline of the work was published in The Engineering Record of Oct. 28, 1905, and was followed on Aug. 18, 1906, by a description of the very novel and interesting methods used in replacing the short spans of the viaduct at a great height without the use of falsework. Since then work has progressed on the longer viaduct spans, on the main spans and on the substructure, and this article will describe the difficult and hazardous operation of reconstructing the anchorage piers and anchorage system while the bridge was under traffic.

The original west anchorage pier was about 48 ft. high, 7 ft. wide and 36 ft. long at the top and 11 ft. wide by 41 ft. long at the base, and had footings seated partly on the solid rock and partly on an inclined stratum of clay. Four longitudinal plate girders 4 ft. deep and 36 ft. long were built into the lower part of the masonry and served as a reaction platform for two vertical chains of eyebars, one in the plane of each truss, which passed between the girder webs and were connected to transverse bearing girders at each end. When the pier was constructed the bearing girders and portions of the reaction girders above them were left exposed in rectangular chambers 6 or 8 ft. long on each side, communicating with vertical wells about 2 ft. square to receive the anchor chain eyebars. The chambers were entirely closed at the bottom, and no access was provided to them through tunnels or in any other manner, but the vertical wells were left open at the top, thus exposing the eyebars and girders to the atmosphere and to rain and snow, but still leaving them inaccessible, as the space in the well was not sufficient to provide entrance for inspection or painting. Water accumulated in the undrained and unventilated chambers, and when a recent thorough inspection of the substructure was made it was found that the condition of both masonry and iron work required very prompt and extensive repairs and reinforcement.

The foundations were not considered satisfactory for modern requirements, and it was decided to improve them and to add materially to the mass of the pier masonry and increase its effective value for anchorage purposes by enclosing the old pier with a thick shell of new concrete thoroughly bonded to the former structure and arranged to greatly increase the anchorage load on the reaction platform. New anchor bars and reaction girders were provided, making the construction of the pier almost entirely new, except that part of the weight of the old structure was retained to provide for the negative reaction. The condition of the masonry and iron work was such that great care had to be taken to prevent any possibility of weakening it. The work thus became very delicate and hazardous and was conducted with the utmost skill and precaution.



Anchorage Pier with New Eyebars and Additional Reaction Girders.

In the reconstructed anchor piers the old reaction girders remained bedded in position in the base of the masonry and served merely to distribute a portion of the increased upward reaction against the old masonry. Three sets of new transverse girders are set in the lower part of the pier, projecting at both ends beyond its outer face so as to form cantilevers, receiving on their upper flanges two sets of longitudinal box girders, one on each side of the pier close to the old masonry. The latter form a reaction platform, on which is built a large amount of new concrete facing, enclosing the old pier and nearly doubling its volume. This arrangement greatly increases the available amount of counterweight in the pier and transfers it to the combined system of old and new reaction girders, which are connected to new pedestals, receiving the ends of the anchor arm by means of inclined adjustable eyebars bedded in the new concrete outside of the original limits of the pier.

The foundations were reinforced by the construction of a concrete buttress 11 ft. wide, 50 ft. long on the east, or down hill, side of the pier, which was carried down about 20 ft. to the foot of the old masonry to extend it and give it a much greater stability against displacement over the inclined surface of the rock. It was built in short sections in sheeted trenches, so that only a small part of the old masonry was disturbed at any given time, and the stability of the pier was considerably increased before any attempt was made to cut the old masonry.

After the inspection and drainage of the old anchor pit a few face stones were removed at the bottom of the pier, and sufficient masonry was cut out to give access to the chambers in which the transverse girders already mentioned were located. The masonry was in such a condition that hesitation was felt in cutting much of it away before additional support was provided, and piers of hard burned brick were therefore built with great accuracy and care between the reaction girders and carried up to bearing against the masonry which formed the roof of the chambers. Sufficient space was left at one end of the chamber for the bricklayers to retreat downward between the yoke girders, and the brick piers were underpinned by concrete placed in forms in the planes of the trusses between the transverse girders. Afterward oblique holes were drilled through the outer wall of the pier to the vacant part of the chamber, and thin, fine concrete under pressure was forced through them from the exterior to fill all cavities between and around the brick work and consolidate it with the old masonry to form solid supports, encasing the girders and carrying the positive reactions down to the footings.

The next operation was to cut horizontal transverse holes through the masonry at the center of the pier and under each of the old trusses of the bridge just below the bottom flanges of the old longitudinal reaction girders. In these holes the new transverse or yoke girders were placed and blocked up to the required height. Steel wedges were then very carefully driven between their top flanges and the bottom flanges of the old reaction girders, insuring a solid contact between them.

There were in all six transverse girders, each of them being a box girder 3½ ft. deep, 2 ft. wide and 19 ft. long over all. They projected about 4 ft. beyond the face of the old masonry at each end, forming cantilevers, on which were

seated, each side of the pier, a longitudinal reaction girder, with a rectangular cross section made up of two 5-ft. plate girders, 43 ft. long and 30 in. apart on centers, web-connected by vertical transverse diaphragms. New anchor bars, inclined somewhat from the vertical, were connected to both extremities of all the transverse girders by 6-in. pins and were enclosed in wooden boxes to give them clearance from the concrete.

In order to key the new concrete to the old masonry a 24-in. 80-lb. transverse I-beam, 18 ft. long, was seated on the tops of the longitudinal girders at each end of the pier, with its web solid against the old masonry and the flanges on one side seated in slots cut to receive them in the pier. Horizontal holes 2 in. in diameter and 1 ft. deep were drilled in all faces of the piers in pairs about 3 ft. apart horizontally and 5 ft. apart vertically, and in them were wedged 1¼-in. anchor bolts 4 ft long, some of them passing through the webs of the 24-in. I-beams, and all of them intended to bond the new concrete to were carried over the pier and independent of it.

This removed the positive loads from the pier tower, after which the top of the pier was cut down about 10 ft., and the upper surface dressed to receive a pair of 2-ft. 10-in. by 5 ft. moulded concrete blocks 83 in. wide, with narrow vertical slots on their opposite faces to clear the old anchor eye-bars when they were set on opposite sides of it, with their slotted faces in contact, thus forming a single pedestal. The concrete blocks, already hardened, were competent to receive their loads immediately without waiting a long time for the concrete to age, as would have been necessary if it was built like the remainder of that in the pier, in moulds. At the west end of the bridge conditions were different, and traffic was maintained across the anchor pier, from the approach to the anchor arm in another manner. The first span of the approach viaduct there is a 58-ft. plate girder, the river end of which was temporarily supported on a falsework bent, releasing the pier and tower. One panel of 8x16-about 6,000 lb .per square inch was developed in the eye-bars. This amount was calculated to be sufficient to produce a compression in the masonry a little greater than the maximum amount of upward reaction and thus maintain a slight initial stress in the masonry, even when the tension in the eye-bars is maximum and preclude the possibility of upward motion of the pedestals.

The well holes around the new anchor eye-bars were grouted, and forms were built enclosing the shoe and the space between them and the exterior forms was concreted, completing the top of the pier, except around the shoes. The wells around the shoes were lined with tar paper, and forms were built around them on top of the pier and filled with concrete, entirely enclosing the shoe and forming a cap over the anchorage bars, which is separate from the main body of the pier, and can, if necessary, conform to a vertical movement of the anchorage bars without transmitting shearing stresses or any danger of pro-

East and West Anchor Piers of the Poughkeepsie Bridge after Reinforcement.

the old pier. Sheets of expanded metal were laid across the projecting end of the anchor bolts, and the pier was enclosed in a form in which 2x8-ft. vertical sheets of expanded metal were placed near the lower part, as indicated in the accompanying illustrations. The forms were filled up to the height of the eye-bar adjustments with 1:3:5 Giant Portland cement concrete, deposited very wet, and the spaces around the old anchor bars were grouted up to the same height.

The pier was thus in a condition to sustain the computed negative reaction of 479 tons. In order to provide for the positive reactions during the transfer of connections from old to new anchorages, falsework bents, intended to support the new center truss of the east anchor arm during erection, were built at panel points of the main trusses, and the double transverse bent under the first panel point from the anchorage was extended to receive both old trusses, which were wedged to bearing on it, thus affording them support independent of the pier. On the opposite side of the pier falsework was erected to carry the approach span, and was connected, over the top of the pier, with the double bent by means of 24-in., 80-lb. longitudinal I-beam stringers, on which the railroad tracks in. longitudinal stringers was supported at one end over the falsework, and the opposite end on the end floorbeam of the anchor arm, and carried the tracks over the top of the pier.

All traffic on the bridge was suspended during one Sunday, and loaded cars were run on the anchor arm to provide a counterweight larger than the maximum negative reaction in the old anchor bars, thus releasing them. The anchor bars were cut off flush with the tops of the concrete blocks by pneumatic drills, boring through them edgeways holes of a diameter nearly as great as the thickness of the bars. The sides of the bars were nicked opposite these holes, and they were broken off, the pins backed out of their upper ends, and they were removed. The removal of the old eye-bars provided clearance for the placing of the new riveted steel shoes about 8 ft. wide and 9 ft. high, which overhang both sides of the pedestal blocks, and were pin-connected immediately to the new anchor bars at both ends, the connection to the anchor arm truss being made with an upper center pin. The driving of these pins restored the anchor piers to its original functions and permitted the withdrawal of the counterweight on the anchor arm.

The next operation was the tightening of the anchor eye-bar sleeve nuts until a stress of ducing cracks in the main concrete of the pier, while at the same time it forms a weatherproof cap over the well.

The work on the pier was necessarily slow and costly and was accomplished by an average working force of 30 men in about 80 days. The reconstruction of the east pier was substantially the same as that described for the west pier, except that the dimensions of the pier were different, and it was surmounted by a tall steel tower supporting the end of the anchor arm.

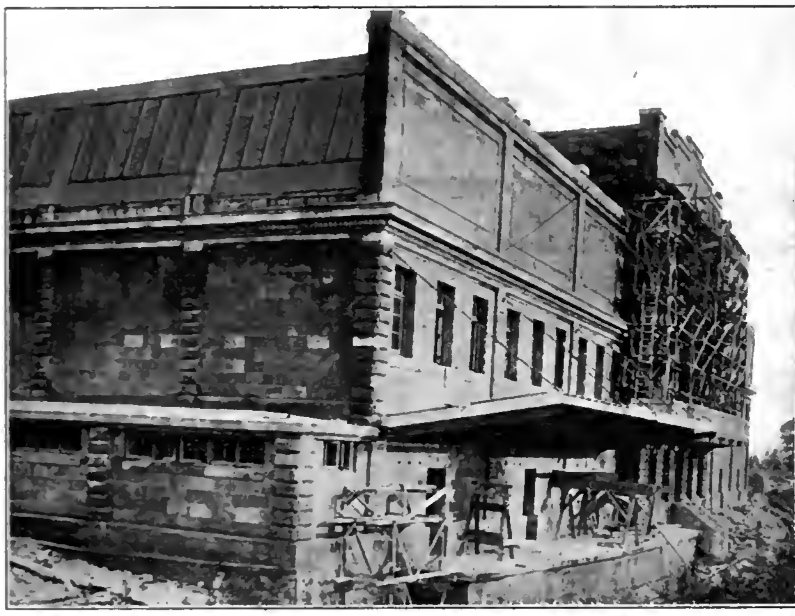
Additional interest is given this construction because it is believed to be the first built-in bridge anchorage. It has been heretofore considered imperative to provide anchorages with inspection wells or chambers, which leave some of the steel exposed to corrosion or possible injury. In such cases proper maintenace is likely to be difficult or impossible and is often neglected, and in several instances serious deterioration of the structure is known to have resulted. In this case it was decided to meet the problem squarely at first and assume final responsibility once for all by providing the most thorough protection and sealing it up. This may be radical, but is considered to be justified by the results of the opposite method.

In the reconstruction of the bridge Mr. Mace

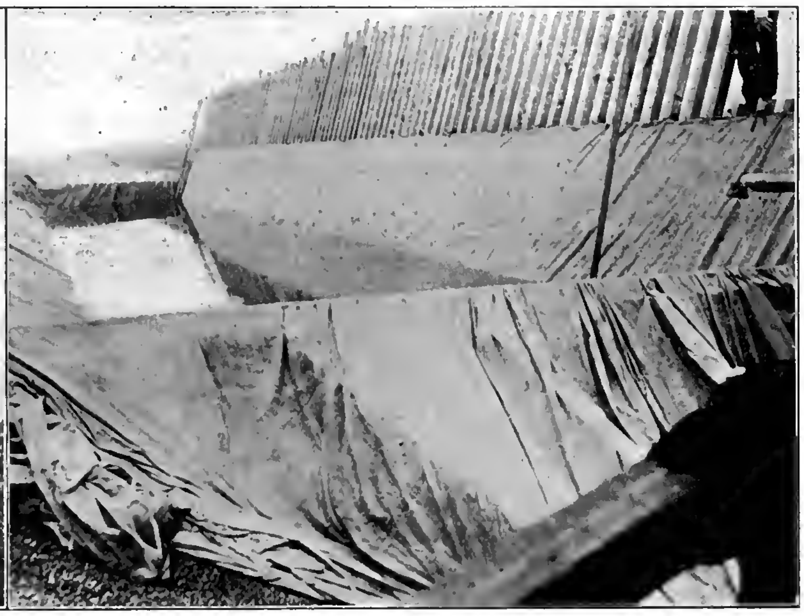
Moulton was consulting engineer for the railroad company. Mr. Paul Wolfel was the engineer in charge of design for the American Bridge Co. The methods and operations of erection were developed by Mr. S. P. Mitchell, who executed the work under a sub-contract from the American Bridge Co

A Concrete Building for a Chocolate Factory.

A large chocolate factory under construction at Stamford, Conn., for Stollwerck Bros., present some unusual features of design among which are a reinforced concrete saw-tooth roof and framework and cement block walls. The structure is 500 ft. long and faces the north with its east end close to the bank of the Mill river. Counting from the west end, 100 ft. of the factory is 200 ft. wide; the next 100 ft. is 50 ft. wide; the remainder has a width of 100 ft. The long 100-ft. section is divided longitudinally by three lines of interior columns into four 25-ft. bays each of which is covered by a roof bay. Transversely the factory is divided into ten sections or "buildings," each of which has a separate entrance extending somewhat in front of the building proper, with toilet and shower bath rooms on each side, as shown in an accompanying illustration.



Office Section of Stollwerck Factory.



Water Test of Saw-Tooth Roof.

The exterior treatment was made extremely simple in order to avoid the necessity for making an undue number of special blocks, as this type of construction is only economical where standardization can be secured to a considerable extent. The facades are relieved by rustic piers, and crowned by a modillion block cornice, over which rises the front slope and the saw-tooth roof. There are no windows in the main building except in the part given up to office use on the west front, all the light for the factory rooms being obtained from skylights in the saw-tooth roof

The foundations rest on gravel 26 ft. below the level of the basement which extends under most of the buildings. The part of the basement under the two center bays is unused, except for shafting and piping, and without a floor and high tides sometimes rise 2 ft. in it. The basement along the north and south side and across the east end is divided from the rest by 3-in. walls and floored with a 5¼-in. slab, forming dry passageways, one of which on the north side is occupied by the rope drive system.

The main floor in general is designed to carry 300 lb. per square foot, though in Building 1, at the extreme east end where the boilers are placed, several girders and beams are designed to support a load equivalent to 1,200 lb. per square foot of floor area.

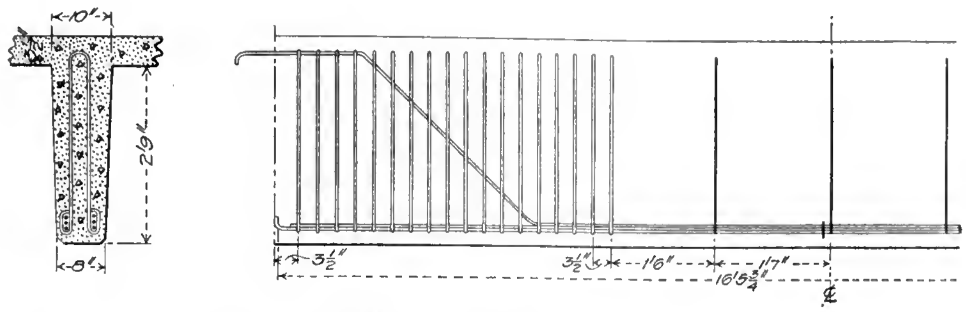
The general arrangement of the columns, girders, and beams supporting the main floor, which extends throughout the greater part of the factory, is shown in an accompanying floor framing plan. It will be noted that the floor in the center bays is carried by longitudinal girders and transverse beams which divide the slab into panels about 5½ x 25 ft., while over the outside bays the slab rests on the wall foundation, on longitudinal girder 10, and on two lines of longitudinal beams carried on 9 x 9-in. columns set in the basement passageways.

Referring to the framing plan, girder 2, on the longitudinal center line of the factory, is 33 in. deep, not including the 3½-in. floor slab, and tapers from 8 in. thick at the bottom to 10 in. at the under surface of the slab. It is reinforced with two 1 1/16-in. and four 1⅛-in. round rods and with 5/16-in. stirrups placed in general on 3½-in. centers, as shown in one of several accompanying diagrams. Girder 10 along the inside of the outside bays, has the same sectional dimensions as 2, but is reinforced with two ⅞-in. and four 15/16-in. round rods and has fewer 5/16-in. stirrups. The transverse floor beams, numbered 1, are 25½ in. deep, 6 and 8 in. thick at bottom and top respectively, and have four 1-in. round rods and 5/16-in. stirrups on 3½ to 18-in. centers. Beam 17 is 23¾ in. deep, not including the floor slab, which is 5¼ in. thick in the outside bays. It is reinforced with two ⅞-in. and two 15/16-in. rods and with 5/16-in. stirrups. The floor over the basement passageways is reinforced with ½-in. rods on 5-in. centers. In the center bays the reinforcement is ⅜-in. rods 4½ in. on centers.

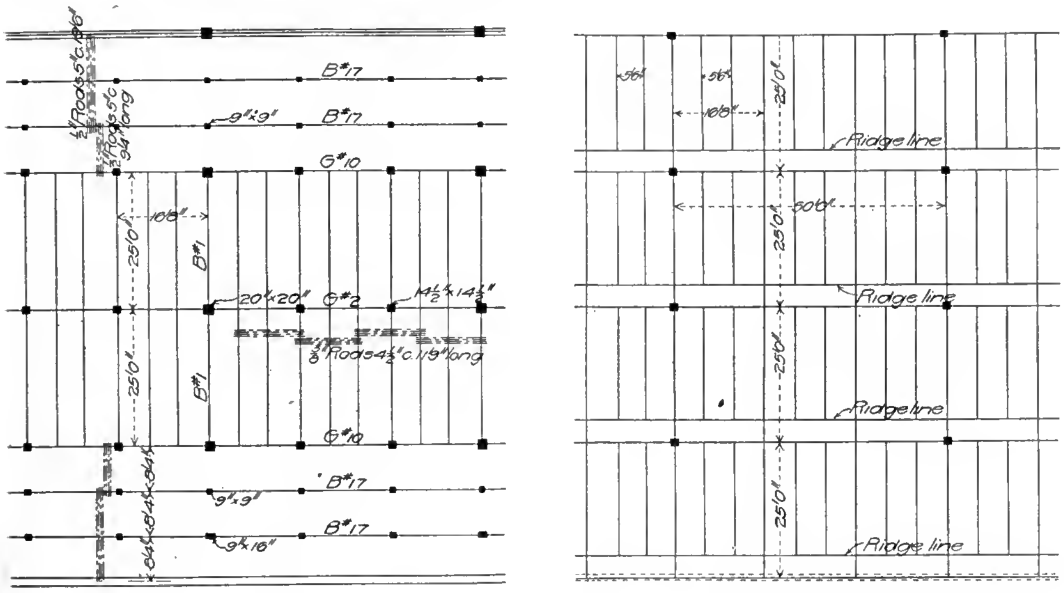
The principal columns extend through the main floor, supporting it and the roof as well, and have a clear height of 24 ft. 8 in. from the top of the floor to the under side of the roof girders. They are 20 in. square below the main floor and 15 in. square above it and have as reinforcement eight ⅞-in. round rods surrounded by 5/16-in. ties at 15-in. intervals. The end wall columns have the same section as the interior columns, but only half as many vertical rods. On the south side of the factory the regular wall columns are replaced by the heavier interior columns to provide for the addition of more bays in that direction. In the outside line of short columns in the north basement passageway every third one is 9 x 16 in. instead of 9 in. square. These heavier columns extend 12 ft. above the main floor and carry part of the weight of a 5-ft. by 7½ to 8¾-ft. reinforced concrete hot air duct which extends the entire length of the factory along the north wall. This duct is supported in 50-ft. spaces by the columns mentioned and, in a few cases, on the block division walls between the buildings; where the duct is carried on these walls a 6-ft. reinforced concrete lintel is provided in each wall to distribute the load. The duct has register openings in its top and bottom and in its free side. Its top serves as an inspection walk through all the buildings.

The saw-tooth roof is supported in 50-ft. spans by longitudinal girders 1 ft. wide and 51 in. deep carried on the several lines of columns. Each span is reinforced with sixteen 1-in. bars and with 5/16-in. stirrups arranged as shown in an accompanying diagram. These girders are intersected at intervals of 16 ft. 8 in. by the roof trusses which are made up of the long and short rake roof beams connected at their lower ends by tie beams. The beams in the short rake also serve as mullions between the skylights. Between each pair of truss beams in the long rake are two intermediate roof beams which are attached to the valley and ridge girders. The arrangement of these beams and girders is shown in an accompanying partial roof plan and the reinforcement is indicated on a section drawing. Special attention is called to the method of locking together the rods in contiguous tie beams at the intersection marked B. This was done by turning the tie beam rods through a quarter-turn so that the right angle bends at their ends hooked in opposite directions about the upper rods of the mullion beams. The upper ends of the latter rods are attached to the ends of the bent rods in the long rake beams by a wired splice.

The concrete used in the framework and roof is a 1:2:4 mixture of Vulcanite Portland cement and washed beach sand and gravel. The sand and gravel is delivered in boats at the east end of the building where it is loaded into two-wheel hand carts with a steam hoist and hauled to storage piles about 200 ft. from the river in front of Building 2 and near the mixer. The latter, a No. 3 Ransome machine, is mounted on an elevated platform and delivers to wheelbarrows or two-wheel carts on the ground. Above the mixer are measuring hoppers and above these are two bins for sand and gravel with a combined capacity of 30 cu. yd. These are supplied from the storage piles by stiff-leg derrick operated by a Lidgerwood three-drum hoist. A 60-h.-p. Ames boiler supplies steam for the mixer and hoisting engines. A platform elevator, operated with a Lidgerwood hoist and handling two



Floor Girder, No. 2, Stollwerck Factory.



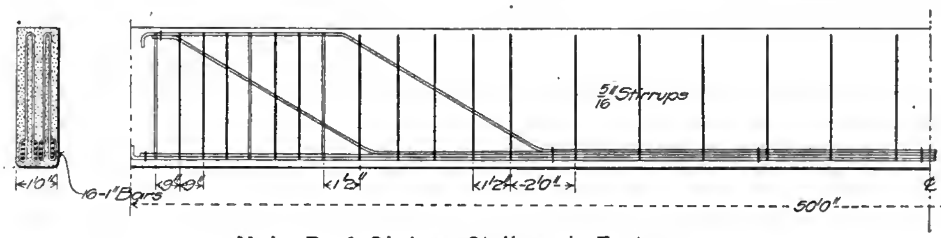
Part Plan of Floor and Roof. Stollwerck Factory.

carts or three wheelbarrows, delivers the concrete to platform runways at suitable levels to serve the various parts of the work, and is moved westward as the work progresses.

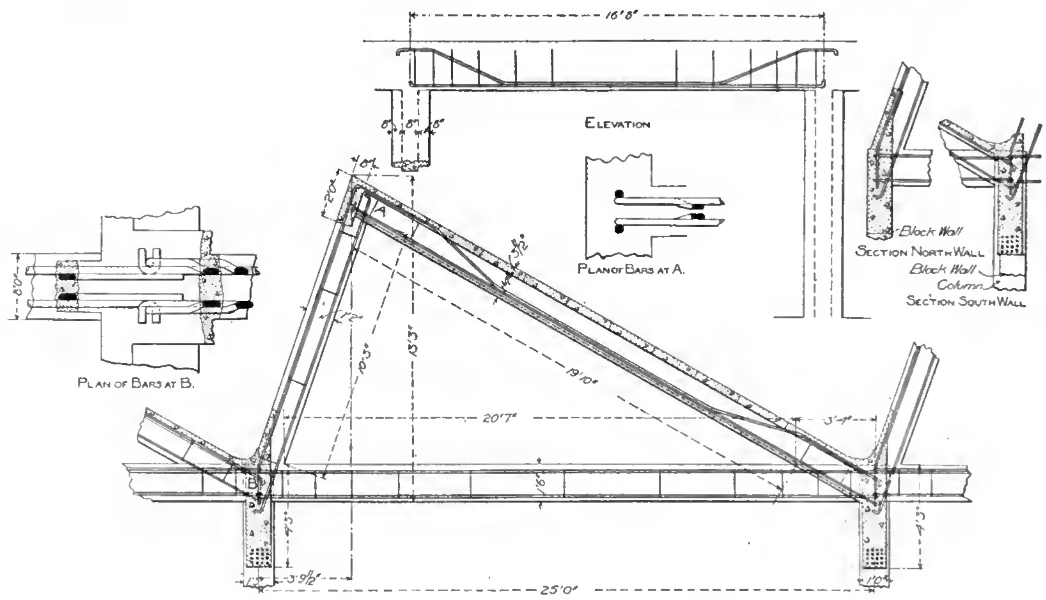
The unit system of reinforcement was used throughout the structure in the beams, girders and columns. This system, which has already been described in detail in this journal, involves the fabrication of the reinforcement for each girder or column into a unit in the shops of the contractor. These units are delivered on the work ready to be placed in the forms, each unit bearing a mark indicating its proper place in the structure.

In constructing the saw-tooth roof the columns were poured first; then the centering for the lower roof slab, the main girders, tie beams, mullions and all other roof beams was erected, 4 x 6-in. vertical posts thickly set and carefully braced being used for supports. The concrete for the lower roof slab and all the beams and girders was poured at once, the work being carried forward by a force of about thirty men who completed on the average one 50-ft. section over one bay in a day. The upper roof slabs were made and placed in 5½x25-ft. panels and covered with tar and gravel roofing. Copper flashings are provided at all projections and openings.

The ornamental cornice along the facade of the building was run on metal lath in place on the main girder at the top of the block wall, the attachment being made by means of brackets fixed in the girder at 2½-ft. intervals. These brackets are formed of three pieces of 2x2¼-in. angles. Two of these pieces project from the face of the girder horizontally near its top and bottom, the one at the top extending out further than the one below. The outer ends of these pieces are connected by the third piece with which slopes diagonally downward and inward. The upstanding leg of each diagonal piece is pierced with four ⅜-in. holes through which are strung ⅜-in. round rods.



Main Roof Girders, Stollwerck Factory.



Section of Saw-Tooth Roof, Stollwerck Factory.

The wall blocks are made of a 1:2:4 mixture of Atlas Portland cement and washed sand and gravel and were formed in a machine made by the American Hydraulic Machine Co.

Two separate load tests were made on the saw-tooth roof. In the first test bags of sand were piled in the valley in the form of a pyramid with its apex at the center of the girder. The total load of 84,800 lb. was applied in such a way as to produce a bending moment on the girder equivalent to that produced by the dead load plus four times the live load which the roof was calculated to sustain. The deflection of the girder at the center under this load was 0.20 inches. The second test load was extended over two adjacent girders for the purpose of testing one of the columns. The method of loading was different from the first test, water being used instead of bags of sand. A canvas bag lined the interior of the valley and was supported by planking along the skylights and at each end. The length of the trough thus formed was 100 ft., and its section was triangular, the sides being parallel to the slope of the roof. The pocket thus formed was filled with water to a maximum depth of 5¾ ft., a total load of 332,000 lb. being thus applied. This was equivalent to four times the calculated live load over an area of 100 x 25 ft. The deflection of each girder at its center under this loading was 0.10 in. Upon the removal of the load the girders recovered almost entirely.

The peculiar virtue of the system of loading adopted in the second test lies in the absolute mobility of the load which prevents the arching effect which sometimes occurs when a very heavy load is applied in solid form. It would be expensive to apply this method of loading in a single test unless the material of which the water-tight receptacle was made could be used afterward for some other purpose, but where a number of tests in series are contemplated it would probably be as inexpensive as the ordinary system of loading.

The architectural drawings for the factory were prepared by Mr. Ernest Flagg, architect, New York City, and the structural designs were prepared and the work is being executed by Messrs. Tucker & Vinton, of New York City, Mr. R. L. Bertin, chief engineer. Mr. P. H. Trout, superintendent of construction.

OPEN-HEARTH STEEL RAILS have recently been ordered by the Great Western Railway Co., of England, the first British company to place a contract for such rails.

Six-Tracking and Reconstruction of the Harlem River Branch of the New York New Haven & Hartford R. R.

The Harlem River Branch of the New York, New Haven & Hartford R. R. runs from a point near the junction of the Harlem and East Rivers in the Borough of The Bronx, New York City, northward beyond the limits of the city to New Rochelle, where it joins the main line. The latter runs westward at this point to Mount Vernon, where it connects with the New York Central & Hudson River R. R., and thus secures an entry into the Grand Central Depot in the heart of Manhattan. The Harlem River Branch carries a very heavy freight traffic which is received and dispatched at the Harlem River Station on car floats which connect with the various railroads in New Jersey, running west from the Hudson River. Considerable freight originates, too, in the territory neighboring the southern end of the Branch, the banks of the Harlem and the East Rivers affording particularly advantageous sites for industrial establishments. The passenger traffic, consisting entirely of suburban travel to various points in the Borough of The Bronx, already a very heavy one, has been increasing rapidly owing to the marked development of this portion of New York City during the past few years. At the Harlem River Station, the southern terminus of the Branch, there is no rail connection of any kind, the passengers transferring as a rule to the Third Avenue Elevated System in order to reach the business part of Manhattan Island, while the freight, that requires transfer to other roads, is handled by car ferries.

A steady increase in passenger and local and through freight business caused the adoption of broad plans for improvement, which are now being carried out. Before starting reconstruction the road had two tracks from the Harlem River Station to Pelham Manor and four tracks from the latter point to the junction with the main line at New Rochelle. The present work consists in four-tracking the road from the Harlem River Station to the Oak Point Yard and six-tracking the remainder of the line, at the same time making such changes in the layout of the stations, in the yards and in the grades both of the railroad and of the intersecting streets as were necessary to realize the greatest efficiency from the new plans and make unnecessary any future rearrangement of street crossings.

At the present time there are car ferry transfer bridges both at the Harlem River Station and at the Oak Point Yard, but when the latter has been fully developed the use of the transfer bridges at the former station will be discontinued, only such freight as originates locally at the industries on the Harlem and East Rivers being handled on the line south of the Oak Point Yard. New transfer bridges, and additional tracks are being constructed at the latter point so as to handle all of the through freight traffic.

Four of the tracks in the six-track section will be used for passenger service, the two outside ones of the four for local, and the two inside ones for express trains. The two tracks to the south are for freight traffic.

There are thirteen passenger stations on the Harlem River Branch, two of them having been established since the reconstruction was started. All of the old stations are being replaced with handsome structures differing in design to suit the location. At the local stations there will be but two platforms, one on the outside of each local passenger track, and at the express stations one local platform along the outside of the local track nearest the station building, and two island platforms, one between each pair of passenger tracks of like movement. Access to these platforms is had through reinforced concrete subways under the tracks.

Part of Former Two-Track System.

Coincident with the other improvements is the change of grade in order to eliminate railroad crossings at street level. At the south end the railroad tracks are on a fill and the streets which cross the line are spanned by plate girder bridges, while on the north end the tracks are at about the level of the surrounding land and the streets cross the right of way on overhead highway bridges. There are 56 bridges in all, in a total distance of 11½ miles, the length of the Harlem River Branch, the spans varying from 44 to 197 ft. Plate girders are used for the short spans and riveted through truss bridges for the long spans. The alignment has also been benefited in the improvement work, the additional property being purchased so as to make easement possible.

There are two crossings of navigable streams, the Bronx River and Pelham Bay, which will be crossed on Scherzer rolling lift through bridges. The channel spans will be 70 ft. in the clear between the fenders protecting the piers. The length of the crossing over Pelham Bay is about 1,600 ft., for which a pile trestle is being built. Near the south end of the branch at Port Morris, provision is being made for the future construction of the tracks of the New York Connecting R. R., which is to cross over the East River from Long Island.

The work was started in October, 1905. Provision was made for maintaining both the passenger and the freight traffic during construction by shifting the running tracks at the south end to one side while the fill was being made, and while the abutments and piers were being built for the bridges. Practically all of the material for this fill was obtained from the largest cut on the line, at Hunt's Point, 85 per cent. of the material being rock, some of it very hard and grading down to a soft disintegrated schist.

The plan on the fill section is to complete the abutments and bridges and roadbed for three tracks, two for running purposes and one for work trains, before abandoning the temporary tracks, which at the beginning of construction were placed to one side in order to allow the fill and bridge work to be carried on. From the present rate of progress it is probable that trains will be put on the fill within the next six or seven weeks. At the north end of the work where the tracks follow, in the main, the level of the surrounding ground, the running tracks were shifted so as to accord with the best methods for handling the work under the local conditions.

Fill and Completed Abutments at Port Morris.

Completed Abutments at White Plains Road.

The sections for the piers and abutments have been made very heavy on account of the treacherous nature of the material along the right of way. Much of the land is very low and is entirely underlaid with marsh and swamp deposits. At the south end piles had to be driven for all of the abutments and piers, their length varying from 25 to 50 ft., in order to reach rock. The average length was about 35 ft. The driving at the surface is very easy for 10 to 15 ft., beyond which a somewhat harder material is encountered for a distance varying from 5 to 10 ft., followed by hard driving and then rock. In some places fills of miscellaneous character were encountered which gave considerable difficulty in driving. Some of these were of rock fill, others of ashes and garbage wastes. The wisdom of selecting the heavy sections was proved after the fill had

been started, when the weight of the deposited materials squeezed out the muck on either side into humps and ridges 5 to 6 ft. high.

The formula for the width of the abutment where earth alone is to be retained is ⅓ of the height, plus 3 ft., and where the earth fill carries tracks, ⅓ of the height plus 4 ft. The tops of the piles are sawed off level and the concrete placed over them for a depth of 1 ft. The footing is reinforced with old rails running parallel to the length of the abutment. In addition to the vertical piles, batter piles are driven to secure greater stability.

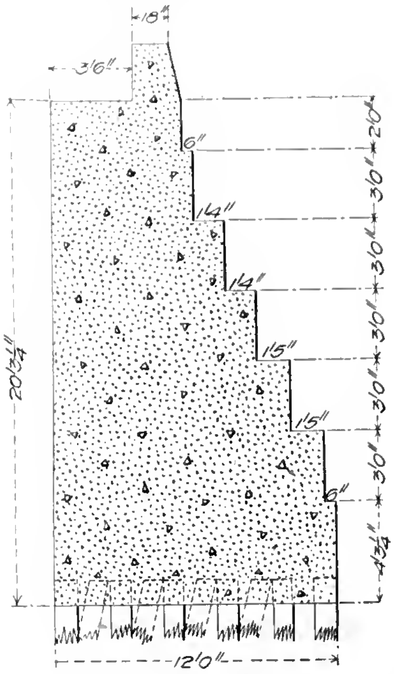
The concrete for the abutments and piers is a 1:3:6 mixture, the rock being trap from the Connecticut quarries. For the bridge seats and copings 1:2:4 is used. Both Alpha and Lehigh Portland cements are used. The concrete was all mixed in 1-yard mixers placed conveniently at the work, and was put into place with bottom dump buckets, handled by stiff-leg or guyed derricks.

In Pelham Bay Park, the city authorities objected to the use of concrete, and stone was therefore used for the abutments of the bridges within the Park limits.

The angles at which the streets cross the right of way and the fact that in some cases a number of streets meet at the railroad necessitated some long bridges and abutments. The Bronx and Pelham Parkway crosses the right of way at a sharp angle, and the abutments and piers are being built for a width of roadway and footwalks of 400 ft. This made it necessary to build the abutments 780 ft. and the piers 710 ft. long. The railroad will provide a bridge 80 ft. wide. At another point, West Farms Road, East 180th St. and Adams St. join at the right of way and are carried over the tracks on a skew plate girder bridge, the abutments for which are respectively 333 and 318 ft. long.

Small toe walls were necessary in places to prevent the slopes going beyond the right of way line, and in one case along the Bronx River, a retaining wall with a maximum height of 15 ft. above high water and a length of 220 ft. was necessary.

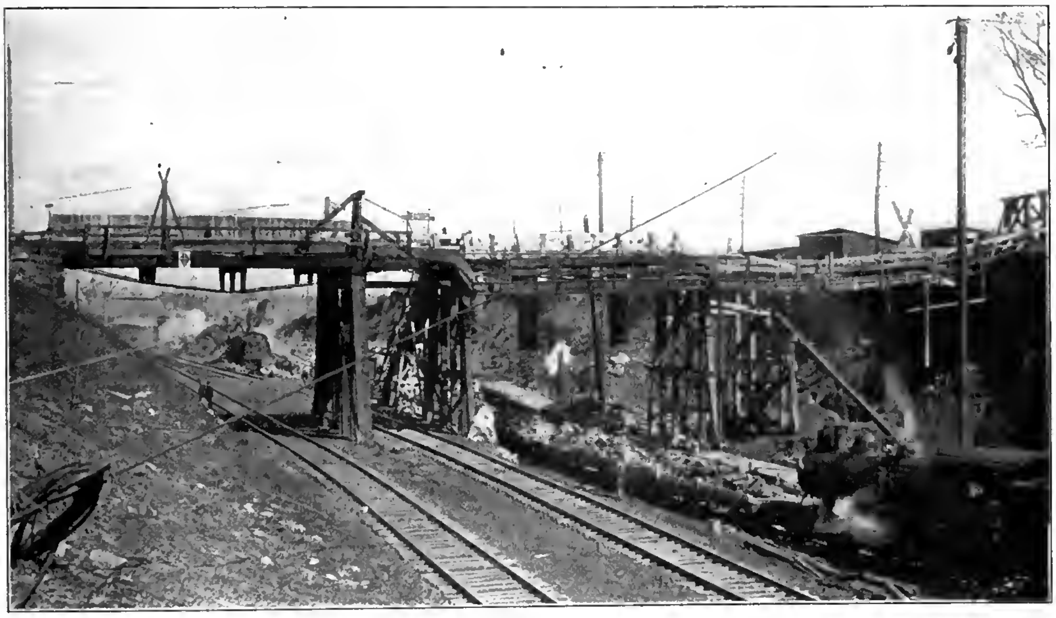
Most of the new passenger stations are constructed with their floors at the level of the tracks, but in some cases are being built overhead. The platforms are to be 700 ft. long and are to be paved with concrete, cement finished. The stairways leading from the station buildings to the subways under the tracks and from the subways to the platforms are to be built of reinforced concrete, the steel consisting of 1-in. corrugated rods. The rods in the walls and the floor are on 12-in. centers in both directions, and in the roof on 12-in. centers transversely and on 4½-in. centers longitudinally. The inclined rods in the roof, shown in the illustration, are on 12-in. centers. The station buildings are to be of different designs in order to harmonize with the local surroundings, some of them of stone, some of brick, and some of concrete.



Abutment for Railroad Bridge.

The freight business along the line has been cared for by reconstructing the yards already in operation, and by adding others where necessary. These are merely large enough to handle the local business. The main freight yard of the branch will be, as is the case now, the Oak Point Yard. This is to be entirely reconstructed and increased in size, with a view to handling all of the through traffic, to and from the car ferries.

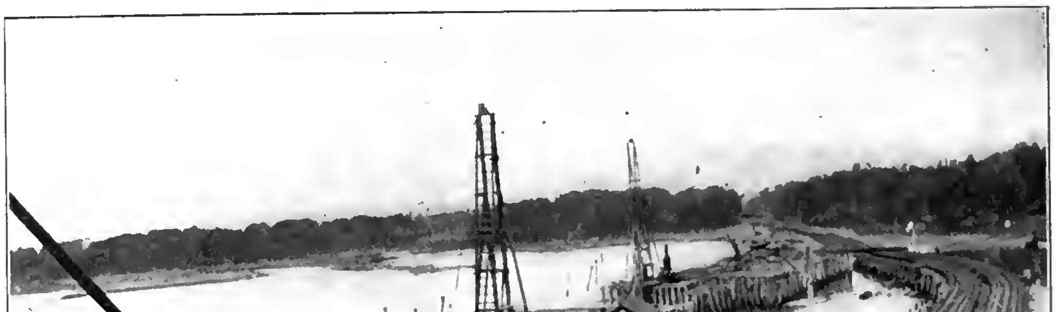
The tracks are laid on 13-ft. centers, except where station requirements and the crossing structures at Bronx River and Pelham Bay necessitated greater distances. The sub-grade, as shown in an accompanying illustration, is crowned from both sides to the center of the six tracks and is covered with rock ballast, the maximum depth of which at the sides of the six-track roadbed is 20 in. below the top of tie. Creosoted white pine ties are being used exclusively, and carry rails which weigh 100 lb. to the yard. About 3,800 cu. yd. of trap rock ballast are required to the mile for the six-track roadbed. The maximum curvature of the center line of the six-track system on the new alignment is 4 deg. 55 min., and the maximum grade is 0.65 per cent., at the point where the road goes up onto the fill at the south end. The greatest difference in grade between the new and the old lines is about 12 ft., in the cut, already referred to, at Hunt's Point.



Hunt's Point Cut, Showing Temporary Highway Bridge and Old Main Line Tracks.

At a number of the streets crossing the right of way the railroad company is building new sewers, reconstructing old ones and providing suitable protection, from the heavy loads of the new filling material and the traffic, for some of the others which are already built. The new sewers are of reinforced concrete, some of them circular and others of an approximately rectangular section.

The Bronx River will be crossed on Scherzer rolling lift through bridges made of three leaves, each accommodating two tracks. The bridge and the river are at a considerable angle, and in order not to make a jog in the river so as to secure a right-angle crossing, or in lieu thereof, put a curve in the railroad, it has been necessary to step back the three leaves successively, each leaf being a right-angled one. This has necessitated complicated abutments and piers. The clear channel between the fenders, which are straight throughout their length, is 70 ft., 26 ft. more than for-



East End of Pelham Bay Trestle under Construction.

merly. The piers and abutments were founded either upon rock or upon good gravel beds. No great difficulty was found in building them, but the rock sloped sharply in places the distance from the top of the pier to the foundation in some cases being as much as 30 ft. more at one end than at the other. The footings are of 1:2:4 concrete, but the superstructure from a point well below the lowest tide level to the bridge seats is of granite. The concrete was placed under water by means of bottom dump buckets. The old bridge at this point was a center pier swing bridge of the through plate girder type carrying four tracks. The method of removing it was explained in an article of The Engineering Record of June 29, 1907. In order to accommodate the traffic during construction a temporary 2-track trestle and a 2-track jack-knife draw-bridge have been built immediately south of the permanent site.

Pelham Bay Bridge and Trestle. The crossing of Pelham Bay consists of a pile-bent trestle 1,600 ft. long, near the center of which is the Scherzer rolling lift bridge, consisting of three leaves for two tracks each. There are 150 bents in the trestle, each containing 36 piles, 2 ft. 9 in. on centers transversely to the center line of the railroad. The bents are 10 ft. apart longitudinally. The bracing of each bent consists of 3x10-in. diagonals on each side of the piles, running from the horizontal bracing at mean low water to the cap. In order to reduce the unsupported column lengths the bents are braced together by 12-in. longitudinals, just above mean low water elevation. In order to prevent swaying longitudinally on either side of the draw-span those bents on the curves at each end of the trestle. In order to guard against any possible error, all of the data necessary for the construction, such as angles, plusses and offset distances, were carefully computed and checked and then embodied in tabular form in a large layout plan, which, in addition, contains a plan and an elevation of the trestle. The plan of the trestle shows the angles of all of the hubbed lines used in connection with the work, the P. C.'s and P. T.'s of the curves on the center line of the six-track system and of the north and south pairs of tracks, the number of each bent and the plusses of each bent, both on the permanent stationing and on the base line which was laid down for construction purposes. The trestle is on a grade at both ends and level at the center, with a vertical curve on each side of the draw-span. For this reason the cut-off of each bent and the data for the vertical curves are noted on the elevation of the trestle on the layout-sheet. The tables give the elevations and descriptions of the construction bench marks, the data for the curves at both ends of the trestle and the angles and distances for locating each of the bents on the curves from the base line. The data for running the curves is given separately for the six-track dimensions as shown have been used for distances up to three-quarters of a mile. The design of the targets as well as the computations and the method adopted in laying out the trestle, are due to Mr. L. D. Fouquet, who is in charge of both the Pelham Bay and the Bronx River crossings for the railroad company.

The building of the foundations and piers for the Scherzer rolling lift bridge proved a troublesome undertaking. The bed of the bay consisted of soft muck, which had to be removed. Solid rock was found at varying depths from —18 to —29, the elevation of mean low water being —5.1, and of mean high water +2.1. The entire site was dredged clean down to the rock by the International Dredging Co. Very accurate and com-

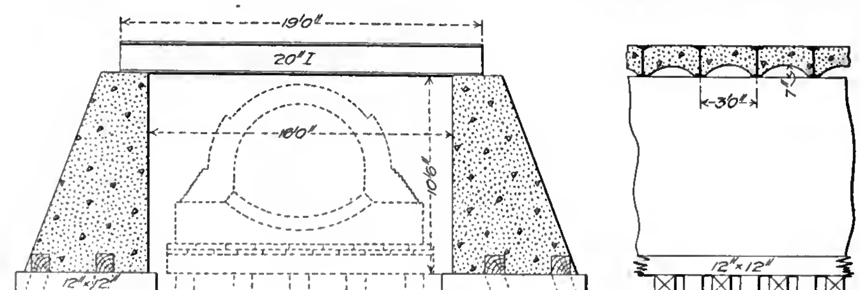
Original Bent and Section of Completed Cofferdam.



I-Beam Protection for Bungay Street Outlet Sewer.

special 4x10-in. bracing in vertical planes parallel to the direction of the track has been placed on the six bents on each side of the lift bridge.

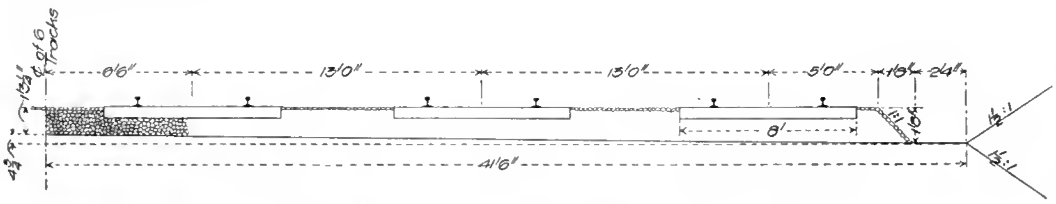
Both ends of the trestle are on 3 deg. curves. The tracks are laid in three pairs of two tracks each, the distance between the two tracks of a pair being 13 ft., and between the adjacent tracks of two different pairs 23 ft. The deck of the trestle is 12.9 ft. above mean high water. The piles in the portion of the trestle west of the draw vary in length from 22 to 50 ft., and east of the draw from 50 to 80 ft. They were driven to a ½-in. refusal, with a 5-ft. drop of a 3,000-lb. hammer. The piles are of long leaf yellow pine, with 8-in. tips and butts not less than 12 in.

The laying out and construction of a trestle of this magnitude required very careful work and close supervision in order to get the piles in each bent in a good line, to preserve the proper distances between the bents and between the individual piles and to secure the proper angles for center line and for the north and south pair of tracks, the deflections being noted both for foresight and backsight.

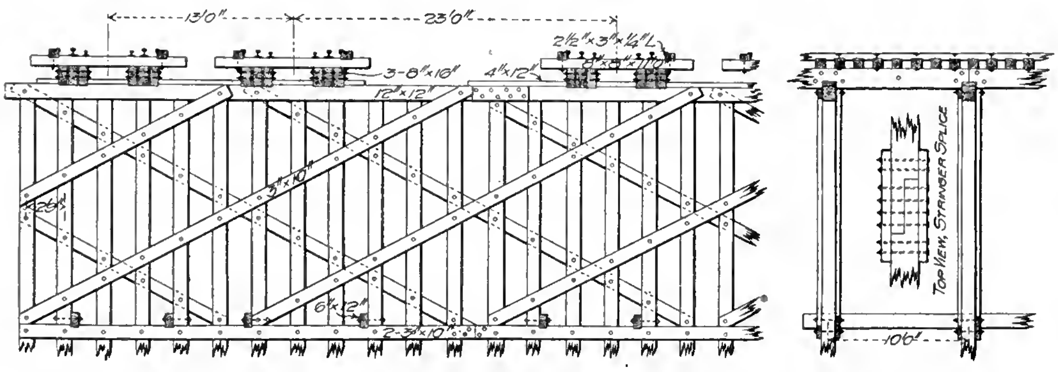
The center line of the six-track structure was first laid out and permanent hubs driven in secure places on each shore on the prolongation of the tangent. A base line was then laid down south of the structure, and on it the temporary trestle for accommodating the traffic during construction was built. From this trestle and the base line the entire new structure was laid out, the line for each bent being sighted from two nails driven in the deck of the temporary trestle. Permanent targets were placed above the hubs on shore on the center line of the permanent structure, on the base line and on the longitudinal center lines of the abutments and piers for the Scherzer rolling lift bridge. These targets, the design of which is shown in an accompanying illustration, were adopted as a result of a series of trials and have given entire satisfaction. The plete soundings were then made by means of long gas pipes, in order to determine the topography of the rock bottom. With the data from the soundings, elevations, both transverse and parallel to the length of the abutments and piers, were platted, and stout frames for the cofferdams were constructed according to these profiles. These frames, after being placed in their proper positions, were loaded sufficiently to sink them to a bearing on the rock, and the cofferdam sheeting was then placed inside the framework. The framed bents when put in position contained temporary braces and struts, which were removed after the bents were lined up and when the sheeting was placed. The upper 6x12-in. clamps and braces were removed while the sheeting was being set and were then replaced. One of the illustrations shows a bent in the original condition and the completed cofferdam. As soon as the sheeting was set a diver was sent down inside the cofferdam and cleaned the rock perfectly by means

of a jet of water, the washings being removed by a 12-in. centrifugal pump. The concrete was then placed under water by means of bottom dump buckets, the cofferdams serving as a form for the footings. When the latter had reached their proper height the cofferdam was pumped out, and the surface of the concrete carefully leveled for beginning the granite work for the piers. At the completion of the latter the nuts were taken off of the bottom rods and the cofferdams removed.

In the early stages of the masonry work precautions were taken to prevent the floating of the cofferdams, and the consequent disturbance of the concrete footings which plugged their bottoms. The head of water on the outside of the cofferdam in high tide was sufficient to more than counterbalance the weight of the concrete, providing the cofferdam above the latter was pumped out. For this reason the cofferdams were flooded at high tide until sufficient of the granite masonry had been placed to overcome the upward pressure due to the head on the outside of the cofferdam.



Half Section of Roadbed for Six-Track System on Harlem River Branch.



Half of 36-Pile Bent and Side View, Pelham Bay Trestle, Harlem River Branch.

The six-tracking work and the other improvements are being done under the direction of the engineering department of the New York, New Haven & Hartford R. R., Mr. E. H. McHenry being vice-president, in charge of engineering, and Mr. Edw. Gagel, chief engineer. Mr. R. M. Berrian, assisted by Mr. M. S. Jameson, was in charge of the work from February, 1904, until August, 1906, since which time it has been under Mr. W. B. Leonard, assisted by Mr. I. D. Waterman. The contractors are Messrs. Daly and Holbrook.

Tests of Concrete Blocks taken from the stock of the National Hydraulic Stone Co. of Baltimore have recently been made by Mr. Allen S. Crocker, M. Am. Soc. M. E., of Rochester, N. Y. There were seven specimens tested, one of which could not be broken by the testing machine which has a capacity of 200,000 lb. The other blocks had an average strength of about 2,907 lb. per square inch. The blocks were made on machines built by the Fisher Hydraulic Stone & Machinery Co., and only one of the specimens had been dampened more than twice within the first week after it was made. This one had a strength of 4,103 lb. per square inch. The lowest strength of any block was 1,178 lb. per square inch, due to the fact that the block was shipped when only 3 days old and had no water from that time until tested at 19 days age. The blocks were made of 1:8, 1:10 and 1:12 mixtures, and had bearing surfaces of 14 sq. in. or more.

Sewage Disposal Plant at Kew Beach, Toronto, Ont.

At the recent convention of the American Society of Municipal Improvements, Mr. C. H. Rust, city engineer of Toronto, read a paper on the sewage disposal plant at that portion of the city known as Kew Beach, situated at the eastern limit on the shore of Lake Ontario and solely a residential district. The level of the ground is only a few feet above the level of the lake and the soil sandy underlaid with clay. The property owners have been for some time asking for drainage, but owing to the municipality of East Toronto procuring their water supply from a point about three-quarters of a mile east of this district, and to the objection of the Board of Health to allowing crude sewage to be deposited in the lake, is was necessary to adopt the sewers and purification works as described. The drainage area of this district is one hundred and eighty-five acres, containing a population of approximately 10,000 during the summer months.

To ascertain the consumption of water a meter was placed upon this district, and it was found that the actual consumption per head in twenty-four hours was 16 gallons.

The main sewer is laid along the lake front at a depth varying from 2 to 9 ft. below the lake level and is constructed of 16 and 10-inch cast-iron socket pipes. All sewers from the north discharge into this sewer and at a point midway between the outfall and the summit is constructed pumping station No. 1, raising the sewage from the low level sewers from the east and north into the high level sewer which gravitates to No. 2 pumping station where the sewage is raised into the disposal works. These pumping stations are constructed of concrete and are circular in plan with a partition wall in the centre and have a reservoir space of 3,200 gal.; and each contains a duplicate set of pumps and motors, No. 1 consisting of two 5-h.-p. alternating vertical motors and two 4-inch submerged centrifugal pumps and No. 2 consisting of two 7½-h.-p. alternating vertical and two 4-in. submerged centrifugal pumps. Motors and pumps are automatically controlled by the rise and fall of the sewage in the reservoir.

The shafts of the pumps are connected direct onto the armature of the motors without any bevel gearing, which practically eliminates all noise whilst operating.

The disposal works consist of three septic tanks and twelve bacteria beds, constructed from plans designated by the Cameron Septic Tank Co. and operated by the gear patented by them.

The works are erected on the shore of the lake about 200 feet from the water's edge, and are supported by 10-in. piles driven 16 ft. through the sand and into the hard clay and surrounded by tongued and grooved sheet piling driven 14 ft.

The construction of these works is of concrete in the proportion of seven of broken stone and sand to one of cement.

The three septic tanks are each 100 ft. x 14 ft. x 7 ft. 3 in. deep at the low end with a total capacity of 183,750 gal. They are covered with a 3-in. concrete roof, made in the proportions of 4½ of broken stone and sand to one of cement and reinforced with 3-in. mesh, 10-gauge expanded metal. At 6 ft. 6 in. centres are 9x6-in. concrete beams supporting the roof, reinforced with ¾-in. Johnson's corrugated steel bars. An inlet channel feeds the three tanks at the high end, each one of which can be operated independently from this channel.

The distribution of sewage into the tanks takes place through one 8-in. pipe, thence through four 12-in. openings, 3 ft. above the bottom of the tank, which accomplishes a maximum flow of sewage with a minimum amount of disturbance. At the low end of the tanks thirteen 4-in. outlet pipes are built into the wall, 2 ft. 7 in. below the water line, connecting with the cleansing chamber and outlet channel. From here the main effluent carrier is built into the wall of the bacteria beds in line with the outlet channel of the septic tanks and runs the whole length to the end of the beds and has three branches at regular intervals, each feeding one set of 4 beds.

There are 12 bacteria beds, 3 sets of 4 each having a combined area of 1,860 square yards. Each bed is 50 ft x 28 ft. x 4 ft. 6 in. deep and is filled 4 ft. deep with furnace slag varying in size from ¼ in. to 1½ in. On the floor are laid 14 lines of 3-in. weeping tile collectors, discharging into a 9-in. main collector, and 6 in. below the surface of the slag are 6 lines of 6-in. weeping tile distributers fed by a 9-in. main distributer. All discharge pipes terminate in one common chamber from which a 15-in. main filtrate carrier is laid down to the lake, the last 30 ft. being supported on piles.

The sewage is raised to a height of 22.5 ft. at pumping station No. 2, into the inlet channel, which is below water line and extends to a point beyond the inlet to septic tank No. 3. From this inlet channel the sewage is admitted into each tank required to be operated through the submerged openings.

The effluent from the tanks flows through the submerged outlets and through the effluent chamber, which arrests any solid matter which may find its way through the outlet pipes in time of excessive flow and thence into the outlet channel.

The semi-clarified sewage now flows along the main effluent carrier and on to the automatic distributing gear from which it is distributed to each bed in turn through its admission valve. The discharge valve will be closed meanwhile so that the interstices of the filtering material will be filled with the tank effluent. The effluent remains in the contact beds for a period of about two hours, according to the rate of flow. The discharge valve will then open, when the filtered effluent escapes, drawing down after it a supply of air into every crevice of the contact bed. The latter will then drain and aerate whilst the remaining contact beds of the set are filling, after which it will again be filled in turn. This method of working renders the contact beds self-cleaning so that they retain their purifying power unimpaired.

The alternate filling and emptying of the contact beds is effected automatically by means of the alternating gear in the following manner: As soon as bed No. 1 is filled, a small quantity of filtered effluent overflows from its discharge well into a float chamber, lifting the float, at

the same time opening the admission valve and closing the discharge valve of bed No. 2. When bed No. 2 is filled, this operation is repeated, the flow of tank effluent is diverted into bed No. 3 and the discharge valve of bed No. 1 is opened and its contents are allowed to discharge.

The construction involved the carrying out of 12,262 ft. of 9-in. pipe; 1,509 ft. of 12-in.; 1,349 ft. of 15-in.; 2,451 ft. of cast-iron pipe; 32 manholes and 982 junctions. The average depth of the sewers was 8 ft. 9 in. A great deal of the work was in sand charged with water involving constant pumping.

The cost of the works was as follows:

Sewers and pumping stations	$37,755
Pumping plant	3,185
Disposal works	13,079
Piling, etc.	5,119
Slag, 2,500 cu. yds. at $1.50	3,750
Automatic distributing gear	4,000
	$66,888

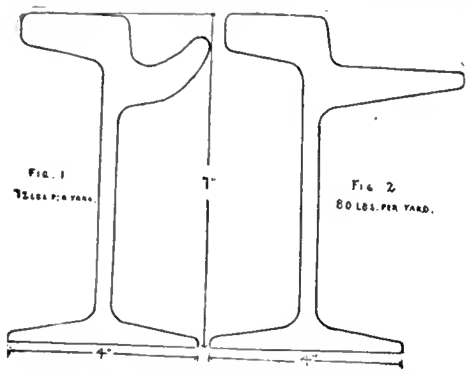
It was found after the slag had been in the beds some time about 10 per cent. of settlement took place. The works have been in operation since April and the effluent so far has been very satisfactory.

The Use of the T Rail in Cities.

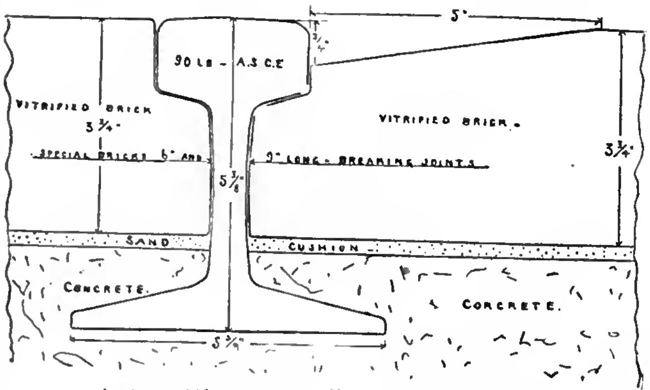
The oft-discussed question of permitting the use of T rails in cities was the subject of a paper read before the recent convention of the American Street and Interurban Railway Association by Vice-President C. Gordon Reel, of the Kingston Consolidated Railroad Co. He pointed out that in the horse-car days the equipment was so light and speeds so leisurely that the problem of a proper track was easy of solution. It was expected that wagon traffic of all kinds would follow along the car tracks and so city ordinances usually required that the street railroad companies make proper provision for the accommodation of vehicular traffic. With the introduction of electricity weights and speeds were increased enormously. The trend of development has been steadily to approach nearer and nearer to steam railroad standards. With the increase in weight of equipment and increase of speed, the grooved and girder rail sections soon demonstrated their inability to carry the car traffic without rapid deterioration. The inefficiency of these sections was due not to the light weight so much as to their unscientific design. The vertical web of the rail was usually directly under the flange of the wheel so that the weight of the car would be carried on a sort of projecting shelf. This unsymmetrical loading was more than the rails could stand. They pounded down rapidly at the joints and could not be held to gauge. The companies with which Mr. Reel is connected were unfortunate enough to build with 7-in. grooved and girder sections shown in the diagrams. These rails were structural wrecks at the joints long before they were worn appreciably.

In other cities similar sections have been used which overcome the inherent weakness in design by brute strength so to speak; that is, they are rolled in weights up to 150-lb. per yard, which would seem absurd to steam railroad men, especially in view of the very much heavier rolling stock used by the steam roads. It is self-evident that a proper section should not be inordinately heavy and should carry its load with no tendency to moving sideways, and furthermore that the track should stand solidly in place without having to strap the rails together every few feet. All T rails fulfill the first two requirements, but the standard steam railroad sections would seem to serve better than the high T sections in regard to lateral stability. Just what is gained by using a high T is hard to understand, still Mr. Reel is willing to concede that, in view of the experience in some of the larger cities which use this rail, there is a chance for an argument between high T sections and standard T sections. Personally he would prefer to pay more per ton for standard sections than for high T sections, although under ruling prices the high T cost considerably more per ton than standard T sections.

When it became necessary to renew the tracks in Kingston, Mr. Reel looked over the experience of other companies and concluded that the T rail was in every way more desirable than the grooved or girder rail and proceeded accordingly. To make sure he laid an experimental piece of track using 90-lb. Am. Soc. C. E. standard rail. This gave such good results that an order was



Rails Formerly Used at Kingston.



Latest Kingston Rail and Special Brick.

placed for several hundred tons in 60-ft. lengths with a view to extending the construction. After the rails were delivered a bitter opposition was engineered by interests which formerly owned one of the roads and who seem to be sore because the present owners have been successful. It was argued that if, when they built the road, it was necessary to use an iron lip, unless the new owners used the iron lip, ruts would form along the track. The only difficulty about this point was that it was not necessary, in the first place, to use any iron lip because experience proves that there is no greater tendency for a rut to form along a T rail than along the outer edges of a grooved or girder rail. They also used letters from city engineers of New York, Brooklyn and Albany, stating that no T rails were used in those cities. This argument we easily answered by asking our opponents to produce letters from cities where T rails had been used. The fact that they produced letters from places where they had not been used was certainly no evidence against their use. After a lot of misrepresentation and personal abuse in the newspapers the company finally got consent from the city to lay T rails in two rather important streets with the stipulation that if, after the end of a year, the city authorities so desired we would remove them and substitute the old rails. Another feature which had to be overcome was a bill introduced in the legislature intended to prohibit the use of the T rail entirely in the State of New York. Whether or not this bill had any connection with the Kingston opposition or was merely a coincidence Mr. Reel was unable to say. In any event the bill was easily defeated and was never reported from the committee.

Since the installation of this 90-lb. standard construction in the two streets referred to, the company has been granted permanent permission without any restrictions to use this 90-lb. standard T rail in the most important streets in the city.

The construction first proposed has been amended as shown in the illustration, using a special form of brick outside the rail as well as inside. It will be noted that the brick on the inside goes up on the head of the rail to such a distance as to barely give room enough for the wheel flange. In this way the obstruction in the street will be much less than though the brick projected under the head of the rail and very much less than any form of grooved or girder rail. It is now standard practice to use only ordinary brick. On the outside the brick is merely laid flush with the rail, and on the inside it is tucked under the head.

The gist of the whole T rail matter seems to Mr. Reel to be that street railway tracks are beginning to be built to serve the companies which build them and the patrons of these companies, rather than every truckman who stubbornly insists on following the car tracks instead of staying out in the roadway where he belongs. If this driving along the tracks served any economic end it might be tolerated, but it does the truckman no good and interferes with the rapid movement and comfortable transportation of countless thousands of more important people.

Cinder Disposal in a Roundhouse.

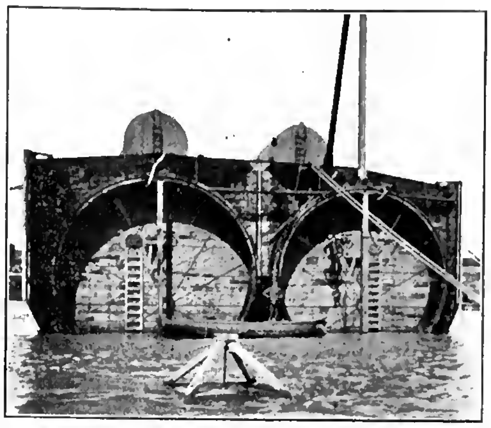
A novel roundhouse with 44 stalls has been built at Dilworth, Minn., by the Northern Pacific Ry. Co. to improve the winter service of locomotives. The object in the design has been to avoid the necessity of sending a locomotive to the cinder pit after a run, for by saving this time the terminal expenses of an engine are reduced. When a number arrive at a terminal at about the same time on a cold day, the last to reach the pit loses much time before its fire is knocked out. At Dilworth the locomotive is run directly into the roundhouse, and does not go to the outside cinder pit unless every stall is occupied. There is a pit under each stall and in a depressed part of the pit containing water are two perforated pans about 72 x 30 in. in size to receive the ashes. The fires will be allowed to die out gradually before being dumped, or after they are cleaned they will be banked, thus saving coal wasted in the ordinary procedure. When the engine leaves the stall, an electric hoist traveling on an overhead track will run over the pan, lift it up and carry it to a cinder shed. This is merely one of the stall spaces into which cinder cars are run to receive the ashes from the pan. There are two pans in each stall so that two engines can use the pit before the ashes need be removed. It is expected that from $1 to $5 will be saved in this way on each engine handled at the new roundhouse.

STATE FORESTRY WORK made great strides during 1906, according to the U. S. Forest Service. Ten States have State forest reservations, and in five of them the removal of mature timber from such public lands is now permitted, thus showing the growing appreciation of a fundamental principle of forestry. Over twenty States have forest officers.

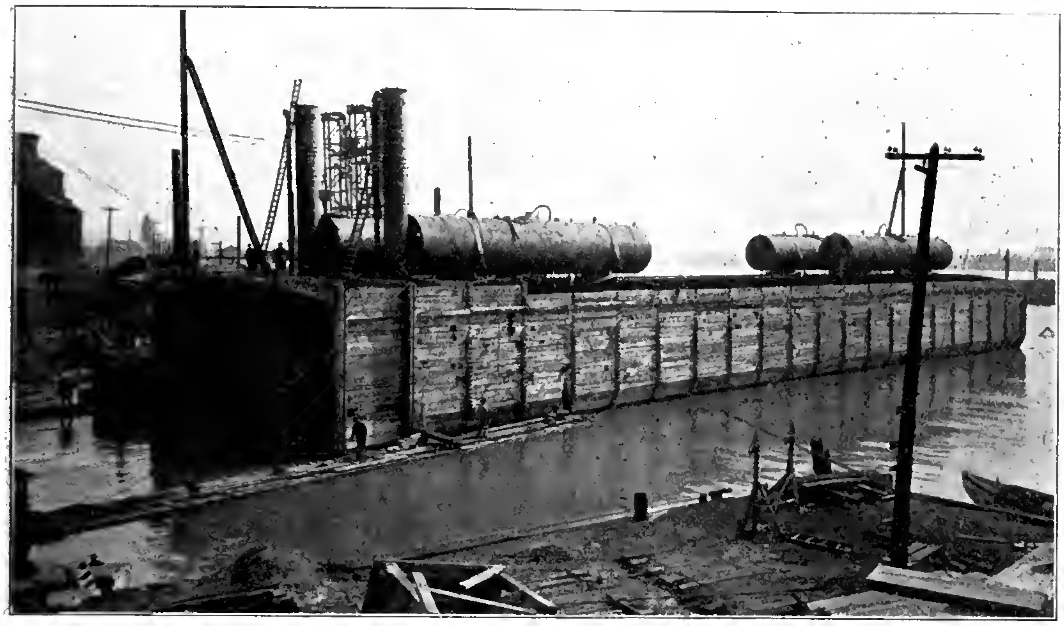
Sinking the Detroit Tunnel Tubes.

The river section of the double-track tunnel under the Detroit River is 2,622½ ft. long, and has a maximum depth of 41¾ ft. from the roof to the surface. It is built in water subject to slight variation of level with an original depth of about 144 ft., and a maximum current of about 6 miles in the center of the river, which is navigated by a very large number of steamboats and sailing vessels. The tunnel is of steel and concrete construction as described in The Engineering Record of March 7, 1907, and is being built in a deep trench dredged in the bottom of the river.

The tunnel is divided in ten equal sections, 262½ ft. long, for which the steel framework is assembled on shore, launched, towed to position, sunk in the trench, united by successive joints and concreted to form a continuous structure. The adoption of this method saved an initial difference of about $2,000,000 between the contract price for it and for the alternative plan of a tunnel constructed by ordinary shield driving methods. It is also built at an elevation of 15 ft. above the minimum necessary for the shield-driven structure and thus eliminates many hundred feet of shore approach tunnels, reducing the grades, and avoiding operation and construction expenses which, capitalized, would amount to about $2,000,000 more. This shows a balance of about $4,000,000 in favor of this construction which, in its details and in the method of execution is novel, although the idea of first constructing a tunnel and then sinking it below the surface of the water was proposed many years ago by the late John C. Trautwine.



Tubes and Sheeting as Launched.



Tubes at Commencement of Sinking Operations.

In this construction the fundamental principles are to avoid ordinary tunnel excavation, to reduce to the smallest practicable amount divers work, and to provide a permanent protective exterior concrete casing which first serves as a shelter in which the permanent tunnel can be built and inspected advantageously and economically under atmospheric pressure.

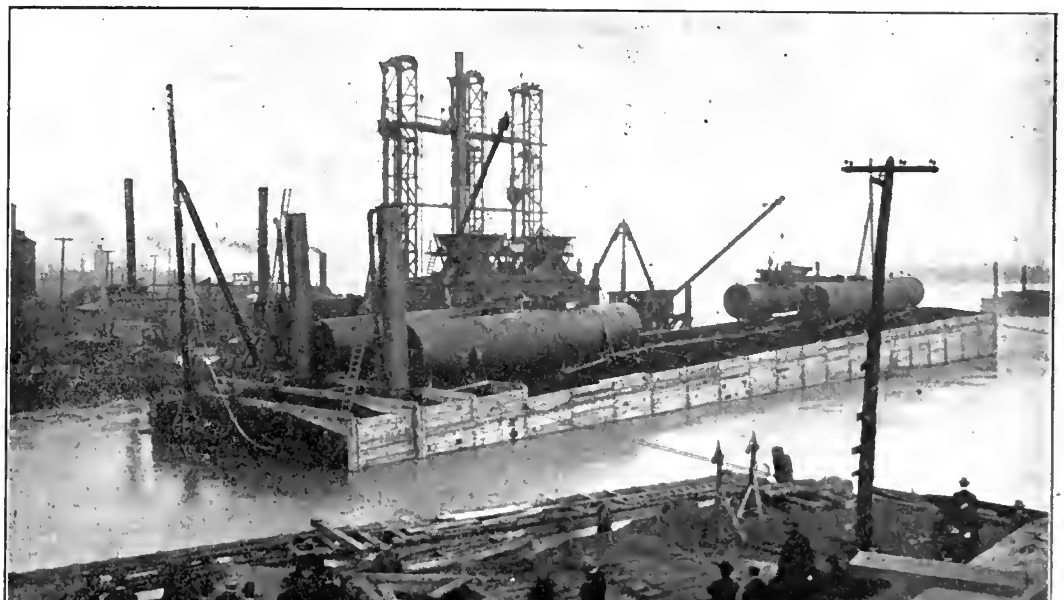
The finished structure consists of two parallel concrete tubes 20 in. thick, 20 ft. in internal diameter and 26 ft. 4 in. apart on centers. They have exterior steel shells, 23 ft. 4 in. in diameter, and are enclosed in a monolithic mass of concrete, about 56 ft. wide and 32 ft. deep.

The steel tubes are built in sections 262½ ft. long and are connected by exterior transverse vertical steel diaphragms 12 ft. apart which are 55 ft. 8 in. long and 30 ft. 10 in. deep with their edges stiffened by pairs of flange angles. The vertical and inclined outer edges of the diaphragms are sheeted with horizontal planks permanently enclosing the tubes like the sides of a bottomless scow and serving, after the tubes are sunk, for the exterior walls of a mould to retain the concrete jacket and prevent the large loss that would otherwise accrue from its lateral extension to fill the open trench if it were deposited without a mould. The tubes, diaphragms and sheeting were assembled and completed on shore and launched like a ship, towed to the site, sunk to position in the trench, coupled together by divers, the exterior concrete deposited under water through tremies and the inside concrete steel tunnel rings will be constructed in the water-tight tubes thus provided.

On the Detroit side of the river the approach is now being constructed by ordinary tunneling excavation methods and about 700 lin. ft. of trench has been excavated in readiness to receive the steel and concrete construction of the submerged portion. The junction with the land tunnel is made in a slip, sheltered from navigation and from the river current where the original depth of the water was about 26 ft., and the excavation was made to a depth of about 45 ft. below the surface by means of a dipper dredge with a 2-yd. bucket working on 1:1 slopes in the hard blue clay. Below a depth of 45 ft., the excavation is continued with 1:½ slopes by means of a clam-shell dredge with a special 2-yd. bucket, designed by the G. H. Williams Machinery Co., Cleveland, O. The jaws of this bucket have a width of 12 ft. when opened and in the hard, tough clay encountered cut off a 6-in. layer from the upper surface and roll it up like a carpet as the bucket closes. The average capacity of the dipper dredge is about 2,500 cu. yd. in 10 hr., and of the clam shell about 600 cu. yd.

It was at first proposed to secure the vertical alignment and uniform bearing of the steel tubes by driving foundation piles in the bottom of the tunnel trench and cutting them off accurately at the required level. It was finally decided that the same result could be more satisfactorily obtained without pile driving by the use of steel grillages supporting the ends of the tubes on the bottom of the trench. Accordingly there are provided for each section of the tunnel two grillages 42 ft. long and 38 ft. wide made with two 12-in. longitudinal and twelve 12-in. transverse I-beams, framed together and web-connected with their top and bottom flanges flush. In each corner of the grillage there is riveted a short vertical 6x6-in. angle to which is bolted an 8x8-in. vertical timber 6 ft. long with a sharpened point, projecting 5 ft. below the bottom of the grillage.

Pin-connected vertical rods 1 in. square, in convenient lengths of about 20 ft. are detachably connected to the corners of the grillage and suspend it symmetrically in a horizontal position under the bottom of the concrete barge. As the latter is only 35 ft. wide, the ends of the grillage project beyond both sides and the vertical rods pass up between pairs of horizontal cantilever beams projected to receive them upon the deck of the barge. The upper ends of the suspension



Tubes Commencing to Tip.

rods have long threads cut on them and the nuts engaging them take bearing on the cantilever beams and enable the grillages to be lowered accurately to position in the bottom of the trench.

Divers then descend and place on the square upper ends of the 8x8-in. vertical timbers a pile driver hammer running in special leads attached to the grillage. The hammer is then operated to drive the vertical post about 5 ft. in the bottom, bringing the grillage to the exact required level and thus providing for the accurate support of the tunnel tubes. Concrete is deposited around the grillage beams by the tremie tube, thus supporting them solidly and giving an extended bearing on the bottom of the trench to distribute the weight of the steel tubes and reduce the pressure to the proper unit values. Divers level off the top of the concrete so as to insure clearance below the upper flanges of the beams and the grillages are ready to receive the tunnel tubes.

The steel tubes are being built by the Great Lakes Engineering Works at their ship yard in St. Clair about 60 miles above the tunnel site. Each pair with its diaphragms and wooden sheathing, weighing in all about 800 tons are assembled and riveted up complete on several transverse supports, each of which contains four sets of loose timber blocking about 4 ft. high and is seated on ordinary launching ways inclined about 1:8 from the horizontal. The ends of the tubes are temporarily closed with solid wooden watertight bulk-heads and as the tubes are launched transversely the sets of blocking move down toward the water on the fixed timbers of the ways and when they reach the lower ends of the latter collapse successively until the tubes strike the water. This method of launching is a modification of that universally used in the ship yards on the great lakes.

After launching, a pair of horizontal longitudinal 10-ft. steel air cylinders 60 ft. long are temporarily attached to the top of each end of the pair of main tubes symmetrical with reference to them. A vertical access shaft 4 ft. in diameter and 32 ft. high is also attached at one end of each of the first pair of main tubes to serve as a manhole providing entrance to the interior after the tubes are submerged. In this condition the tubes have a draft of 4½ ft., with the diaphragms projecting 3 ft. farther down, and are towed 60 miles to the site and moored to pairs of anchors on the up and down stream sides. These anchors are of special design, built of steel and concrete, and weigh about 8 tons each, submerged.

The first pair of tubes was moored in a slip protected at one end from the current, which at the other end had a velocity of only about 1 mile an hour. At each end of the downstream side of the tubes was attached a single 2-in. manila hawser led through a snatch block on the anchor and another on an adjacent steel buoy of 5 tons buoyancy and then supported on a line of buoys carrying it to the capstan head of a hoisting engine on the concrete barge moored alongside the tube.

The moorings on the up-stream side of the tube were the same except that the 1¾-in. steel anchor cables were not connected to buoys, but led directly from the anchors to 8-part tackles rove with 2-in. manila line and operated by capstan heads of the same hoisting engines on the concrete barge. Provision is made for attaching four more sets of tackles and anchors to the up-stream side of the tunnel sections as they extend farther and farther into the river and the velocity of the current increases to 4 and 6 miles per hour. The mooring was found to be so efficient that the tubes could be adjusted quickly to within a very few inches of position by overhauling and slacking the lines.

As the first pair of tubes had to be sunk about 63 ft. special provision was required for locating them accurately under the surface of the water and was secured by providing at each end a riveted steel column about 50 ft. high temporarily seated on the center line on top of one of the tubes at each end and thoroughly braced by diagonal rods and struts. The column was conspicuously painted with alternate red and white marks, giving an accurate vertical target for leveling as well as centers for alignment.

The 35x155-ft. concrete barge 10 ft. deep was moored alongside the tubes to serve as a tender and its two 65-ft., 8-ton derrick booms were found very useful in handling the tubes and for various auxiliary services.

The tops of the shore ends of the first pair of tubes are provided with a seat for the cofferdam which will be sunk on it to make connections with the adjacent ends of the shore tunnel. Each tube is provided at the quarter points of its length with an inside removable wooden transverse vertical diaphragm reaching from the center of the tube to the top and forming a sort of trap which when sealed by the water rising in the tube as the latter is submerged, prevents the air from moving freely from one end of the tube to the other.

At 2.53 P. M., October 1st, men stationed on outside platforms, bracketed to the bulkheads in the ends of the tubes, opened four 14-in. valves in the bottom of the tubes allowing the water to enter them as the air escaped through openings provided for the purpose.

The tubes commenced to sink very uniformly and steadily at the rate of about 4 in. per minute until they were about two-thirds submerged when the extra weight of the access tubes, which had an unbalanced effect of about 24 tons, caused them to pitch downward more at that end.

This movement, gradual at first, was clearly perceptible at 3.53 P. M., and increased more rapidly thereafter until at 4.02 P. M., the river ends at the shore end air cylinders were partly submerged, and at 4.10 P. M., their upper ends were scarcely half way above the water. About this time their buoyancy began to overcome the unbalanced load of the tube and as the latter gradually righted themselves to a horizontal position, the shore end air cylinders ascended and the river end cylinders descended until at 4.37 both of them assumed the same horizontal position with their upper surfaces about 10 in. out of water.

The main tubes and their diaphragms and sheathing were thus floating in perfect equilibrium below the surface of the water and the efficiency of the air cylinders and the accuracy of their proportioning was abundantly demonstrated. When they were designed it was uncertain whether the sheathing would be made of hard or soft wood and a considerable discrepancy in weight, which might be expected to vary from 36 to 60 lb. per cubic foot was thus encountered and was provided for by the volume of the air cylinders. Green maple planks which weighed about 60 lb. per cubic foot were finally used for the sheathing and the air cylinders had to sustain the maximum weight. The inlet valves were closed and as it was growing late the tubes were left moored in position over night.

Before the tubes were sunk timber cradles were built on the upper surfaces of their air cylinders at both ends and on each of them was set a 6-ton counterweight made with two cross tiers of I-beams bolted together in a convenient manner. Each of these counterweights was provided with a bridle attached at each corner and secured to the hoisting tackle on one of the derrick booms of the concrete barge alongside.

On October 2d, the inlet valves in the bottoms of the air cylinders were opened and water enough admitted to cause the cylinders to be almost entirely submerged. The boom tackles were overhauled allowing enough additional load from the counterweights to be applied to overcome their remaining buoyancy, and slowly sink them, followed down by the partly supported counterweights. Evidently this motion could be arrested at any moment by hoisting on the tackles which would cause the tubes to rise upward.

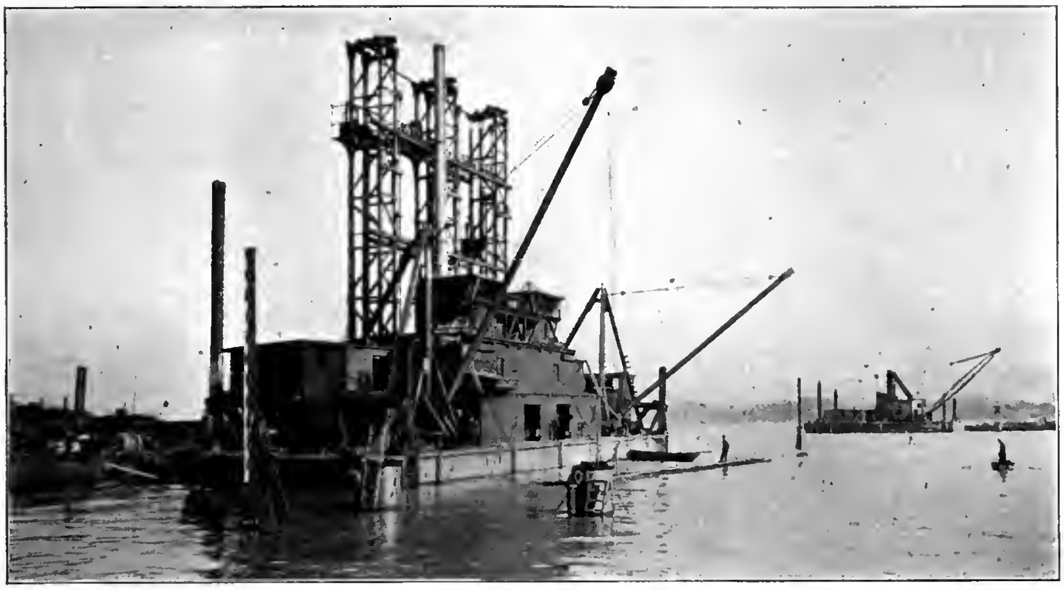
Tubes near Maximum Inclination.

During the sinking the maximum lateral displacement of the tubes from their center line was about 2 ft. When they were within a few inches of the bottom their vertical motion was stopped and they were easily set by adjusting the mooring tackles to within 2 in. of their required alignment. The tubes were allowed to sink to bearing on the steel grillages and sufficient water was admitted to the air cylinders to give a reaction of about 10 tons, under which it was very easy to pull them with the mooring tackles until their position was exact.

The total time required for filling and submerging the tubes was 1 hr. 43 min., and the computed time was 1 hr. and 45 min. Sinking the tubes from the surface of the water to their position on the grillages occupied about 30 minutes. The work was done with a total force of about 30 men, and was considered so satisfactory that no changes have been planned for the next pair of tubes which it is expected will be sunk before Nov. 15.

Soon after the tubes were seated on their grillages, the concreting underneath and around them was commenced and the concrete was deposited by the three 12-in. tremie tubes 80 ft. long which are suspended in three square towers on

the concrete barge and can be raised vertically clear above the surface of the water or lowered to rest on the bottom of the trench. Sand and gravel is dredged at Port Huron, 75 miles away, and delivered by scows to the concrete barge where it is unloaded by clam-shell buckets and deposited in elevated hoppers discharging on inclined screens which separate the sand and gravel and deliver them by gravity to hopper bottom bins with bottom gates through which they can be run into the charging hoppers of one 1-yd. and two ⅔-yd. cubical concrete mixers.



Tunnel Tubes in Position on Grillages in Trench, with Tops of Access Shafts Visible.

Bags of Alpha and Peerless brand Portland cement are delivered by a belt conveyor to the concrete charging platform and the mixed concrete is discharged from the machine into tilting buckets hoisted from 5 to 70 ft. in the tremie towers, to which are bolted guides for the bucket elevator. At the required height the bucket is tripped by a trigger which causes it to dump directly into the funnel at the top of the tremie tube, after which the bucket automatically reverses and is lowered for another batch and so on.

The tremie tubes were proportioned to discharge their contents within 5 minutes after it leaves the mixing machine so as to avoid all danger of set in the concrete before being placed, and the dimensions thus obtained have been found very satisfactory and have enabled the concreting to progress at the rate of 30 to 36 cu. yd. per hour for each tremie, giving very excellent results in water 72 ft. deep. This is considered notable since it is believed to be the first instance in which concrete has been successfully deposited by tremies at a depth of more than 45 ft.

All danger of breaking the seal at the foot of the tremie tube is avoided by the use of a telltale which constantly indicates the height to which the concrete rises above the foot of the tube on the outside. This consists of a 12-in. ball with a specific gravity a little greater than unity, which is suspended alongside the tremie tube by a wire passing through a vertical pipe and led around a sheave at the top of the tube to a counterweight and index which constantly registers the position of the ball on a scale alongside. It is found that the height of the concrete outside immediately adjacent to the tube varies from 6 to 12 in. above the bottom of the tube and that the moderately wet concrete flows almost horizontally about 10 ft. each way from the bottom of the pipe.

The water will be pumped out of the tunnel tubes by an electrically-driven Gould centrifugal pump in the bottom of each at the foot of the access shaft, which discharges through a 10-in. vertical pipe carried up outside to avoid obstructing the shaft.

After the tubes are firmly settled on their grillages, water is admitted into the air cylinders, reducing their buoyancy enough to relieve the strain on their connections to the tubes. They are then disconnected by divers and air being forced into the cylinders the water is expelled and they regain their buoyancy, rise to the surface and are installed on another set of tunnel tubes and so on.

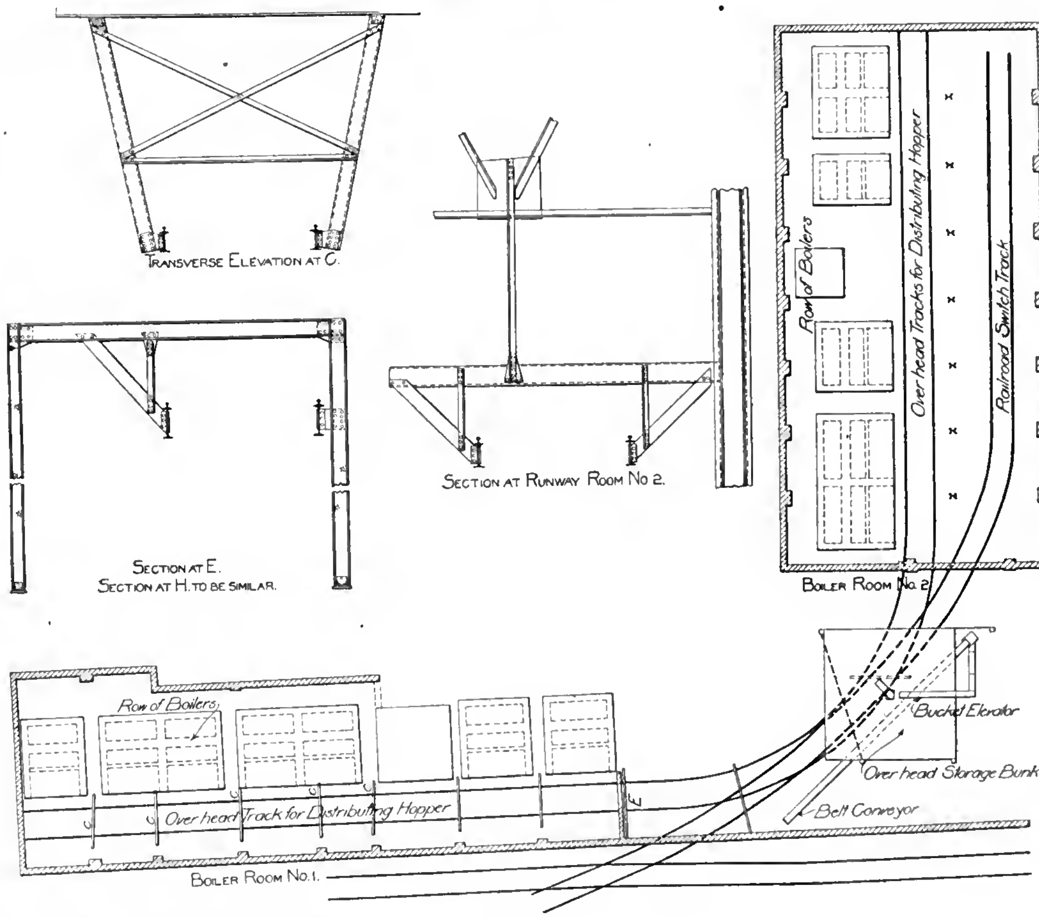
The tunnel is being built under the supervision of Mr. W. S. Kinnear, chief engineer of the Detroit River Tunnel Co., by Butler Bros.-Hoff Co., of New York City, under the personal supervision of Mr. Olaff Hoff. The design for the subaqueous section was made by Mr. Olaf Hoff, of the contracting firm, and was approved by the board of engineers consisting of Mr. W. J. Wilgus, Mr. H. A. Carson and Mr. W. S Kinnear. The Dunbar & Sullivan Dredging Co. are sub-contractors for the dredging.

An Unusual Coal and Ash-Handling Equipment for a Power Station.

The extensive by-product works of Armour & Co. are nearly all centered in a group of large factory buildings at Thirty-first and Benson Sts., Chicago. The great quantity of heat and power required by many of the processes in the various buildings is all supplied from a single central station, which replaced a number of separate mechanical plants in the different buildings when it was completed about three years ago. This station is specially designed to meet the many unusual demands for heat and power brought about by the by-product processes, such as the manufacture of soap and glue. Live and exhaust steam for heating are piped to the different buildings, but the mechanical equipment in all of the latter is driven by electric power generated in the central station.

The central station is contained in three buildings, a generator and engine house and two boiler houses, all of which are interconnected. The general arrangement of these buildings is shown in one of the accompanying illustrations. The two boiler houses form two sides of a hollow square, with the generator and engine house inside this partially enclosed space. As is shown in the plan, the adjacent ends of the boiler houses do not come together, but a connecting building has been erected over the space between them.

These houses contain thirteen Stirling water-tube boilers with a capacity of about 5,000 h.-p. Part of the boilers were formerly hand-fired, and the remainder were equipped with chain-grate stokers, which were also supplied by hand. Coal was delivered on a railroad siding that extends along the side of one house and on a second siding extending the full length of the other house, directly in front of the boilers. It was shoveled from cars on these sidings to firing floors in front of the boilers and from the latter into the furnaces. The ashes were hauled out of the basement in wheelbarrows operated on inclines extended to the firing-room floor. When the de-



Plan of Boiler Houses and Coal-Handling Equipment, Armour & Co.

cision was made to install mechanical equipment for handling the coal and ashes, arrangements were also made to equip the hand-fired boilers with chain-grate stokers, in order to eliminate as fully as possible all manual labor in the coal handling. The boilers are therefore all served by the new coal-handling installation, which is designed so it is common to both houses.

Essentially, the coal-handling equipment consists of a large overhead storage bunker, in the connecting building between the two boiler houses, and a hopper, carried by a crane traveling on a track suspended from the roof of this building and of the two houses, in which the coal is delivered to the boilers. The ashes are handled from a space under each boiler furnace to a storage hopper over the siding by a pneumatic exhaust system in which the only moving part is an exhaust fan.

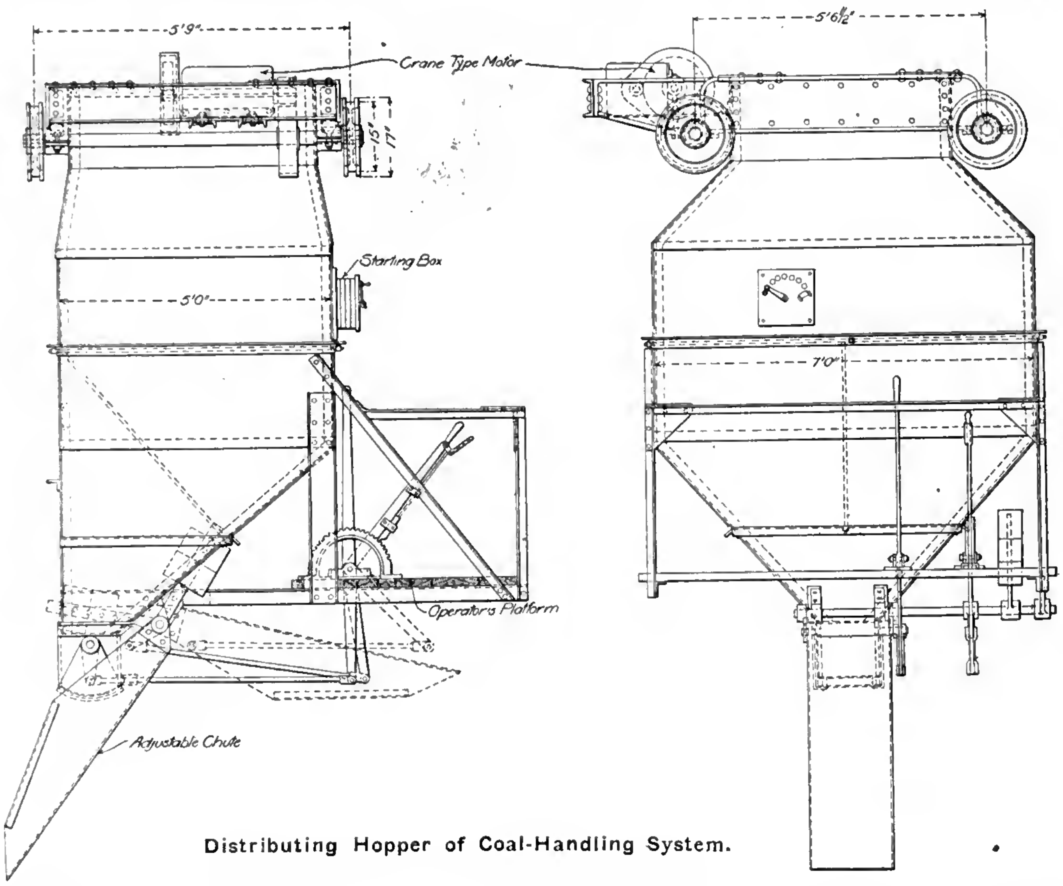
The coal is at present delivered into the connecting building between the two houses on cars on the railroad siding, and is shoveled from these cars on a horizontal belt conveyor, 55 ft. long between the end pulleys. Coal can also be shoveled through windows in the side of the connecting building on a second belt conveyor along that side which delivers to the one along the track in the building. The siding is on a 35-deg. curve at the latter conveyor, so the apron between the conveyor and the sides of the cars had to be built to meet this condition. The coal is delivered from the end of this conveyor through a crusher into the boot of a bucket elevator, or directly into the elevator boot by by-passing the crusher. The bucket elevator, 65 ft. 7 in. between the sprockets, is practically vertical, and is driven by a 7½-h.-p. motor, which also drives the belt conveyors. The elevator delivers the coal into the overhead bunker at one side of the latter, a horizontal run of a broad link chain serving as a distributer to carry the coal across the bin as it piles up on that side.

While this is the present method of filling the storage bunker, arrangements have been made to install a clam-shell bucket on a trolley on the roof of the building so the coal can be hoisted to the bunker from cars on the track at the side of the building by this bucket. As screenings are burned almost exclusively under the boilers in the two houses, this arrangement can be used, except when run-of-mine coal is received and has to be passed through the crusher. The men now required in shoveling coal from the cars to the conveyor belt can thus also be eliminated.

The overhead storage bunker is 32 ft. square in plan at the top and has a capacity of 400 tons. It is carried by four steel columns, two of which are each at a corner, while the other two had to be placed at a considerable distance from their corners to provide space for the switch track and the belt conveyor. The bottom of the bunker is built as a hopper with an undercut gate controlling the outlet.

The traveling hopper in which the coal is distributed from the storage bunker to the boilers has a capacity of 7 tons and is supplied from the undercut gate at the bunker. The four-wheel crane which carries this hopper runs on an overhead 5 ft. 9 in. gauge track. This track extends the length of the single row of boilers in each boiler house, a 55-ft. radius curve in the building between the ends of the two boiler houses connecting the track on tangent in the latter. The track consists of two 25-lb. T-rails carried by 15-in. I-beams. These beams had to be suspended in different ways, as the roof of one boiler house is carried by steel rafters, while the other boiler house roof is on steel trusses designed to carry overhead bunkers, and in the connecting building special supports were required.

The sides and ends of the distributing hopper had to be converged at the top, in order to permit the four-wheel truck carrying the hopper to be shortened sufficiently to travel around the 55-ft. radius curve without difficulty. The truck is built of structural steel shapes and carries a doube-flange traveler wheel at each corner, the pairs of wheels being 5 ft. 6½ in. apart on centers, which is the same wheel base as used for the trucks of heavy interurban railway cars. The truck passes readily around the curve in the track on which it travels, the hopper, in fact, being loaded from the overhead bunker while on the curve. The hopper is propelled along the track by a 9-h.-p. crane type motor, geared in the ordinary manner to the axle of one pair of wheels. This motor is designed to operate at about 850 r.p.m., thus giving the hopper a traveling speed along the suspended track of about 260 ft. per minute. The motor is controlled by a starting box mounted on one side of the hopper where it is within reach of an operator on a platform carried on that side of the hopper. Two of the traveling hoppers are provided, one for each boiler house, but a single hopper is used to supply coal to both of the latter and the second one is held in reserve.



Distributing Hopper of Coal-Handling System.

The operator on the platform carried by the hopper controls the undercut gate on the storage bunker, and also an undercut gate on the hopper, by a lever for each gate at the platform. As the gate on the hopper is opened and closed, the lever operating it simultaneously lowers and raises, respectively, a hinged chute extending to the charging hoppers of the stokers. These hoppers of the stokers have been enlarged to hold two tons each. When the distributing hopper reaches a stoker to be supplied with coal, the chute is lowered and the distributing hopper moved slowly along the track until the stoker hopper is filled, without spilling any coal. The distributing hopper is then moved along to the next stoker to be supplied. Working in this manner one distributing hopper has demonstrated that it can easily supply coal to the thirteen boilers, and give the man who operates it sufficient time to operate the pneumatic ash-handling system.

The coal-handling equipment was designed by Messrs. Orton & Steinbrenner, commercial engineers, of Chicago, and was manufactured by the C. O. Bartlett & Snow Co., of Cleveland, Ohio.

A tunnel, 8 x 8 ft. in cross-section, was built the length of both boiler houses, under the floor in front of the boilers, to provide in each case for a 10-in. pipe header of the ash-handling system. Each header is connected to the ash pit of each of the boilers in the row served by it. The 10-in. headers both terminate in a specially-constructed separator placed close to the roof in one of the boiler houses. An 18-in. pipe leads from the separator down to a 40-in. exhaust fan on the floor below and thence up to a free exhaust above the roof.

The connection to each ash pit from the header is ordinarily closed; when ashes are to be removed from a pit, a plug in a tee on the connection is removed and a small hopper is inserted in order that the ashes may be pulled into the connection readily. The two headers are connected with the separator on diametrically opposite sides near the top. They are both extended into the separator by an elbow with the open end down, so the ashes are discharged to the bottom of the separator. The connection between the fan and the separator is taken out at the top of the latter. With this arrangement the inflow of ashes and air is not only directed to the bottom of the separator, but also has a much higher velocity than the upward outflow of air, due to the relative cross-sectional areas of the inlet pipes and the separator. A spray of water, directed from a nozzle in the top of the separator, is continuously played on the ashes as they enter, which, together with the difference in velocity between the inflow and the outflow, results in the ashes being completely deposited in the bottom of the separator. The ashes are drawn from the separator through a pipe controlled by a continuous discharge gate of the revolving pocket type. This gate is always sealed to prevent the admission of air and is turned by a small motor. A storage bunker, with a capacity of 60,000 lb. of wet ashes, is placed immediately under the separator, where its contents can be discharged through an under-cut gate, operated from the boiler room floor, into a car on the switch-track on that floor.

This installation of pneumatic ash-handling equipment has operated with complete satisfaction during the brief period it has been in service. The Economic Engineering & Construction Co., of Chicago, by which it was designed and

installed, has also furnished the same equipment to a number of other power plants, in which it is operating with surprisingly excellent results. A velocity such as is furnished for the equipment that has been described, by the fact that is a part of the latter, will lift paving brick from the ash pits and deliver them to the separator. In fact, in a test of an installation of this kind recently made by the engineering department of the Western Electric Co. bricks were carried 200 ft. in a horizontal pipe and elevated to a separator 110 ft. above the ash pits.

It is expected that the ash-handling system in this plant will not have to be operated more than four out of the twenty-four hours to handle all of the ashes produced by the furnaces of the thirteen boilers. Following the practice that has been evolved in operating previous installations, the equipment will probably be operated for short intervals at a time, as the contents of an ash pit can be removed very quickly. The man who operates the coal distributing hopper will therefore also be able to operate the ash-handling equipment, since the latter requires only a small amount of labor involved in pulling the ashes into the portable hopper placed on the connection to the ash pit.

The central station in which the installations that have been described were made is operated under the direction of Mr. C. W. Brown, chief engineer of the station and of the works supplied with power by it.

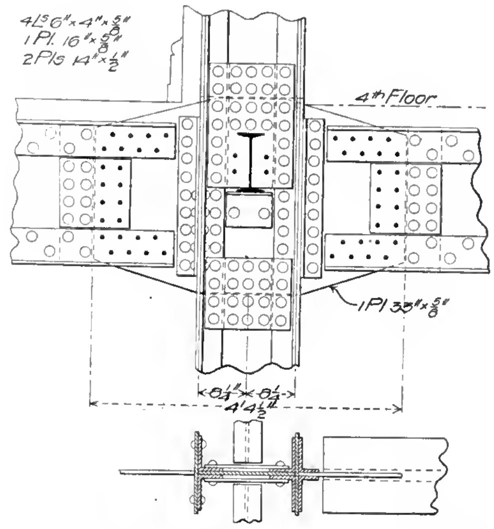
Temperature Changes in Pipe Tunnels.

Cracking from temperature changes has not occurred in a 750-ft. concrete subway having a 350-ft. branch, in which steam, water and air pipes have been run, according to a committee report to the recent convention of the Association of Railway Superintendents of Bridges and Buildings. The tunnel is 4½ ft. wide, 3 to 5½ ft. deep, with side walls and bottom 12 in. thick and a 4-in. cover slab of reinforced concrete, which is used for trucking materials between different buildings. No provision for expansion was made in the walls or bottom, but joints were made in the cover by cutting through the concrete at every 5-ft. joint in the sheets of reinforcement before putting on the top surfacing. The temperature in the tunnel has ranged from 110° to 175° during the last three years, during which no cracks have been observed in the concrete.

A STEAM DRIVEN TURBO-GENERATOR of the Curtis type, having a normal capacity of 20,000 h. p., has been ordered from the General Electric Co. through the Pacific Coast office.

The German-American Insurance Building, New York.

The new steel cage office building for the German-American Insurance Co. is a 20-story and basement building, about 273 ft. high from the curb to the roof, located at the intersection of Liberty St. and Maiden Lane, adjacent to the congested banking district in lower New York. It occupies a trapezoidal area, about 19 ft. wide at one end and 62 ft. at the other end, with fronts of 128 ft. on Liberty St. and 137½ ft. on Maiden Lane. The superstructure is supported on twenty rectangular concrete piers, carried down to hardpan about 40 ft. below the curb in wooden pneumatic caissons. At the wide end of the lot there are two very large piers, each supporting 4 columns; at the narrow end there is a single full-width pier, supporting four columns, and all intermediate columns are each supported by separate piers. The column loads, of a maximum of 1,800,000 lb., are transmitted to the concrete pier through I-beam grillages, which extend the bearings sufficiently to reduce the unit pressure to 30,000 lb. per square ft. on the concrete.



Connections to Column 21 at Fourth Floor.

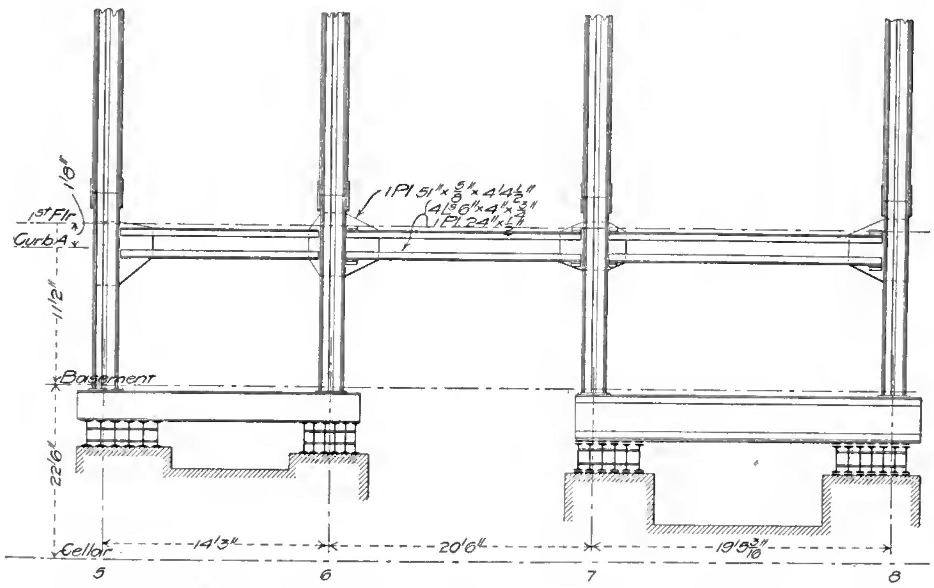
The largest loads carried by the intermediate columns are 940,000 lb., which are transmitted from the column base to the grillage through three distributing beams 5½ ft. long, each of which is made with a pair of 15-in. 45-lb. channels, riveted together back to back to provide thicker webs for the heavy shear than could be secured in single I-beams. The channels are seated across the top flanges of eight 12-in. 35-lb. I-beams, 5½ ft. long, connected together with six tie rods and gas-pipe separators. The beams are set in the usual way on a ¾-in. layer of grout, and the interstices between their webs are filled with concrete, which is extended to enclose them with a minimum thickness of 3 in.

At the ends of the building there are three groups of 4 columns each, seated at the corners of the piers on grillages symmetrically arranged so that the center of gravity of the system corresponds with that of the pier. As the centers of all wall columns are located 22 in. from the building line, it is impossible to make them concentric with the grillages or with the piers, and they are seated on the short arms of transverse cantilever girders, with their fulcrums on the center lines of the grillages, which in turn are either central or symmetrical with the piers.

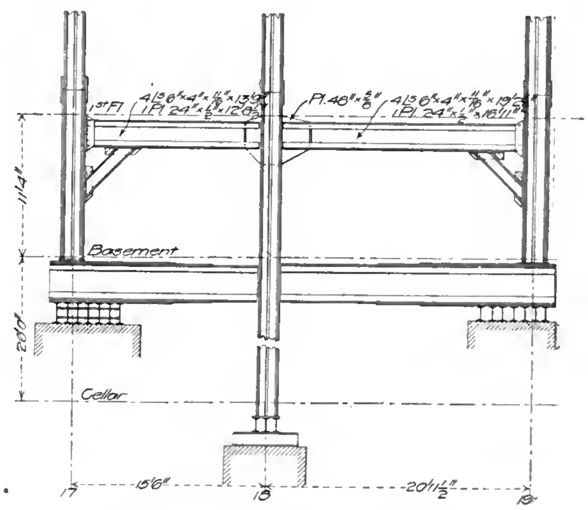
At the narrow end of the building the three last transverse bents of the framework are made with two columns each, which are seated at the opposite extremities of double cantilever girders, the upper flanges of which are 3½ in. below the basement floor line. In these bents the columns are from about 16 to 24½ ft. apart on centers, the respective girders are about 4 ft. longer over all than the distance between centers of the columns, and the distances between centers of their bearings on the grillages is about 2 ft. less than the distances between centers of columns, thus making each girder consist of two short cantilever arms connected by a long anchor arm. Each girder is composed of two independent plate girders, about 3 ft. deep, with single or double cover plates on their top and bottom flanges.

Where the building is wider each transverse bent contains three or four columns, from about 14 to 23 ft. apart on centers. In the wide bents the transverse cantilever girders are not continuous across the full width of the building, but are arranged in two different ways, both of them corresponding to the construction already described over the wall piers, but varying at the inner end. In the three-column bents the inner ends of the girders abut against the opposite faces of the interior columns and are field riveted to them several feet above their bases, which are carried down to a lower level than are the wall columns. This arrangement conforms to the construction of the interior piers, with their tops 3 or 4 ft. below the cellar floor, and of the wall columns, with their tops correspondingly close to the basement floor, which is 26 ft. above the cellar floor.

In some of the four-column bents in the wide part of the building the cantilever girders in the side panels are like those already described in the three-column bents, with the inner ends connected to the exterior columns between the basement and cellar floors, and with the girder essentially continued across the center panel by means of a 20-in. I-beam, with its top flange flush with the top flanges of the girders. Other four-column bents



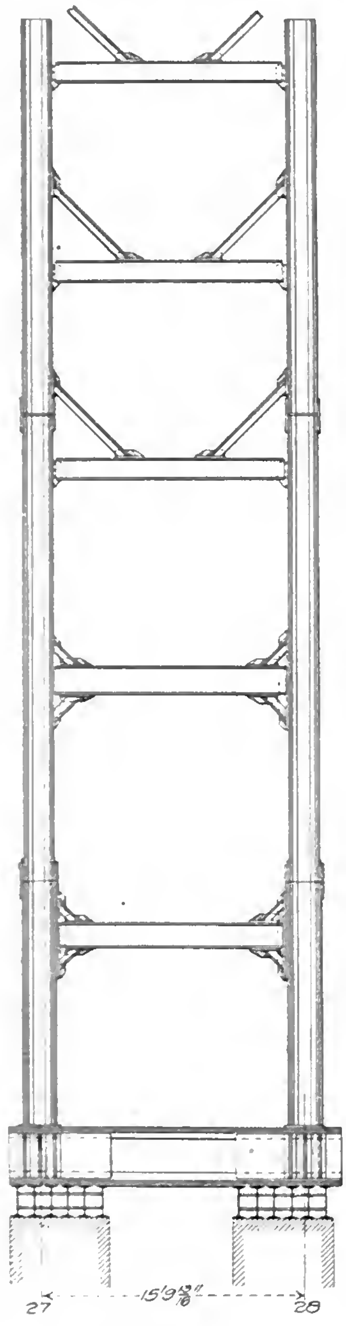
Transverse Section at Wide End of German-American Insurance Building.



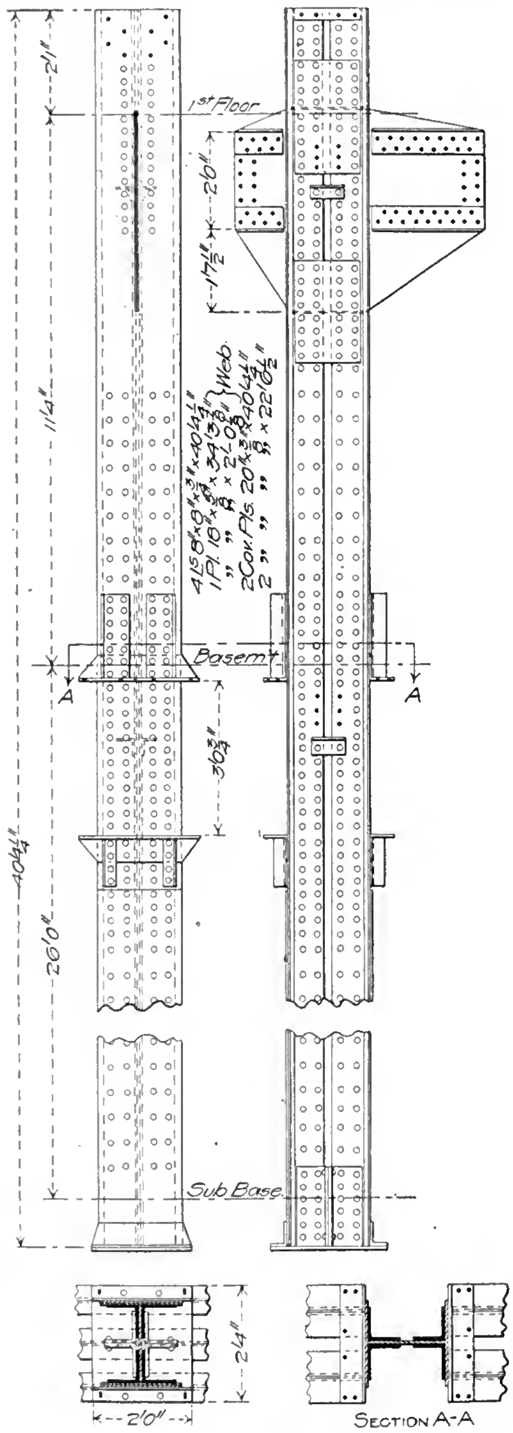
Intermediate Transverse Section.

are made with the cantilever girders quite symmetrical about their center line and supporting the interior columns on their top flanges the same as the wall columns. In this case the interior columns are not connected, and there is no floor beam across the center panel below the first floor above the top.

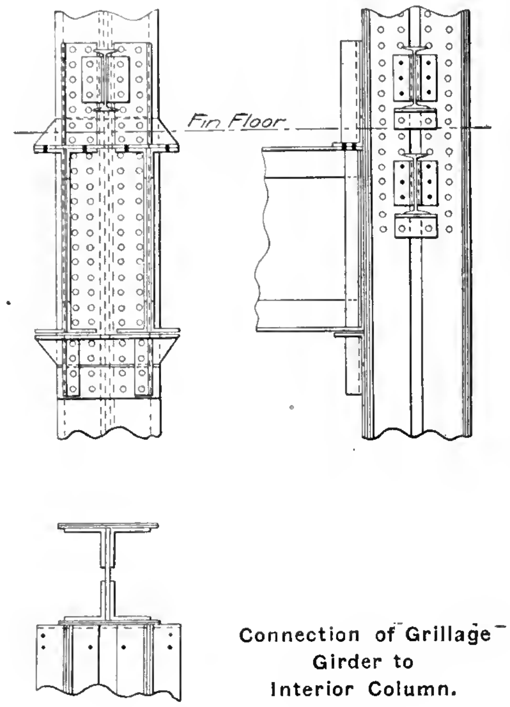
It was assumed that the mass of the building, the stiffness of its walls and the rigidity of the regular connections are sufficient to resist the horizontal stresses in longitudinal planes produced by the assumed wind load of 30 lb. per square foot. Transversely, however, the building is so narrow that special wind bracing was introduced in every bent, and the details were arranged to facilitate shop riveting, to eliminate as much as possible field riveting, to cause the minimum obstruction to the windows and to conform with



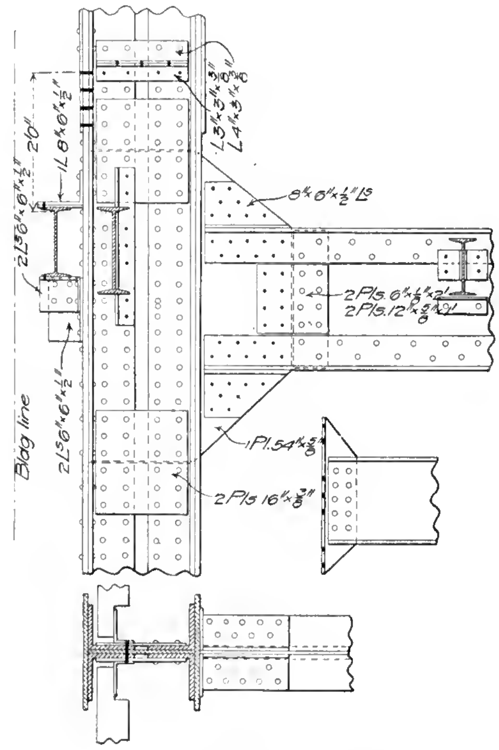
Wind Bracing, Narrow End.



Lower Section of Typical Column 18.



Connection of Grillage Girder to Interior Column.



Wind Brace Connections.

the requirements of the general architectural treatment.

In all panels there are horizontal struts just below the floor line, which increase in depth and cross-section from the top downward. All of them are knee-braced to the columns at both ends; in most cases the knee-braces are formed by deep, vertical gusset plates integral with the column web and projecting beyond both top and bottom flanges of the horizontal struts. In some cases, however, these are replaced by entirely detached knee-braces.

In the end panel the transverse struts are omitted above the 15th floor, and from the 15th floor to the 3d floor, inclusive, the struts are made with a pair of channels having vertical connecting angles to the columns and provided on the upper side only with knee-braces, made of a 6x3½-in. angle. At the first and second floors the struts have short detached angle braces on both top and bottom flanges, which are connected to the columns through the same vertical angles that engage the webs of the strut.

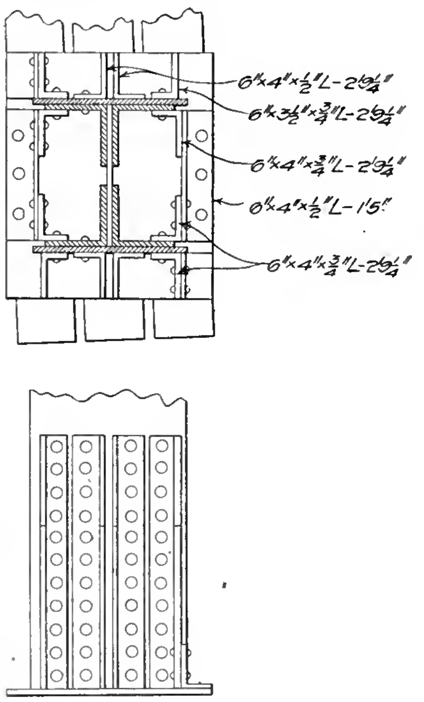
All other transverse bents have channel struts without knee-braces at the 16th and 17th floors, and below that have struts made with pairs of plate girders and solid gusset plate knee-braces to both top and bottom flanges, except in some cases at the first floor, where in one two-column bent and one three-column bent the lower flange only is knee-braced with pairs of 12-in. channels. The minimum plate girder struts are made with four 3x3x⅜-in. flange angles and one 24x⅜-in. web plate. The maximum have four 6x6x13-16-in. flange angles, and one 24x½-in. web plates, or four 6x6x13-16-in. flange angles, and a 36x½-in. web plate, and are connected to the columns with 66x⅝x35½-in. gusset plates.

The walls in the street fronts of the building are carried at every story on I-beams, bracketed out from the face of the columns and abutting on the center lines of the latter. They are 15 in. deep, except at the third floor, and in one panel of the first floor, where they are 20 in. deep. Above the second floor all of them are knee-braced at both ends with single 6x3½x⅜-in. angles at 45 deg. with the top flanges. Below the third floor all of these knee-braces are omitted, except in the end panels and in one special first floor panel, where there are also two long knee-braces to the center point of the second floor wall girder. In the lower end panels the knee-braces are made with 12-in. channels, and in the basement the lower flanges of the wall girders are braced with single 6x3½ in. angles.

All of the columns have I-shaped cross-sections, made up with a web plate and four flange angles, with or without cover plates, as required for different loads. At the floor points the regular column webs are cut to clear short sections of wider web plates, which are shop riveted between the column flanges and project beyond them far enough to provide gusset plates punched for field rivets in the ends of the transverse girder braces. Where the braces are plate girders their webs

are cut to clear the column webs and are spliced to them with cover plates, while the flange angles project across the column webs, and in some instances have additional connection angles riveted to their outside flanges to develop the full strength of the angles.

The details of the wall columns are clearly shown in the engravings of their connections with the transverse braces. They are of simple construction, spliced just above floor level with jaw plates, shop riveted, to the lower ends of the upper sections of the columns and with horizontal angles riveted to the webs of both columns. Columns 23 and 24 are seated on the top flange of the basement cantilever girder, to which they are connected by rivets through horizontal transverse flange angles at the lower edges of extended web plates, reaching across the full width of the girder. Two pairs of 8x8-in. vertical angles, back to back, are riveted to the lower end of the web and faced to bearing on the top of the girder so as to thoroughly distribute the column load.

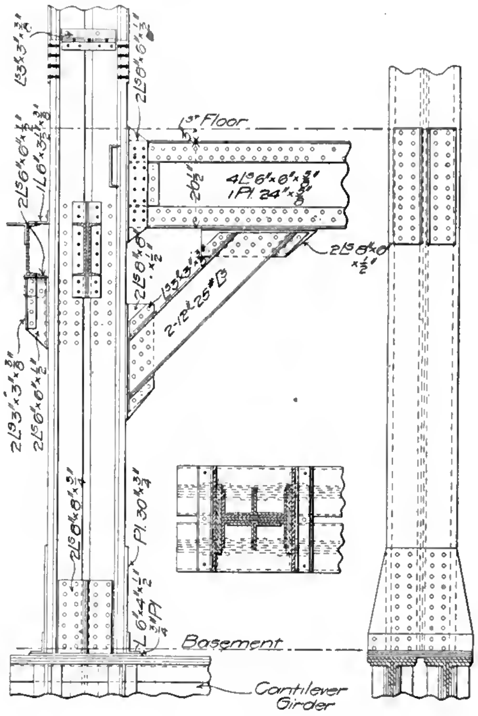


Base of Column 2.

Columns No. 10 and 11 receive the ends of the basement cantilever girders one story above their pedestals, and the heavy upward reactions are transmitted to them through double rows of rivets in 2 vertical 8x8-in. angles, riveted to the inside of the webs of the girders. Transverse angles riveted to the column face also form reaction seats for the upper flanges of the girders and are reinforced and their loads distributed somewhat through the column by 8x8-in. vertical angles, faced to bear against their horizontal flanges. The lower flanges of the girders are also seated on horizontal shelf angles, riveted to the column faces and reinforced with small vertical angles milled to bearing on their outstanding flanges in the usual manner.

Column No. 2, in the party wall at the end of the building, is seated directly on a group of three distributing I-beam girders. It has a wide base extended to cover the full width of the I-beams and distribute the load upon them and stiffened by 12 vertical angles, riveted to the extended side plates at the base of the column in pairs back to back on the center line of the web and at the corners of the base plate. The interior columns are of very simple construction, with horizontal shelf angles engaging the top and bottom flanges of the connected girders and vertical web-connection angles for the I-beam floor beams, which are also, for convenience in erection, seated on bottom flange shelf angles.

Throughout all the floors the I-beams are placed longitudinally and are from 4 to 5 ft. apart, with spans of about 18 ft. In the basement they are connected directly to the transverse cantilever girders, with the top flanges of the beams flush with those of the girders. In the basement they are generally single 12-in. 31½-lb. I-beams, except in some cases where they are made with a pair of 12-in. channels riveted together back to back, in order to provide spaces between their webs for the connection of hanger plates. The upper floor beams are nearly all 10-in. 25-lb. I-beams, connected directly to the columns at panel points and intermediately web-connected to the transverse girders which serve as wind braces, as previously described.



Detached Knee-Braces at Columns 23 and 24.

Messrs. Hill & Stout are the architects and Post & McCord are the general contractors for the steel work.

Foundation Reconstruction of unusual difficulty has been carried on for some years at Winchester Cathedral, in England, under the direction of Mr. T. J. Jackson. The original Norman church was built in the eleventh century on the edge of a peat bog 7 ft. thick, covered by a bed of chalky marl washed down from the surrounding elevations. The early builders encountered water at a depth of about 10 ft. and were unable to go deeper, so they drove some short oak piles and laid their foundations on them. When the presbytery and first bay of the lady chapel were undertaken, at the end of the twelfth century, it was necessary to go out into the bog farther. The water kept the builders from excavating below 10 ft., and at that depth they constructed a platform of trunks of great beech trees. This foundation has been gradually sinking, the vaults have been disturbed, and this part of the building has split off from the Norman portion. These sinking walls have been underpinned, down to a gravel bed underlying the peat at a depth of 16 ft., by concrete foundations put in place with the help of divers, who were employed in order to avoid the danger of settlement attending any attempt to pump water from the peat. The older Norman portions of the cathedral are now being partly underpinned in the same way, but other necessary repairs, such as iron ties to hold together some of the old walls must be deferred until more funds can be raised.

Removal of Manganese from Deep Well Water.

The "Journal für Gasbeleuchtung und Wasserversorgung" for Aug. 17, 1907, describes an interesting experience with manganese in the water supply of Arad, in the southern part of Hungary, where Rudolf Hajek is the director of waterworks. The city lies at an elevation of 348 ft. above the sea, and like others in that region suffers from a lack of good drinking water. In 1895 some test wells were driven in the diluvial strata to a depth of 328 ft., and assurance was given by the Municipal Chemical Institute, after having analyzed the water, that a good supply, satisfactory in quality, could be obtained at a depth of 138 ft. Accordingly works were built to take the water from wells at this depth. Although the chemical analyses had shown that the water contained only slight traces of iron, with no mention at all of manganese, the builders, Messrs. Hughes & Lancester, of London, advised that the water be aerated and filtered in order to prevent incrustation of the pipes. Sufficient aeration was obtained from the compressed air used for lifting the water, and the Fischer system of sand filtration was installed.

The wells, which were 9 to 12 in. in diameter and 132 to 138 ft. deep, were sunk in a line at right angles to the direction of the flow of the underground water. By means of compressed air, at 3.5 atmospheres, the water was lifted at the rate of 600,000 to 720,000 gal. per day. 1.5 cu. ft. of air at atmospheric pressure being required for each cubic foot of water. From a small receiving reservoir into which the water was thus pumped, there was a gravity flow to the filter beds. The filtered water was collected in a pure-water reservoir, holding 16 to 24 hours supply, and from this reservoir the water flowed by gravity to a pumping station, 300 ft. distant, where high-duty pumps sent it through two 14-in. force-mains 23,000 ft. long, to the distribution system of the city.

The works were put in service about the end of 1896 and for a number of months operated without trouble, but at the end of the first year the water drawn from the taps began to have a yellowish-brown color, which was especially marked whenever the circulation in the pipes was increased by sudden draft occasioned by the use of water for street sprinkling, fire service, or the like. A vigorous system of flushing was resorted to in order to prevent this trouble, and at the same time some investigations were begun to ascertain its cause.

These investigations showed that the water from the deep wells before and after filtration was perfectly clear. A large amount of iron oxide accumulated on the filter. There was practically no deposit in the concrete pure-water reservoir after one year's use, but in the pipes which conveyed the water from the pure water reservoir to the pump well, and in the force mains from the pumping station to the distribution system, where the velocity of the water was only 0.85 ft. per second, there were found numerous brown flocks on the upper surface of the pipe. On the bottom there were deposits about 0.04 in. in thickness. The service pipes, which, with a few exceptions, were of 1-inch galvanized iron pipe, contained very little deposit, although, in a few cases, the inside diameter was reduced considerably by incrustation. But the galvanized iron strainers of the water meters were found to have their holes almost completely choked with a yellowish-brown mass, though the strainers made of copper or brass were but little stopped up.

In 1903 samples were sent to the London chemist, Mr. Bertram Blount. He found that the suspended matter contained 71.02 per cent. of manganese dioxide (MnO_2), and 5.95 per cent. of manganese oxide (MnO), although the Hun-

garian Chemical Institute failed to find a trace of manganese in samples taken under the same conditions. The investigations showed that the trouble was not due to iron, which was present in the water only to the extent of 0.025 part per million, but rather to the compounds of manganese which had been reported as existing only in traces. This manganese did not separate out in the quiet water of the reservoir, but the deposits were greatest on the vertical rough sides of the pipes, and on the screens of the meters in similar places.

The trouble was found to occur intermittently, and was found to be greatest after periods of heavy rain. The reason for this was made clear by a study of the local geological conditions. The underground water at Arad flows from east to west, coming from the direction of the Carpathian Mountains 15 to 20 miles distant. Between the upper diluvial stratum and the lower stratum from which the well water is derived, there is a clay bed about 45 ft. thick which separates the two. The dip of the strata is such that the lower water-bearing stratum outcrops at the Carpathian Mountains, and it is known that at this point manganese is very abundant. In fact, manganese compounds often lie upon the surface of the ground exposed to the rains. The dissolved compounds thus find their way into the ground and to the wells at Arad.

From the location of the manganese deposits in the pipe, it was thought that the trouble could probably be avoided by installing a pressure filter at the end of the force mains, but it did not seem practical to do this. The most feasible plan seemed to be to place a filter at the lower end of the force main just outside the pumping station, and this was accordingly done. The results fully justified the expectations, and during the last 32 months the water in the city has been clear, while the street mains have not had to be cleaned, examinations showing that they were in no way incrusted. The pressure filters were furnished by Bell Bros., of Manchester, England, and this particular system is said to have been used because of its low cost and its simple operation. The filters are cleaned once in 10 to 25 days, and it is said that from 13,000 to 21,000 gal. of water are used each time for washing.

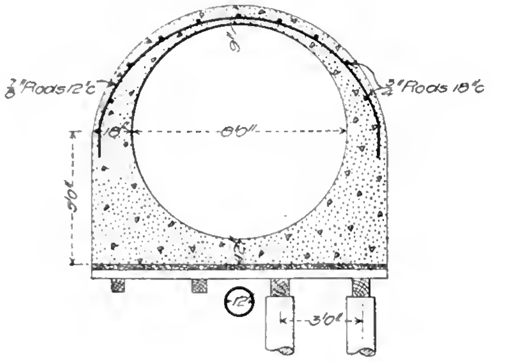
Experiments which were made on a small scale showed that by the addition of milk of lime to the well water, which has a hardness of 140 parts per million, a more complete separation of the manganese compounds could be obtained, but thus far it has not been necessary to resort to the use of chemicals. Had they known originally that this water contained manganese, it is probable that the design of the works would have been quite different with respect to the filtration of the water.

AN ENORMOUS TUNNEL on the proposed canal between the Rhone River and Marseilles is reported in European papers to have been approved by the Bureau of Bridges and Highways of the French government. The tunnel is to be 4⅜ miles long, 72 ft. wide and 46.6 ft. high, and is estimated to cost $6,900,000.

The Ingleside Sewer, Borough of Queens, New York City.

A large, circular, reinforced concrete trunk sewer is now being built in the Borough of Queens, New York City, which will serve ultimately about 1,200 acres in the Ingleside district of that borough. Ingleside is a suburb of Flushing, and, while it is now only partially settled over most of its area, these conditions will soon be changed by the influx of population which will follow the improved transportation facilities soon to be afforded by the East River tunnels and new bridges. The surface of this district is flat or gently rolling, and the general elevation above mean high water varies between 10 and 110 ft.

The Ingleside sewer, which is to carry combined storm-water and house-sewage flow, has its outlet on Flushing Creek, a small creek which empties into Flushing Bay, on Long Island



Section of 8-Foot Sewer.

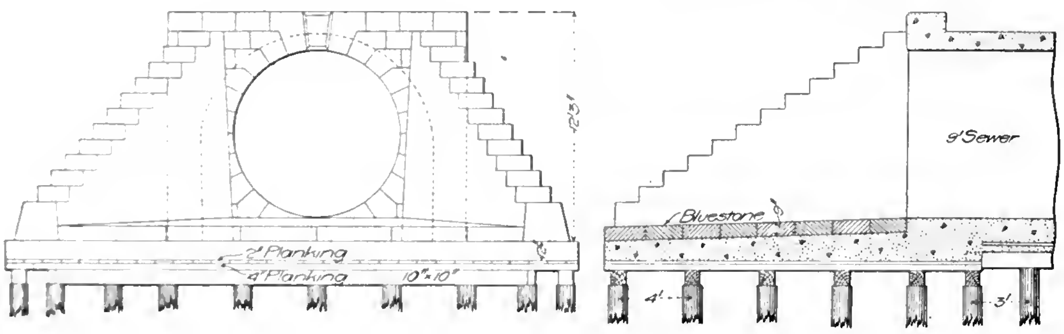
Sound. To comply with a State law, which prohibits the discharge of crude sewage into Flushing Bay, a cut-off has been provided near the outlet, where the dry-weather flow will be diverted through a 24-in. pipe and led to a disposal plant: this cut-off will be referred to later. The storm-water flow will be discharged directly into the creek, the dilution when the cut-off becomes inoperative being sufficient to make this admissible.

The work now under contract involves the construction of 725 ft. of 9-ft. sewer, 1,580 ft. of 8 ft. 9 in., 1,007 ft. of 8 ft., 774 ft. of 6 ft. 6 in., 810 ft. of 6 ft., 1,830 ft. of 5 ft. 3 in. and 245 ft. of 2 ft. 6 in. A special outlet portal will also be built.

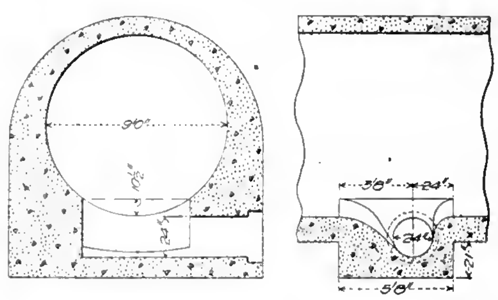
The sections for all sizes of the sewer, down to and including the 5 ft. 3 in. size, are alike in form, the outer sides of the invert below the springing lines being carried down vertically to meet the plane of the base. Ransome bars are used throughout as reinforcement, the transverse bars in all the larger sizes being bent to a three-centered curve, as shown in an accompanying cross-section of the 8-ft. sewer. Pile foundations are specified, to be used where necessary, but so far no piles or planking have been required. A sub-drain of 12-in. farm tile, laid as the work progresses, drains the trench without difficulty.

The outlet portal is designed to distribute the flow of storm water and prevent erosion near the mouth of the sewer. This portal consists of a 12-in. slab of concrete extending about 17 ft. in front of the mouth of the sewer, to form an apron, with a flaring wing wall at each side, as shown in accompanying sketches. The concrete apron is paved with 9-in. bluestone slabs, and the inside faces of the wing walls have a 2-in. facing of special mortar made of one part of cement, one part of sand and 1½ parts of granite dust. This facing mortar is placed at the same time as the body of the concrete. To divert the storm water into the channel of the creek the downstream wing wall forms an angle with the axis of the sewer 10 deg. greater than that formed by the upstream wall. The angles formed by the wing walls with the axis of the sewer are 30 deg. and 20 deg., respectively. Piles and planking, arranged as shown in the sketches, support the portal.

The dry-weather flow cut-off will be placed just above the outlet portal and will consist of a transverse depression in the main sewer, into which the sewage will drop and from which it will be carried away by a 24-in. pipe leading to the sewage disposal plant, to be constructed later on a site already secured near the outlet. The details of this cut-off are shown by accompanying sketches. With a cut-off of this type the flow to the disposal plant would continue uninterruptedly, even though the quantity of storm water entering the sewer diluted the sewage so greatly as to make the direct discharge of the mixture into the bay permissible. To avoid operating the disposal plant unnecessarily and to save the expense of constant attendance, which would be necessary with a manually-operated cut-off, an automatic cut-off will be placed on the 24-in. pipe outside



Elevation and Section of Ingleside Sewer Portal.



Dry-Weather Cut-Off.

the main sewer, so that as the storm-water flow increases the flow to the disposal plant will be gradually and automatically reduced and finally stopped entirely.

At this time the 9-ft. sewer, except a short length near the outlet, has been completed, and work is in progress on the 8-ft. 9-in. section. The trench is excavated with pick and shovel, and the spoil is hoisted and delivered in 1-yd. Hayward buckets as back-fill over the completed part of the sewer by a Carson conveyor, operated by a Lidgerwood engine and boiler. This conveyor, which is one of the standard type manufactured by the Carson Trench Machine Co., consists of a series of A-frames spanning the trench and supporting a hanging rail, on which a hoisting carriage is drawn back and forth by cables. The A-frames are placed 16 ft. apart on centers, and each leg of each A-frame has a double-flanged wheel placed in a vertical plane parallel to the axis of the sewer. A line of light rails on each side of the trench forms a track, on which the whole conveyor, including the platform carrying the boiler and engine, runs. On the work in question the entire conveyor is about 300 ft. long. The soil in which the trench has been excavated thus far is gravelly and very firm, so that close sheeting has not been required.

The concrete, which is a 1:2:4 mixture of Alsen Portland cement and Cow Bay sand and gravel, is mixed by hand on a platform beside

the trench and delivered to place through sheet-iron pipes. Hand mixing was adopted on the first part of the work because certain conditions prevented the economical use of a mixer. A Smith machine is on the ground, however, and will be used for the greater part of the work. For forming the crown and invert, sheet-steel centers of the standard type supplied by the Blaw Collapsible Steel Centering Co., are used. These are handled in 30-ft. sections, made up of 5-ft. lengths braced with rods equipped with turnbuckles in the usual manner. A mixture of kerosene and slush grease is used to lubricate the surface of the centers. Special care is taken to insure the construction of the invert at the proper grade, and to this end steel pegs are driven into the foundation slab, at 25 ft. intervals, while the concrete is still green, the tops of the pegs being exactly at grade. In addition to these there are the usual grade stakes outside the trench. The center line of the sewer is given by a double row of stakes, one on each side of the trench, the stakes in each line being at 25-ft. intervals and 25 ft. from the center line of the sewer.

Invert Forms in Place, Ingleside Sewer.

The curved transverse rods are bent by a blacksmith, assisted by two laborers. Each rod is first run through a three-roll tire-bending machine, such as is commonly used in wagon shops. After the rods have been roughly bent in this manner they are tested on a wooden template and brought to exactly the right shape by blows with a sledge. In general, 60 or 70 rods can be bent in an 8-hr. day, and the results secured by this method have proved very satisfactory. In placing the rods in the trench they are hung from a ridgepole over the center of the invert and wired securely in place in the usual manner.

The work of the Bureau of Sewers in the Borough of Queens is under the general direction of Joseph H. De Bragga, superintendent of sewers, and Mr. J. H. Johnson, chief engineer. The plans and specification for the work described were prepared by Mr. Alberto F. Schreiner, assistant engineer. Mr. William L. Pyne, assistant engineer, is in charge of construction. Messrs. P. J. Murray & Bro., Brooklyn, are the contractors, Mr. A. B. Nichols, superintendent.

Construction Methods in the Second Bergen Hill Tunnel of the Lackawanna R. R.

The second Bergen Hill Tunnel of the Delaware, Lackawanna & Western R. R. lies parallel to and with its center line 51½ ft. south of the center line of the present tunnel, which carries all of the traffic of the railroad from the West to Hoboken, N. J. The work on the new tunnel has been in progress since March of last year, and the rock excavation is approximately 40 per cent. completed at the present time. A general description of the traffic conditions at Hoboken and of the designs of the new tunnel were published in The Engineering Record of January 12, 1907.

Bergen Hill runs in general parallel to the Hudson River, and the tunnels, which lie in a general east and west direction, have their east portals about a mile west of the river front. The completed section of the new tunnel will be 30 ft. wide and 23 ft. 5 in. above the base of rail to the crown of the semi-circular roof arch. It is being driven through a very hard trap rock. The new tunnel will be lined throughout its entire length with concrete.

For construction purposes, as well as good ventilation after the tunnel is in operation, the work has been divided into sections by open cuts and air shafts. The two open cuts and the three shafts bear separate series of numbers, the shaft and the cut nearest the east portal being each called No. 1. In the construction work the cuts play the more important part, because from them headings are being driven in both directions, allowing the work to be carried on with full force at six different points. The shafts, on the other hand, though used to some extent for hoisting excavated material, are of more value in assisting ventilation, both during construction and future operation, by enabling the smoke from the blasts and the locomotives to be drawn off quickly.

Each of the open cuts is 80 ft. wide and 100 ft. long, and the shafts are 30 ft. wide and 10 ft. long. The open cuts are wide enough to take in both the old and the new tunnels, so that the four tracks are exposed, and cars can be switched from the one to the other to facilitate the removal of rock from the new tunnel during construction. The shafts, however, are wide enough to take in only the new tunnel, their axes being placed vertically over the center line of the latter.

The center of open cut No. 1 is about 1,650 ft. west of the east portal of the tunnel; center of open cut No. 2 is about 1,500 ft. beyond open cut No. 1, and the west portal is about 1,100 ft. from open cut No. 2. The three shafts are placed about midway of the divisions made in the tunnel length by the open cuts. The total length of the new tunnel is 4,280 ft., the same length as the present one.

The contract for the original construction of the tunnel was let to the William Grace Co., and work was started in March, 1906, the drilling being done with electrically operated drills. Air drills were later substitued on the work, and on April 15, 1907, the contractor gave up the work, and since that time it has been carried on by the railroad company. The work of sinking the open cuts was started simultaneously with the opening of the approaches to the two portals, in March, 1906, and the shafts were sunk in time to meet the headings driven from the portals and the open cuts, though in the case of shaft No. 1 headings were driven from it for a short distance in each direction.

The work has been carried on by two different methods, illustrated in the accompanying drawings. One method consists in driving a top heading, having a width of 16 ft., symmetrically on each side of the center line of the tunnel, and a height of 8 ft., the roof approximating the outside line of the rock excavation. The other method is a combination of heading and bench excavation, in which the heading is driven 28 ft. wide and 8 ft. high, its end being at least 25 ft. in advance of the rest of the work. The headings are driven by placing the drill holes in the regular fashion, and the benches in the second method are blasted off by holes drilled vertically for the full depth of the bench. About 29 holes were required in driving the small top headings, the depth of the holes being from 7 to 8 ft. In blasting off the bench eight holes are placed in a line transverse to the axis of the tunnel.

In driving the top heading each shift consists of 5 drill runners and 5 helpers, 10 muckers, 2 foremen, a water-boy and a hoisting engineer and a signal man for the derricks. For driving the full heading, where the steam shovel was used, 10 drill runners and 10 helpers were required; 16 muckers, 2 foremen, 2 men for carrying drills to and from the blacksmith's shop and a water-boy. In using the traveling derrick for mucking, the force was 2 foremen, 6 drill runners and 6 helpers, 13 muckers, 2 drill carriers and a water-boy. In addition to this force, where rock had to be hoisted up through the open cuts, a hoisting engineer, a signal man and a dump man were required for operating the derrick and teams for disposing of the spoil on the surface. In the east portal headings an engineer and brakeman were required for handling the narrow gauge locomotive and a crew for the steam shovel. Work is being carried on night and day in two 10-hr. shifts. Almost all of the drills are sharpened in an Ajax Junior drill sharpener, though some are sharpened by hand.

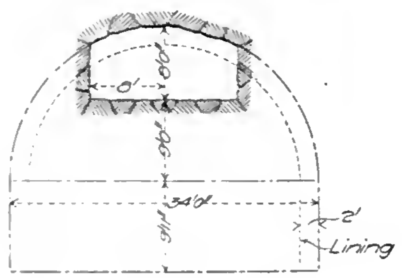
The work in the heading extending from the east portal has been carried on entirely by the heading and bench method, opening the full section at once. A standard gauge track is laid

along the north wall of the tunnel for the use of a Marion steam shovel. Alongside of this track are two narrow gauge tracks, on which are operated 3-yd. dump cars, hauled by a dinky locomotive. The track farthest from the steam shovel, used for pushing in the empty cars, is extended up close to the face of the work and a switch cut in to the other narrow gauge track a short distance back toward the portal. The empty cars are pushed forward by hand beyond the switch to the face of the work and after being loaded are hauled out by the dinky locomotive which runs over the narrow gauge track next to the steam shovel. The cars are hauled out through the east portal to a trestle where they dump into standard gauge Hart convertible dump cars in which the spoil is hauled to Hog Mountain, on the other side of Bergen Hill, to be crushed for ballast. At the present time the full section of the tunnel has been excavated between the east portal and shaft No. 1. As stated above, a short distance of top heading was driven in each direction from this shaft, but now that the full section is completed east of the shaft the heading and bench method will be used. continuing with the steam shovel and the narrow gauge track utilized in the section already completed.

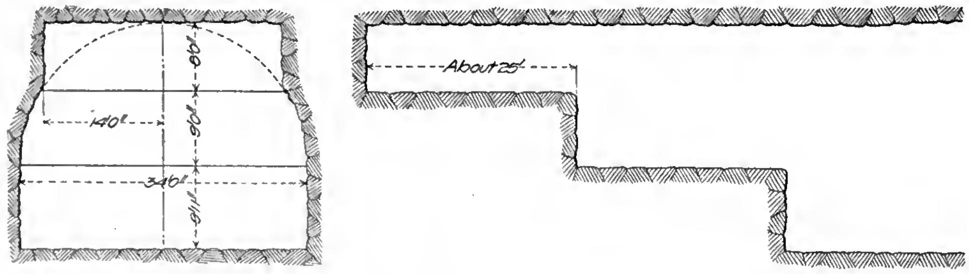
The tunnel driving from open cut No. 1 has been entirely by the top heading method, the work westward from the cut being started in March and eastward in June of this year. Up to October 1st, 462 ft. of the small heading had been driven eastward and 876 ft. westward. The bottom of the cut has been carried down to the sub-grade level on the south side for the new tunnel, but on the north side the rock has merely been removed from the top of the old tunnel, the arch as yet being undisturbed. As soon as the arch of the old tunnel is removed a cross-over can be built from the tracks in the old tunnel into the new one and the spoil hauled away in standard gauge dump cars as is now being done in open cut No. 2. All of the spoil from open cut No. 1, from the excavation of the cut itself and the driving of the headings in both directions, has been hoisted to the surface in scale pans by a derrick placed on the side of the cut and dumped into wagons which hauled it about 650 ft. to a crushing plant, which supplies all of the stone for the concrete lining of the cuts and the tunnel.

Shaft No. 2 was sunk in time to meet the top heading coming west from open cut No. 1, and the muck was hoisted up through it instead of being hauled back and hoisted through the open cut. The derrick is so placed that it can swing the scale pans from the shaft and dump them directly to the storage pile alongside the crushing outfit. The top heading, which was started by driving west from open cut No. 1, had, on Oct. 1 advanced 325 ft. beyond shaft No. 2.

The tunneling operations from open cut No. 2 were started in March of this year by driving top headings in both directions and after the one to the east had advanced 80 ft., and the one to the west 100 ft., the use of the full section method was adopted. On October 1st, 1907, the latter had been pushed 245 ft. westward from the cut and 200 ft. eastward. This cut has been carried down to the sub-grade level of the new tunnel and the arch of the old tunnel has been removed and a cross-over installed on which standard gauge dump cars are run into the new tunnel for hauling away the spoil. Previous to the removal of the arch of the old tunnel, however, all of the material excavated in sinking the cut and driving the headings was hoisted in scale pans to the surface and hauled away in wagons. The cross-over runs from the old tunnel into the west headings of the new tunnel. At the present time two standard gauge tracks are laid in the heading west from the cut and one of these tracks, the one against the south wall of the new tunnel, is continued backward, beyond the cross-over to the old tunnel, into the east heading. A small derrick mounted on a flat car works on the northernmost of the two standard gauge tracks in the west heading and hoists the scale pans into which the muckers load the shattered rock, and dumps them directly into standard gauge Hart convertible dump cars on the other track. These dump cars are handled directly by a locomotive, switched over into the present tunnel and hauled to Hog Mountain, where the rock is crushed for ballast. The heading has not been pushed far enough westward to allow tail-room for switching cars backward beyond the cross-over into the east heading. For this reason the muck in the east heading is loaded by hand into scale pans running on low push cars. These cars are brought out into the open cut and a derrick at the surface lifts them from the push cars and dumps them into one of standard gauge cars standing on the cross-over.



Top Heading Method.



Combination Heading and Bench Method.

Shaft No. 3 was sunk for purposes of ventilation, the only rock that was hoisted out of it being removed in sinking the shaft.

The operations from the west portal had been carried on since the beginning in full section by the heading and bench method, using a derrick car similar to that which is now working west from open cut No. 2. The excavation from the west portal has been discontinued for a period of about four weeks in order to get in a section of tunnel lining near the portal where some bad roof was encountered, the tunnel driving meanwhile being prosecuted by the top heading method and the muck thrown back into the portion of the tunnel where the full section has been excavated. Three hundred and fifty-six feet of the full section have been driven and the top heading on October 1st extended 276 ft. further. The two headings, that eastward from the west portal and the one west from open cut No. 2 will meet this month. On the completion of the section of lining a steam shovel will be run into the heading from the west portal and the work carried on in the same manner as described for the east portal.

Up to October 1st of this year, 1,748 ft. of top heading and 1,499 ft. of the full section had been driven, this being approximately 41 per cent. of the excavation. At the present rate the full section should be blasted out by September of next year. The work has been considerably held back by the restriction of blasting periods. No blasting is done at night and during the day it has been confined to four periods by the train schedule, so as not to interfere with the traffic through the old tunnel. The blasting is done at three periods in the morning, at 7, 9:45 and 10:50, and in the afternoon at 2:30. Immediately after the shots have been fired, an inspection car is run through the old tunnel and with the aid of acetylene lights the brick arch and side walls are carefully inspected. During the entire time that the work has been in progress no damage has been done to the old tunnel. The arch of the old tunnel consists of seven rings of brick laid in cement mortar and such is its strength that in removing it at the open cuts it has been necessary to use heavy wedges to dislodge the brick.

About 31,000 cu. yd. of concrete will be required for the tunnel lining.

In order to assist in the removal of the brick arch from the old tunnel, lagging was placed on the intrados of the arch. It consisted of 4-in. timbers held in place by old rails bent to the curve of the arch, the rails being carried by sills and posts against the tunnel walls.

Ingersoll-Sergeant drills are used entirely on the work. In the blacksmith shop the cylinder of an air drill has been mounted on a standard and is used as a steam hammer for welding broken shanks of drills. A 125-h.-p. Ames engine and a 25-h.-p. Atlas engine are used for driving direct current generators which supply current for lighting the tunnel and for the motors of two electrically operated derricks. The crusher already referred to is a Scholl Climax jaw crusher. The compressor plant is situated a short distance west of the west portal of the tunnel, and contains four compressors, three of the Ingersoll-Sergeant Class A piston inlet type with a capacity of 1,200 cu. ft. of free air per minute each and one McKiernan Drill Co. compressor with a capacity of 1,200 cu. ft. Steam is generated by nine locomotive boilers, with a combined capacity of 800 h.-p.

The work is being carried on by the forces of the Delaware, Lackawanna & Western R. R., under the direction of Mr. L. Bush, chief engineer. Mr. F. L. Wheaton is in direct charge, assisted by Mr. O. H. Kellogg.

COAL PRODUCTION in the United States is classified by the Geological Survey in some recent statistics which show that in addition to the anthracite produced in Pennsylvania, 50,400 tons were mined in Colorado in 1905, and 60,300 tons in 1906. New Mexico produced 24,400 tons in 1905, but none in 1906. This is all the anthracite production in the country, but semi-anthracite was reported from Pennsylvania, Colorado, Indian Territory, Virginia, Montana and Arkansas. Bituminous coal was produced in 27 states and territories in 1905 and in 24 in 1906. Semi-bituminous coal was mined in 17 states and territories, West Virginia leading. Wyoming is in the lead in the production of lignite, over 70 per cent. of the coal from that state being so classed. The so-called black lignites of the Rocky Mountain states are distinct from real lignite or brown coal and are termed sub-bituminous coal by the Geological Survey. Wyoming leads in producing this variety, Colorado is second and New Mexico third. The principal producers of true lignite or brown coal are Texas and North Dakota. The comparatively small amount of cannel coal was from Kentucky, Indiana and West Virginia.

Coal and Ash Bins.

The cost of handling coal and ashes is often an expensive item in the operating expenses of a power station, and it has been found that even in the smaller plants the design of coal and ash bins may have an appreciable influence on maintenance charges. This subject was discussed at some length by Messrs. H. T. Campion and Wm. McClellan in a paper on the "Influence of the Design of Railway Structures on Economy of Operation," read at the recent convention of the American Street and Interurban Railway Association, from which the following notes are taken:

In the suspended, or catenary type, the structure requires frequent painting and, to insure a reasonable long life, a lining is demanded. This lining is usually built of concrete in which a metal mesh should be placed to prevent, as much possible, the cracks which arise, not only from temperature variations, but also from alterations in the shape of the structure due to load changes. If long life and low maintenance is to result, the effect of this alteration in shape due to change of load must be carefully looked after in design. Water draining over coal forms an attacking sulphurous acid. Should cracks and fissures develop in the concrete lining, this acid will enter, not only corroding the steel structure but also eating its way into the more porous concrete and possibly neutralizing its alkaline properties.

In the rigid type of bunker, we have other conditions to guard. The typical sketch of this type which is shown has steel for the main supporting members because the loads, or their resulting movements are so great as to make the entire use of concrete inadvisable on account of the great bulk necessary and the expense entailed by its added dead load on the foundations of the structure. The principal danger to be guarded against is its tendency to crack from temperature changes, opening it to the dangers enumerated in the case of concrete linings of steel bunkers, and, furthermore, causing unsightly leaks in the boiler room. There is also the abrasive action of the falling coals on the surface of the concrete.

The last item can be guarded against by applying to the inner surfaces of the structure a hard, well-rubbed granolithic surface which, if properly applied, will resist such abrasion as a comparatively soft material as coal will cause.

The first objection, temperature cracks, can and should be taken care of in the design. The units of the structure should be in short lengths and a water-tight joint can be provided in a number of ways. An accompanying illustration shows one simple and effective way of making a joint.

It is difficult to give any accurate comparison of costs of the two types of bunkers. There is, of necessity, great variation owing to difference of size, design, and amount and kind of coal passing through. The life of the unlined bunker with average coal will be perhaps eight to ten years. Messrs. Campion and McClellan took down one and found, by drilling, the metal shell reduced more than one-half in thickness in this time. Maintenance on the rigid concrete type and on the lined catenary type is practically zero, though the rigid type has somewhat the advantge. Depreciation on the rigid type and concrete lined type is practically zero.

What is more surprising, however, is the great lack of attention given to economical handling of coal for hand-fired boilers. Frequently an overhead bunker is advisable. If not, the scheme shown in one of the accompanying cuts is very useful and inexpensive. A series of bins is built using the boiler room wall for one side. The illustration is self-explanatory.

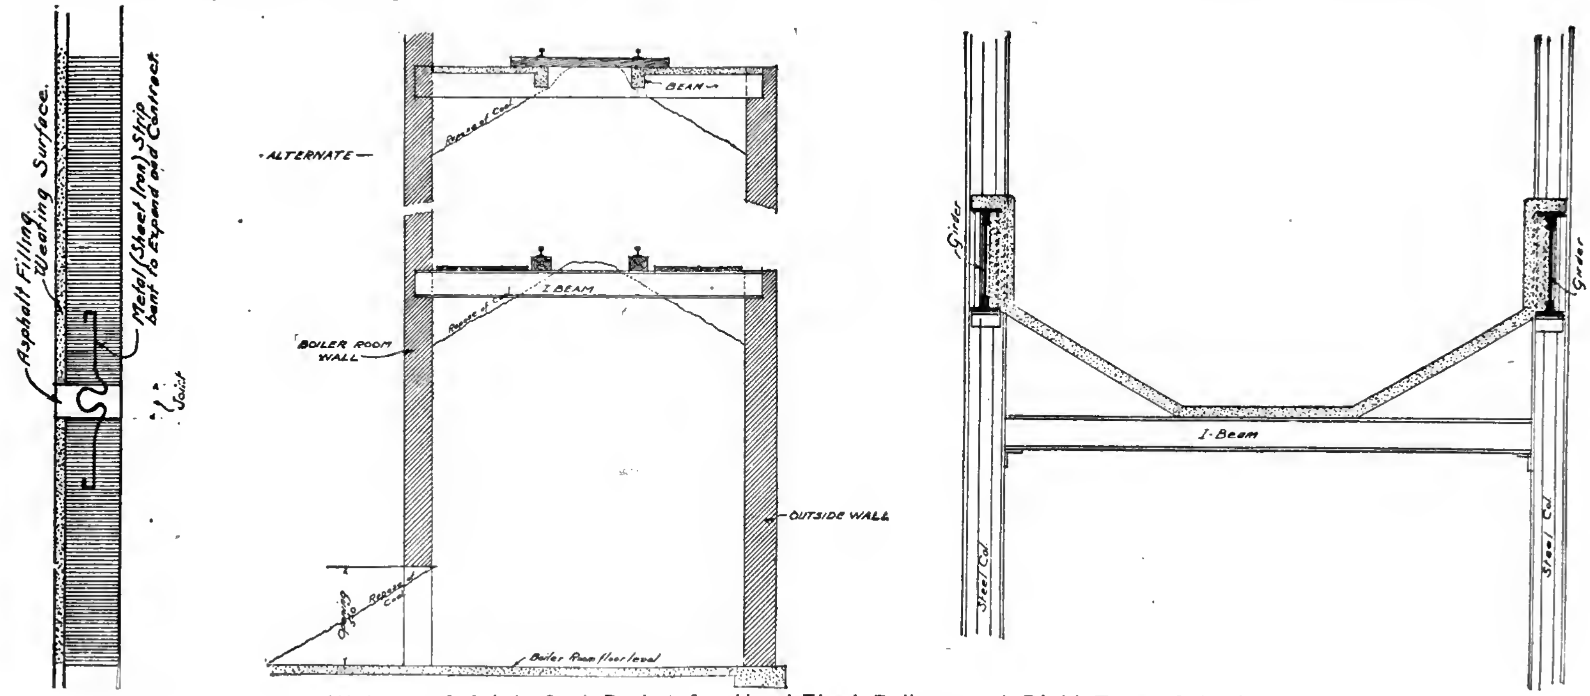
In the handling of ashes, there often could be much improvement.

Where the ashes drop directly underneath the boilers, pockets can be most effectively and economically constructed of concrete and made a part of the boiler room floor structure, leaving a comparatively clear basement for the handling of ashes, either by the industrial railway method or by some conveying scheme.

In some cases, pockets of this description have been lined with fire brick but the temperatures are so much under the point where concrete loses its water of crystallization that it seems an unnecessary expense to spend money for this purpose.

In storing ashes removed from the boilers for final disposal at such times as best suit the operating conditions of a railway, reinforced concrete ash bins have been almost universally adopted on account of the fact that metal structures are not only costly but have a very short life under the trying duty of containing coal ash with its high percentage of corrosion acids.

These concrete structures too can be arranged in so many ways to suit local conditions, that they meet requirements that no other material could. Their cost varies considerably on account of location, height, and ratio of wall, floor, and roof area to cubical contents, but a range of from 30 to 50 cents per cubic foot of contained space will cover most cases. In large structures, the price may be even lower, but as no maintenance of the structure is required, the first cost is the last cost.



Waterproof Joint, Coal Pocket for Hand-Fired Boilers, and Rigid Type of Bunker.

Mechanical Spreader for Roadway Screenings.

A contract for bitulithic pavements covering about one mile of street is now being executed in Providence, R. I., by Warren Bros. The streets have an electric car track in the center and the deep girder rails are seated on continuous concrete longitudinal stringers. On each side of each rail there are two rows of granite blocks. Narrow strips of concrete are placed outside each outer row to retain the hot tar or grout which is poured between the blocks, and the remainder of the surface is covered with the usual bitulithic finish. The fine screenings are liberally applied and the residue swept off.

A quick and uniform distribution of the screenings is secured by a ¼-yd. steel rectangular hopper mounted on two wheels and pushed by hand over the surface of the pavement. A circular opening about 4 in. in diameter in the bottom of the hopper is closed by a sheet steel cone about 2 ft. in diameter with a vertical axis projecting above the top of the hopper where it is miter-geared to a small horizontal transverse shaft operated at the opposite end by a sprocket chain engaging the axle of the wheels on which the hopper moves.

The cone has a vertical adjustment controlled by a lever engaging a row of notches in a guide bar attached to one side of the hopper. By this means it can be raised or lowered to regulate the amount of screenings delivered from the hopper through the annular opening between it and the cone and distributed around the circumference of the cone. Short radial ribs project above the surface of the cone on the lower edge between which the screenings are discharged uniformly in all directions as the hopper is pushed rapidly over the pavements, causing the cone to revolve.

STEEL STRUTS AND BEAMS for lining tunnels have been used for 12 to 15 years by the Susquehanna Coal Co., in Pennsylvania. The consulting engineer of that company, Mr. R. V. Norris, designed a form of gangway support consisting of posts of channels with an I-beam cap. The members are put together with pins and wedges, and the posts rest on cast-iron bases, which enable the whole construction to be taken down or to be adjusted very quickly. Some of these frames have been exposed to constant contact with mine water but they show little sign of corrosion, although the only protection given them has been a good heavy coat of paint from time to time.

A Long Plate Girder Bridge.

The main line of the Lehigh Valley R. R. crosses the Susquehanna River at Towanda, Pa., on a double-track skew bridge with 14 deck plate girder spans about 26 ft. clear of the water and about 5 ft. clear of high water. The sub-structure consists of two abutments and 13 piers, all of concrete founded on rock and most of them skewed about 50 deg. with the bridge axis. In the superstructure there are 56 nearly duplicate plate girders from 110 ft. to 129½ ft. long over all with their transverse and lateral bracing.

At each end of the bridge several spans form chords of a 3½ deg. curve and in the middle of the bridge they are on a tangent symmetrical with the bridge axis and carry the tracks at a level grade about 38½ ft. above low water level. They are made of soft steel designed according to the railroad company's specifications for a maximum load on each track of two locomotives each with 200,000 lb. driver load on a 15-ft. wheel base followed by a train load of 5,000 lb. per lin. ft. For the longest span the dead load is assumed at 2,600 lb. per lin. ft., and for the shortest at 2,400 lb. The maximum flange stress is 290,000 lb. and the maximum end shear is 308,600 lb.

On the curved section the maximum top lateral diagonal stress is 44,000 lb. wind stress and 16,000 lb. centrifugal force, resisted by two 6 x 4 x 9/16-in. angles at a 10.6 sq. in. area and secured at the end by sixteen ⅞-in. field driven rivets. In the tangent spans the centrifugal force disappears and the 44,000 wind stress is provided for by two 4 x 3 x 9/16-in. angles with a cross-section of 5.76 sq. in. The minimum diagonal stress is 1,800 lb. resisted by a single 4 x 3 x 7/16-in. angle. The vertical transverse frames at the skew end are made with pairs of 5 x 3½ x ½-in. angles and with pairs of 4 x 3 x 7/16-in. angles at the intermediate skew points. At intermediate tangent points they are made with single 5 x 3½ x ½-in. angles.

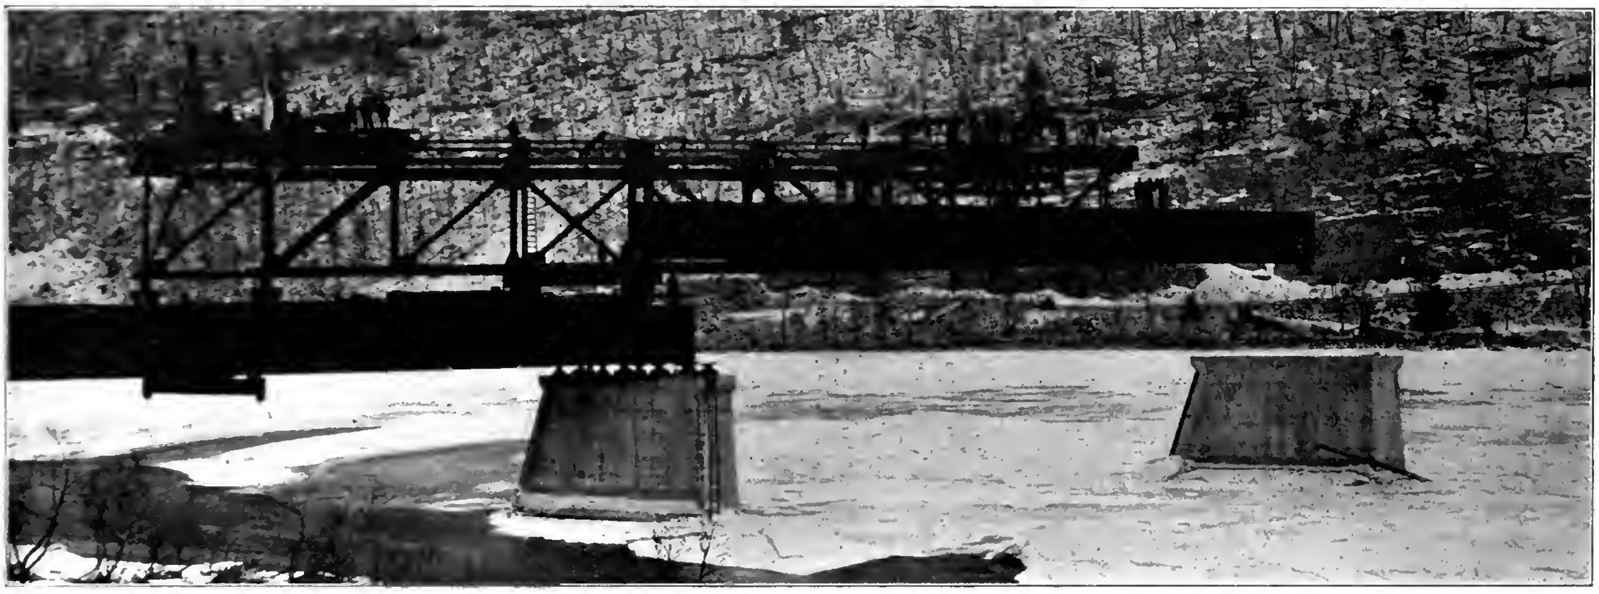
The long girders have a 120 x 9/16-in. web in lengths of 18 to 24 ft. spliced with four vertical rows of shop driven rivets through pairs of 13 x ¾-in cover splice plates 7 ft. 4 in. long. The webs are assembled to provide a cambre of ¾ in. at the center point. In each flange there are two 8 x 8 x ¾-in. angles spliced about 99 ft. from one end with an 8 x 8 x ½-in. cover angle 3 ft. long. The splices are staggered on opposite sides of the webs and in the top and bottom flanges. The flange has also a pair of 16 x ⅝-in. side plates made in two pieces each and spliced at the same point as a flange angle.

The top flange has one full-length 23 x 9/16-in. cover plate, 84 ft. 3 in. long; one 67 ft. 9 in. long and one 23 x ½-in. cover plate 49 ft. 9 in. long. The bottom flange has four 23 x 9/16-in. cover plates, the longest of them being 95 ft. 9 in. long. Pairs of 6 x 4 x ½-in. angles and fillers divide the webs into panels of 6 ft. except at the ends where they are slightly irregular and over the bearing are reduced to 2 ft. 9½ in. reinforced with four pairs of angles.

A 20 x ¾-in. sole plate 3 ft. long is countersunk riveted to the bottom flanges at each end, and to it there is secured by eight 1¼-in. bolts a cast-steel shoe with a continuous half-hole bearing for a 4½-in. pin 25 in. long between centers. At the expansion end a pedestal similar to the shoe inverted engages the same pin with a clearance of ¼ in. between it and the shoe and is seated on a nest of seven segmental rollers 6¼ in. in diameter, slotted at the center to engage 2¼ in. guide ribs projecting from the bottom of the pedestal and from the top of the bed plate. The 36 x 37½-in. bed plate is planed on the upper face to a thickness of 1 in., and has riveted to the longitudinal edges Z-bars about 7¾ in. high which protect the ends of the roller nest and engage the upper surfaces of the base plate of the pedestal, thus excluding snow and rubbish to a large degree from the bearings. The bed plates are seated on sheets of lead ¼ in. thick and similar sheets are provided under the fixed end pedestals, which differ from those at the expansion ends in that they are made enough higher to compensate for the absence of the rollers and bed plates and allow the masonry seat to be finished at the same height at both ends. The 129 ½-ft. girders are 126½ ft. long on centers of bearings and weigh 113,000 lbs. each. The total steel weight of the bridge is 7,500,000 lbs.

The bridge was erected by an overhead cantilever traveler running on the completed spans and projecting far enough in advance to set the girders of the succeeding spans in position on the substructure. The traveler virtually consisted of a 147-ft. lattice girder span, with trusses 23 ft. apart and 18 ft. deep on centers and connected by overhead bracing in the planes of the top chord thus allowing clearance for the girders to pass between them from end to end over a single lower chord transverse strut about the middle of the span. The lattice girders were divided by vertical members into 21-ft. panels, each of them braced with a single diagonal, and one truss was set one panel in advance of the other to correspond with the skew of the substructure. The lattice girders had rectangular top and bottom chords, each made with a pair of 15-in. channels back-to-back, having web connection plates shop riveted to them and projecting beyond their inner flanges to receive the vertical and diagonal members field bolted to them.

The transverse beams connecting the upper ends of the vertical post support longitudinal beams which provide tracks for carriages with hoisting tackles operated by two engines on a top chord working platform at the rear of the traveler. The traveler was nearly balanced on wheels at four lower chord panel points near the center of the girder and was partly counterweighted by the hoisting engines and their boilers and supplies. When in service the traveler was moved out to the end of the last completed span with its forward end projecting beyond the center of the next span. The rear end lower chord panel points were blocked up from the finished span and were securely anchored to it by a yoke made with vertical screw rods and the horizontal transverse girder connected to them and taking bearing on the bottom flanges of the permanent girders. The girders for the next span were delivered on three cars each inside the rear end of the traveler and were unloaded and moved forward by the trolley hoist which lifted them clear of the cars, moved them forward and lowered them to their final position on their pedestals. By this method the use of falsework was eliminated and the girders were unloaded and erected at the same operation, by a comparatively small force of men. The traveler was adapted to be easily assembled and taken apart and shipped back to the shops for future use, thus making it a permanent tool.



Girder of the Lehigh Valley R. R. Bridge at Towanda, Pa., Suspended from Traveler Overhang.

The bridge was built and erected by the Phœnix Bridge Co. Mr. John Sterling Deems, chief engineer, and Mr. A. B. Milliken, superintendent of erection.

The Aluminum Cell or electrolytic lightning arrester is one of the most recent developments in the field of high-tension transmission lines. The property of this cell in allowing free flow of current in one direction and but slight flow in the opposite direction, until the applied voltage reaches a certain critical value, is used to permit static charges to be freely dissipated to the earth, while high resistance is offered the opposite flow. Each cell will withstand 250 to 280 volts alternating, and arresters for high voltages are constructed of a multiplicity of cells with a "horn" air gap of merely sufficient opening to assist in suppressing an arc. The arrester then serves as a safety valve to the system, taking no current at the operating potential, but discharging any abnormal high potential, so that the circuit potential is not materially disturbed.

Punishment for Waste of Well Water in California.

Early this year, the California legislature passed a bill to prevent the waste of water from the artesian wells that are such an important source of supply for domestic purposes and irrigation in some parts of the State. The law is a drastic one, and naturally enough has led to a suit by J. L. Elam to test its legality. This has been settled by the following unanimous opinion of the California Court of Appeal, delivered by Judge Allen:

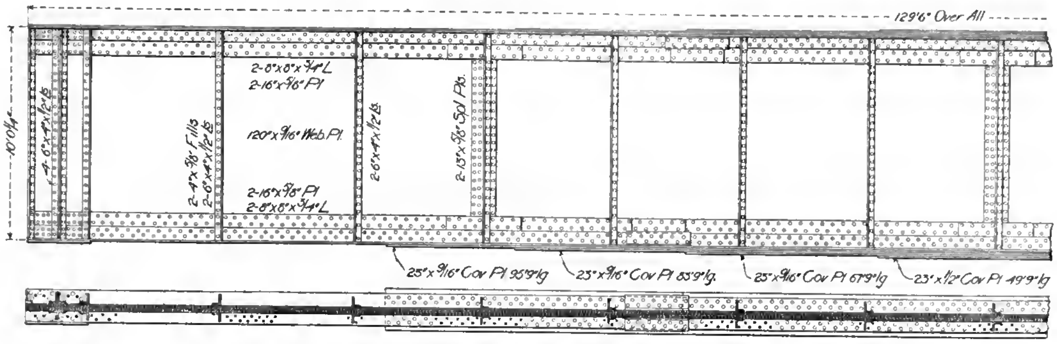
This is an application for a writ of habeas corpus presented by petitioner, who alleges that he is restrained of his liberty under a commitment issued upon default in payment of a fine assessed against him for a violation of the act of the Legislature approved March 6, 1907 (St. 1907, p. 122, c. 101), entitled "An act to prevent the waste and flow of water from artesian wells, and prescribing penalties therefor, and defining waste and artesian wells."

It is petitioner's contention that this statute is violative of the Constitution of the United States and of the Constitution of the State of California, and in conflict with the general laws. Section 1 of the act under consideration provides that an artesian well which is not capped or provided with mechanical appliances for arresting the flow of water therefrom is a nuisance, and the owner of the land upon which the same is situated is declared guilty of maintaining a nuisance if he suffers it to remain so uncapped or unprovided with mechanical appliances for arresting the flow, and any person maintaining such nuisance, or causing or permitting water to unnecessarily flow from such well, or to go to waste, is guilty of a misdemeanor. By Section 2 an artesian well is defined to be an artificial hole made in the ground through which water naturally flows from subterranean sources to the surface of the ground. By Section 3 waste is defined to be the causing, suffering or permitting the flow from an artesian well to run into any bay, pond or channel, unless used thereafter for the beneficial purposes of irrigation of land or domestic use, or into any street, road or highway, or upon public land, unless it be used for the irrigation thereof or for domestic use or the propagation of fish. It is further provided that, when water is run upon land for irrigation purposes, if more than 10 per cent. thereof be allowed to escape therefrom, the same shall constitute waste. Section 5 provides a penalty for the violation of any of the provisions of the act.

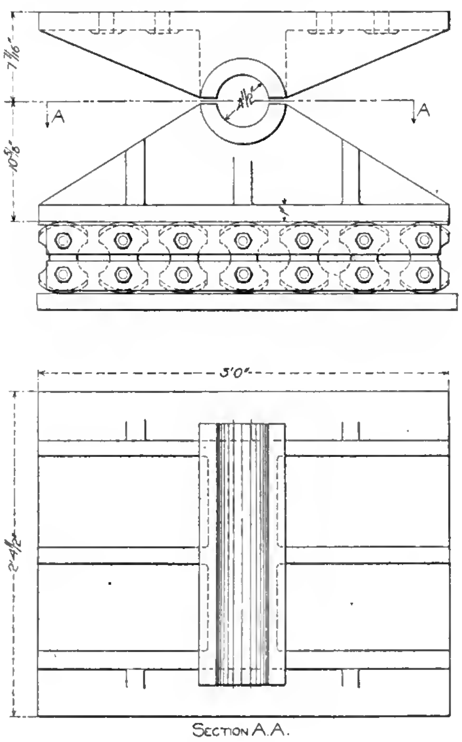
The first point made by petitioner—which is that the act is violative of the fourteenth amendment of the Constitution of the United States, which provides that no State shall "deprive any person of life, liberty or property without due process of law, nor deny to any person within its jurisdiction the equal protection of the law," and of article 1, section 1, of the Constitution of this State, which provides that "all men are by nature free and independent, and have certain inalienable rights, among which are those of enjoying and defending life and liberty, acquiring, possessing and protecting property," and of section 13, article 1, which provides that no person shall be "deprived of life, liberty or property without due process of law"—seems to have been met and demonstrated to be untenable by the Supreme Court of the United States in the case of Ohio Oil Co. v. Indiana, 177 U. S. 190, 20 Sup. Ct. 576, 44 L. Ed. 729.

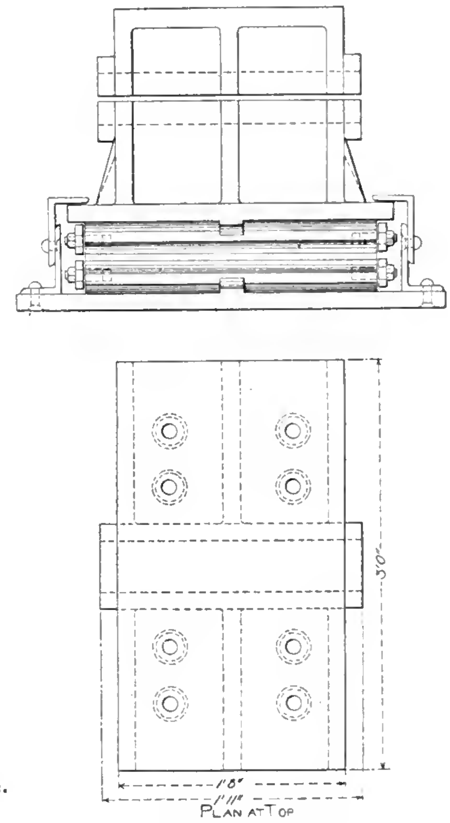
By that case it is established that water, oil, gas and all fugitive substances held in their natural subterranean reservoirs are exceptions to the general rule establishing absolute ownership in the proprietor of the surface of all that lies underneath; that these minerals, being migratory in their nature, having no fixed situs, are a part of the soil only so long as they are on or in it, but after they escape and go to other lands the title of the former owner is gone; that it follows therefore that no one owner of the surface of the earth within the area beneath which these minerals move can exercise his right to extract from the common reservoir in which the supply is held without diminishing the source of supply as to which all other owners of the surface must exercise their rights; that, in consequence of the nature of the deposits, of their transmissibility, of their interdependence, of the right of all, and of the public at large, the State could lawfully exercise the power to regulate the right of the surface owners among themselves to seek to obtain possession, and to prevent the waste of the products in which all the surface owners within the area wherein they were deposited, as well as the public, had an interest. "No devesting of private property under such a condition can be conceived, because the public are the owners, and the enacting by the state of a law as to the public ownership is but the discharge of the governmental trust resting in the state as to property of that character." This water, the ownership of which until actual possession is acquired being in the public, or at least that portion of the public who may own the surface of the soil within the artesian belt, is subject to a reasonable use only by those interested therein.

This reasonable use is determined in Katz v. Walkinshaw, 141 Cal. 134, 70 Pac. 663, 74 Pac. 766, 64 L. R. A. 236, 99 Am. St. Rep. 35, to be the use of such amount of the subterranean water "as may be necessary for some useful purpose in connection with the land from which it is taken." The conditions existing in this state with reference to the necessity for the conservation of irrigating waters are most clearly set out in the case last cited, and the reasons for the rule restricting the use clearly shown. Whenever a landowner exceeds this reasonable use, he is appropriating to himself that which belongs to others who are entitled to a like use, and to that extent is obstructing the free use of property so as to interfere with its comfortable enjoyment, and which, by sections 3479 and 3480 of the Civil Code, is declared to be a public nuisance. Whatever right one has, even in his own, is subject to that established principle that his use shall not be injurious to the rights of others, or of the general public. This act therefore relates to waters, the right to the use of which is common to a large portion of the community, and affects the general public right. Legislation in relation thereto affects the public welfare, and the right to legislate in regard to its use and conservation is referable to the police power of the state, which is declared in Ex parte Whitwell, 98 Cal. 78, 32 Pac. 870, 19 L. R. A. 727, 35 Am. St. Rep. 152, to be "the power to make laws to secure the comfort, convenience, peace and health of the community." "The police power deriving its existence from the rule that the safety of the people is the supreme law, justifies legislation upon matters pertaining to the public welfare, the public health, or the public morals." Ex parte Drexel, 147 Cal. 766, 82 Pac. 429, 2 L. R. A. (N. S.) 588. It is settled law that all



Part Elevation of a Girder of the Lehigh Valley R. R. Bridge.





Expansion Bearing of Lehigh Valley Bridge.

property is held subject to the exercise of police power, and that provisions of the Constitution declaring that property shall not be taken without due process of law have no application in such cases. Odd Fellows' Cem. Ass'n v. San Francisco, 140 Cal. 230, 73 Pac. 987.

It is further contended by petitioner that the act violates section 21, art. 1, of the state Constitution, which provides that "no special privileges or immunities shall ever be granted which may not be altered, revoked, or repealed by the Legislature, nor shall any citizen, or class of citizens, be granted privileges or immunities which, upon the same terms, shall not be granted to all citizens"; and he endeavors to demonstrate this proposition by the assumption that the surface owners are not prohibited by this act from extracting from this common source of supply any quantity thereof by means of pumps, that no attempt is made to restrict the use after the same is so pumped, and that the waste of such water so pumped is not violative of the act, and illustrates the claimed distinction by the statement that certain gun clubs within the arid region are pumping large quantities of this subterranean water, by means of which duck ponds are filled and maintained, while other gun clubs whose ponds are fed by artesian wells are restricted in the use of the flow therefrom.

It may be conceded that the courts have recognized the right of gun clubs to practically create a monopoly in wild game over large areas of land, and have protected them in a so-called private proprietorship and limited dominion over such portions of the common property of the people of the state as they may induce to stay upon such reserves by feeding them and maintaining ponds therein. It may also be conceded that an exclusive right to hunt upon such preserves has also been held to be a species of property, and injunctions have been issued to prevent interference with the full exercise of such rights. Kellogg v. Kings, 114 Cal. 378, 46 Pac. 166, 55 Am. St. Sep. 74. But, while the maintenance of such duck ponds no doubt contributes greatly to the enjoyment of the owner of the hunting privilege, it will scarcely be contended that this is a use of the water which is beneficial to the land. Neither does it follow that because the courts have recognized such exclusive hunting privileges they must support the owners thereof in an encroachment upon another more necessary common right of the public, that of the conservation of the subterranean waters of the state for domestic uses and purposes of irrigation.

We are not to be understood in thus meeting the reasons of petitioner's argument as admitting that there is anything in the language of the act in question that would affect a gun club any more than an individual association, or incorporation. That one may show matters dehors an ordinance which is referable to the police owner that such ordinance by reason of particular facts and circumstances is unreasonable anl oppressive as to him is determined in Re Smith, 143 Cal. 370, 77 Pac. 180. No reason suggests itself why such right may not be recognized when the state has sought to exercise the same power; and, while courts may to a degree supervise such power, "they will not intereferc except where the case be plain that needless oppression is worked and constitutional rights invaded." In Re Smith, supra. Nothing appears upon the face of the act, or in the record on this application, from which it can be said there is any discrimination as to the class of persons who may violate the provisions of the law. No special immunities or privileges are granted to any club, clubs, persons, or persons. That some clubs may maintain their ponds by pumping, while others, more fortunate, have theirs maintained by artesian wells or running streams, or tide water from the ocean, in no way affects the question. As well might it be said that Legislative action affecting tide lands created special privileges or immunities because the duck ponds of the clubs relying upon tide water might be affected thereby.

As we have before attempted to show, no surface owner possesses the right to extract the subterranean water in excess of a reasonable and beneficial use upon the land from which it is extracted. Any additional extraction is not in the exercise of a right, if by such exercise the rights of others are injuriously affected. Nor can an appropriator take more water than he can beneficially use. Hence it follows that no discrimination is made between parties entitled to the exercise of a common right. Under the act in question, all may exercise their full legal right with reference to this water.

As to the right to use any portion of that which belongs to the public, legislative control is applicable, and if, as a matter of fact, public rights are abused by the improper extraction of this public water by means of pumps, it is presumable that the Legislature in the exercise of its proper functions will in due time arrest such waste. The game of the state belongs to the people in their collective capacity in a more general way than does the subterranean water within an artesian belt, yet no one will question the right of the state to restrict the manner in which fish may be taken from the water, whereby it is made a public offense to use a seine, while those who adopt the hook and line may take without offense. There is no special privilege or immunity granted to the man with the hook and line. The right to take at all, or in any particular season, either of game or any other thing public in its character, comes from the state and is subject to its regulation and control, and it is for the Legislature to say what reasonable restrictions are necessary for the protection of this public property. Ex parte Kenneke, 136 Cal. 527, 69 Pac. 261, 89 Am. St. Rep. 177.

It is further contended that this act is violative of subdivision 33, sec. 25, art. 4, of the state Constitution, which provides that "the Legislature shall not pass local or special laws in any of the following enumerated cases, that is to say: . . . in all other cases where a general law can be made applicable"; and also violates section 11, art. 1, which provides that "all laws of a general nature shall have a uniform operation." Assuming all that the petitioner claims for the act as to its establishment of a class, nevertheless "the true practical limitation of the legislative power to classify is that the classification shall be based upon some apparent natural reason, some reason suggested by necesity, by such a difference in the situation and circumstances of the subjects placed in different classes as suggests the necessity or propriety of different legislation with respect to them." Nichols v. Walter, 37 Minn. 272, 33 N. W. 802. "A law which operates only upon a class of individuals is none the less a general law if the individuals to whom it is applicable constitute a class which requires legislation peculiar to itself, in the matter covered by the general law, and which is germane to the purpose of the law." People v. Central Pac. R. Co., 105 Cal. 576, 38 Pac. 905.

It is obvious that different legislation is required peculiar to those whose lands are so situated with reference to the artesian supply that a natural flow results from a penetration into the subterranean reservoir. The distinction between wells having a natural flow and those not so constituted is natural, and reasonably indicates the necessity or propriety of legislation restricting the former class. The right to so legislate when the reason exists is determined in Pasadena v. Stimson, 91 Cal. 251, 27 Pac. 604, People v. Central Pac. R. Co., 105 Cal. 576, 38 Pac. 905, and People v. Mullender, 132 Cal. 221, 64 Pac. 299. This act operates uniformly upon every one owning lands upon which is located an artesian well of the kind and character specified in the act. "Section 11, art. 1, of the state Constitution, requiring all laws of a general nature to have a uniform operation, is satisfied when the law operates uniformly upon all persons standing in the same category, and upon rights and things standing in the same relation." Wigmore v. Buell, 122 Cal. 144, 54 Pac. 600.

It is further contended that a discrimination exists because of the provision which permits the maintenance of ponds for the propagation of fish, as distinguished from the maintenance of ponds for other purposes. The propagation of fish has always been recognized as a legitimate pursuit and as an effort to increase the food supply of the world, and the use of water therefor a beneficial use, which, like the use for irrigation or domestic purposes, is declared by the act to be the highest use to which this natural element may be applied. The Legislature has the right to determine what uses are superior in kind and to protect the same, and it is within its province to determine that certain uses of this public property are of a higher character and superior in right to other uses. This right is subject only to the constitutional limitations against discriminations. Having so determined, and no just criticism being applicable thereto, the value of such uses must be held to be established.

We are not called upon in this case to determine the legislative right to regulate or protect the extraction of this subterranean water for transportation or sale of those owners of the surface whereon the use of water is not required for those higher uses, nor of prescriptive rights asserted or claimed in such instances, but simply to hold that for the uses which have been determined subordinate the great subterranean water supply may not be applied to the detriment of the higher uses, and that legislation directed to the conversation of such water, as in this act, is not prohibited by any constitutional provision. "Every possible presumption is in favor of the validity of a statute, and this continues until the contrary is shown beyond a rational doubt. One branch of the government cannot encroach on the domain of another without danger. The safety of our institutions depends in no small degree on a strict observance of this salutary rule." In re Spencer, 149 Cal. 400, 86 Pac. 896; Sinking Fund Cases, 99 U. S. 718, 25 L. Ed. 496.

Writ denied.

Book Notes.

The eighteenth edition of the "Western Blue Book and Buyers Reference." It is a volume of over 700 pages, giving the names and addresses of architects, engineers, contractors and parties interested in supplies for mills, mines, foundries, iron furnaces, steel mills, quarries, machine shops, railroads and other engineering industries. The names are classed in two ways. In the first part of the book those of Chicago parties are omitted and the rest are grouped by states; the names then subdivided according to calling or industry. In the second part of the book, all the Chicago names are classified alphabetically according to calling or industry. This list gives not only the street addresses, but also the telephone numbers. (Chicago, Milton E. Lowitz Publishing Co., 66 Sherman St., $5.)

A book that will appeal strongly to engineers who have had to live in wild districts is Lieut-Col. J. H. Patterson's "The Man-Eaters of

Tsavo." The author was one of the leading engineers of the famous Uganda Ry. in East Africa, a piece of work described in several articles in this journal. As explained in one of those articles, the railway work was completely stopped for a long period by the forays of lions, which terrorized the construction camps. At one station they carried off 28 coolies in a short time, and finally they took the assistant superintendent of police out of a first-class car on one of the sidings. For a while the men slept in trees, the station water-tanks and freight cars until lion-proof iron huts could be built for them. Every means to prevent their ravages or to kill them failed until Col. Patterson took charge of the work. The many thrilling adventures which he had before finally accomplishing the task make a unique story in the history of railway engineering. The author has also traveled in many other parts of wildest Africa and a section of the book describes some of his experiences elsewhere than on the Uganda line. (New York, Macmillan Co., $2.50.)

The third annual number of the "Beton-Kalender," for the year 1908, is 74 pages larger than the last issue of this excellent pocket-book and contains many new features. For those unacquainted with previous numbers it may be stated that the book is in two volumes, each about 4 x 6½ in. in size. The first volume is cloth-bound, and contains a diary and tables and articles relating to general statistics, money, weights and measures, mathematics, surveying, the strength of materials, cost of construction, the theory of reinforced concrete beams, various regulations regarding reinforced concrete construction, requirements for Portland cement and tests of the material and a digest of patent law. The second volume is bound in paper and contains articles on all kinds of works executed in concrete, with and without reinforcement. All the articles are written by specialists, and the book is edited by Dr. F. von Emperger, editor of "Beton und Eisen" and well known to American engineers on account of his former activity in introducing the Melan arch in this country. In addition to a complete revision of the different articles in the former edition, some of them have been completely rewritten, the latter relating to the cost of works, staircases, theatrers, waterworks and sewerage. The official regulators include those of the Prussian and French governments of the current year. The book is invaluable to the concrete specialist who can read German. (Berlin, Wilhelm Ernst & Son, 4 marks.)

A valuable contribution to the records of American engineering is the two-volume "History of the Canal System of the State of New York, together with Brief Histories of the Canals of the United States and Canada," written by Mr. Noble E. Whitford and published as a supplement to the report for 1905 of the New York State Engineer. It is the first authoritative history of the first important engineering undertaking in this country, which began in 1793 with the construction of a small canal at Little Falls and is still being continued. The work was the training school of our first engineers and of many of the men of succeeding generations who followed them in important positions in the national life, as is well shown by an interesting collection of brief biographies of those who held the rank of assistant engineer or higher. The preparation of the history became necessary in connection with the work of the State Engineer's Department, and it is fortunate that Mr. Whitford was assigned to the work, for along with a knowledge of engineering subjects he has shown excellent judgment in the references to historical topics forming an essential part of his narrative. It is a most instructive record of engineering achievement, covering not only the existing canals, but also the abandoned canals, the canals built by private parties, and general studies of the effect of the canals on some features of State life, particularly the development of communities along the line of the Erie canal. The second volume contains engineering and financial statistics of the State canals, a bibliography of them, and a description of all the leading canals of the world.

It is not often that a reviewer of technical books has an opportunity to draw attention to a work which so well answers a very strong demand as does the "Principles of Reinforced Concrete Construction" by Professors F. E. Turneaure and E. R. Maurer, of the University of Wisconsin. Up to the present time there has been no American book which discussed reinforced concrete with the same authoritative thoroughness as Mr. Sabin goes over the subject of plain concrete in his treatise on "Cement and Concrete." While there have been a number of volumes on reinforced concrete none has answered the great demand for a thorough discussion of principles, for a large part of each of them is devoted to descriptions of structures and of methods of carrying on construction, already available in greater detail in the pages of the many journals devoting all or part of their space to concrete. The authors of this volume have followed the plan of covering in a systematic manner at the outset those principles of mechanics underlying the design of reinforced concrete, then bringing together the results of all available tests that may aid in establishing reliable coefficients and working stresses, and finally giving such information concerning actual designs as may be needed to make clear the principles involved. The properties of plain concrete and steel are explained sufficiently in the second chapter to give definite knowledge of their relation to the general subject in hand, and adhesion, contraction and expansion are discussed. The third chapter is a full theoretical treatment of reinforced concrete, in which empirical rules and methods are avoided so far as possible in order that the reader may acquire such a firm grasp of the real principles that he may appreciate the nature and effect of any approximate methods brought to his attention. The fourth chapter supplements the third by reviewing, in the light of the previous theoretical study, the results of the most important tests of beams and columns. Working stresses and economical proportions are taken up in the fifth chapter. The sixth chapter is an excellent practical summary of working formulas, diagrams and tables for use in designing beams, slabs and columns, so arranged that they can be employed without reference to any other part of the book. These six chapters take up 236 pages, and are followed by 77 pages explaining the application of reinforced concrete to building construction, arches, retaining walls, dams and miscellaneous structures. These chapters explain principles of design rather than details of construction and thus furnish just the information which is necessarily omitted in articles in technical journals. Special attention should be given to the authors' analysis of the solid arch rib, which they consider superior to the ordinary graphical methods, and may be shortened by simple graphical aids. The rather hasty examination on which these notes regarding the book are based shows it to be a conservative, safe guide. There are some things in it to which The Engineering Record does not agree, but these are things where differences of opinion will always exist. The authors are always on the safe side and the volume they have prepared deserves a warm welcome and thorough study. (New York, John Wiley & Sons, $3.)

Letters to the Editor.

Traffic on New York Streets.

Sir: Duirng the examination made by the Commissioners of Accounts of New York City of the administration of the pavements, etc., of Manhattan, and subsequent investigation by Governor Charles E. Hughes of New York State, it became necessary to know the quantity of traffic on representative avenues and streets. I was employed as consulting engineer on pavements, and among other matters reported to the Governor the traffic on several streets and showed its relation to the maintenance or neglect of the pavements. The heavy traffic streets in wealthy and influential districts, as Fifth Ave., are maintained in good order, whereas the lighter traffic streets in poor districts have not been kept in repair. Traffic records have heretofore been made for 10, 11 or 12 daylight hours. Therefore for purposes of comparison with previous traffic, I made records for 11 daylight hours on various streets. The heaviest traffic recorded in New York for 11 hours was on Oct. 14, 1907. It was 11,170 vehicles, weighing about 13,360 tons, on Fifth Ave. between 33d and 34th Sts., or 279 vehicles, or 324 tons, per foot of width of roadway for 11 hours. The traffic on First Ave. between 26th and 27th Sts. for 11 hours on the same date was 4,445 vehicles, weighing about 6,734 tons, which was about 79 vehicles, or 120 tons, per foot of width of roadway for 11 hours.

The accompanying tables show the traffic on Fifth and First Aves. for 24 consecutive hours. This is probably the first time that traffic for 24 hours has been recorded in any American city.

Vehicles in 24 Hours on Fifth Avenue, New York, Between 58th and 60th Streets. From Wednesday Noon, Oct 9, to Thursday Noon, Oct 10, 1907.

Hours.	Horse Vehicles. Av. Weight with Load. 1 ton.	2 tons.	4 tons.	Total Horse Vehicles.	Automobiles, Av. Wgt. 1 ton.	Total Vehicles.
12-1	437	69	30	536	230	766
1-2	421	107	20	548	184	732
2-3	296	60	11	367	142	509

7-8	122	57	12	191	31	222
8-9	211	53	6	270	187	457
9-10	263	51	19	333	179	512
10-11	437	51	17	505	308	813
11-12	432	65	10	507	232	739
Totals	5,825	1,026	219	7,010	3,309	10,379

The estimated weight of Fifth Ave. vehicles and loads was 12,062 tons. The width of Fifth Ave. at the place of recording this traffic is 41⅓ ft. There were therefore 251 vehicles, or 292 tons, per foot of width per 24 hours. This can be regarded as an average weekday traffic on Fifth Ave. between 9th and 59th Sts. The Sunday traffic on Fifth Ave. is about one-fifth the weekday traffic.

The estimated weight of First Ave. vehicles and loads was 3,898 tons. The width of First Ave. at the place of recording this traffic is 56 ft. There were therefore 48 vehicles, or 69⅔ tons, per foot of width per 24 hours. This can be regarded as an average weekday traffic on First Ave. between 22d and 109th Sts. The Sunday traffic on First Ave. is very small; sometimes none is in sight for an hour or more.

Fifth Avenue, New York, has probably the most numerous, if not the heaviest traffic in total quantity, as well as per foot of width, found in any American city. It is exceeded by a few streets in Paris, London and Berlin. It is interesting to

note the large proportion of automobiles now in use.

VEHICLES IN 24 HOURS ON FIRST AVENUE, NEW YORK, BETWEEN 77TH AND 78TH STREETS. FROM WEDNESDAY NOON, OCT 9, TO THURSDAY NOON, OCT 10, 1907.

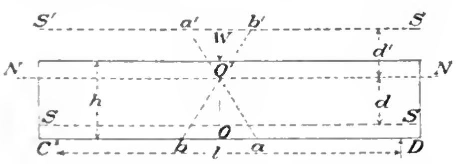
Records of street traffic help solve the paving problems of cities and should be made at reasonable intervals in every important city. The flow of traffic needs controlling, guiding and relief, not only on account of pavements but for other obvious reasons. J. W. HOWARD, C. E., E. M.

1 Broadway, New York.

THE DEFLECTION OF CONCRETE BEAMS.

SIR: In my work recently I was asked to compute the deflection of a reinforced concrete beam under a certain loading. As I have never seen any method for making this computation, it may be of interest to some of your readers to know of one which is at least correct for the assumption that the concrete takes only compression.

Given a concrete beam as shown in the diagram, reinforced with steel SS and having a con-



centrated load W applied at the center between the supports C and D, it is required to find the deflection of the beam at the point O due to the load W.

Knowing the amount of steel and h, the distance of the steel reinforcement from the top of the beam, the neutral axis NN can be located. For an infinitesimal length, $\Delta\, l$, ba represents the elongation of the steel and cf the contraction in the concrete after the application of the load W. If we replace the concrete compression side of the beam by a steel member S^1S^1 of the same area as SS and so placed as to maintain the neutral axis at NN, and if we properly increase W so as to produce the same stress, and hence deformation, in the steel SS for this hypothetical beam as for the reinforced concrete beam, we shall have a beam whose deflection can be readily calculated and will be the same as that of the original beam.

To do this make $d^1 = d$ and increase W by the ratio, (moment of resistance of hypothetical steel beam) to (moment of resistance of reinforced concrete beam). The moment of resistance of the hypothetical steel beam is $2d$(area of $S\ S$) (stress per square inch). The moment of resistance of the reinforced concrete beam is (area of SS) (stress per square inch) $(d + \tfrac{2}{3}\,k)$.

Hence $2d\ W \div (d + \tfrac{2}{3}\,k)$ is the load that will give the required deflection of the hypothetical beam. The required deflection is, therefore, readily obtained from the familiar formula for the deflection of a beam of uniform material and is given by the expression

$$[2d\ Wl^3 \div (d + \tfrac{2}{3}\,k)] \div 48\,EI.$$

In this expression I is $2d^2$ (area of SS).

Hoping that this may be of some interest, I am,

Yours sincerely,

ELI WHITE.

New York, Oct. 21.

HEATING AND VENTILATING TESTS.

SIR: As your recent editorial under the above title clearly shows, there is certainly a fertile field, as yet almost untilled, for the investigation of the present practice in heating and ventilation. But the problem in its entirety is exceedingly complicated, for the heating and the ventilation are interdependent. In any system the variables are so numerous as to greatly increase the difficulties. Attention must therefore be centered upon details and the engineering structure built up therefrom.

In any modern system of reasonable magnitude the fan will be found as a relatively positive factor in the movement of the air. As a basis for further investigations of complete systems, it appears that the fan should first receive consideration.

Almost without exception the manufacturers' ratings and incidental guarantees have been heretofore accepted as the measure of performance. Because of the great flexibility of the fan as regards possible changes in speed, volume, pressure and power, established conditions have been difficult to maintain, and hence departure from the results shown by the standard basis of measurement was to be expected.

Tests sufficient to meet commercial requirements in engineering and selling have been made by manufacturers and individual engineers, but, as your editorial suggests, the results have been kept secret and retained as personal stock in trade. In a rough way the information thus collected has appeared to serve the purpose. The failure of the purchaser to demand test before acceptance, and in reality, the lack of real necessity for such a test, have had much to do with the continuance of this policy. But the time is now at hand when methods of testing should be standardized; when exhaustive tests should be made, and the results become public property. The age of secrecy is passed; the leader in disseminating knowledge of this character may likewise be the leader in the commercial field.

For years the comparison of fans upon their capacity areas has been prevalent. That is, for each and every cased fan, with little consideration of its proportions or speed, it has been assumed that this capacity area was equal to one-third of the product of the diameter and the width of the wheel at its periphery. This area has represented the maximum over which maximum velocity and pressure could be maintained. In point of fact it varies with the width of the wheel, the number and curvature of its blades, and the proportion of its casing; it is influenced by the speed, and by the presence of one or two inlets.

Although to a limited degree the general effect of these variables is known to some manufacturers and engineers, there is no well defined public or private knowledge upon the subject. Even the best method of testing the independent blower is far from established or approved. The old-time method consists in providing the standard outlet in the casing with a tapering pipe, reduced at its end to an effective area equal to the capacity area as above described, and then taking pressure measurements by a single water gauge. Velocities, if low enough, were measured by the anemometer, which, however, was seldom accurately calibrated. If too high for the anemometer, they were calculated from the total pressure.

The tests on ventilating fans conducted a few years ago by Mr. D. W. Taylor probably represent the greatest accuracy in methods, instruments and measurements. They have been made public in "Transactions" of the Society of Naval Architects and Marine Engineers, but unfortunately not in a form to be essentially valuable to the average man. The Pitot tube was used with great care, and tests conducted upon numerous relatively small standard fans discharging through extended lengths of straight piping. But no general comparison of types and proportions of fans was made.

Tests made under either of the two preceding methods are concerned directly with the creation and measurement of pressure and velocity within the pipe.

An entirely different method consists in discharging the air into a large, air-tight chamber against a known maintained resistance, the practical extinction of the velocity therein, and its re-creation when the air is allowed to escape through an opening out of the line of direct discharge from the fan.

Results based upon the first method lead one to think in terms of the pressure produced by the fan to overcome resistance; the second brings first to mind the resistance to be overcome as a factor in determining the volume which a given fan may be able to deliver.

Between these, and possible other methods of testing, some choice should finally prevail in the engineering world as a fundamental basis for determining the performance of a fan. The relations and influences of static and dynamic pressures should be clearly understood. The proper methods, the proper instruments, and the proper calibration should be likewise established and figured.

Much of this work, particularly in the preliminary stages and in isolated detail, appears to lie peculiarly within the province of the technical school. Unity of purpose and concerted effort on the part of the leading schools would, through investigation for thesis and similar work, soon add materially to the fundamental knowledge we so much need. Aside from the general interest which any school should properly take in the matter, the existence of courses in heating and ventilation in many of the leading schools should furnish a reason for conducting the tests. It cannot be doubted but that broad-minded manufacturers would readily co-operate in any such effort.

Anything that would remove the present confusion in published or private tables of fan performance, and which would establish standard results for typical forms, would be a distinct gain to all concerned.

In the field of the disc and propeller fan, which is distinct in principle from the centrifugal type just under consideration, there is room for excellent work.

As a foundation for any series of investigations in fan performance, a reliable bibliography would be of inestimable value. Through society transactions, engineering periodicals, text-books, and the like, there is scattered much of real value. Unfortunately there is an excess of the unreliable, which should be carefully eliminated. A careful consideration of the residuum would avoid much duplication of effort, and clear the way for effective work. In all of this it appears that the technical school could play an effective part; the most vital results could be published in the name of the professors under whom the work was conducted, and who were generally responsible for its accuracy.

Manifestly a body like the American Society of Heating and Ventilating Engineers should be deeply interested in the subject. It has already done much to awaken interest, and promote investigation. Concerted, combined, systematized effort would bring eventual returns of great value.

Boston, Oct. 31. WALTER B. SNOW.

THE ENGINEERING RECORD

PUBLISHED WEEKLY BY THE

McGraw Publishing Company

James H. McGraw, Pres.; Curtis E. Whittlesey, Sec. and Treas.

MAIN OFFICES:

239 West 39th Street, New York.

BRANCH OFFICES:

Chicago: Old Colony Building.
Philadelphia: Real Estate Trust Building.
Cleveland: Schofield Building.
San Francisco: Atlas Building.
London Office: Hastings House, Norfolk St., Strand.

SUBSCRIPTION RATES.

United States, Cuba and Mexico...........$3.00 a year
Canada ....$4.50 a year
Foreign subscription.........................$6.00 a year
25 shillings. 25 marks. 31 francs.
Foreign subscriptions may be sent to our London office.

NOTICE TO ADVERTISERS.

Changes in advertisements intended for a particular issue should reach the office of The Engineering Record on Friday of the previous week. New advertisements can be received up to noon of Wednesday of the week of issue.

NOTICE TO SUBSCRIBERS.

Remittances.—Remittances should be made by check, New York draft, or money order, in favor of The Engineering Record.

Change of Address.—The old address should be given as well as the new, and notice should be received a week in advance of the desired change.

Back Copies.—No copies of issues prior to July, 1906, are kept on sale, except in bound volumes.

Date on Wrapper indicates the month at the end of which subscription expires. The sending of remittances for renewal prior to that date will be much appreciated by the publishers.

Club Rate.—In acknowledgment of assistance rendered by subscribers in the securing of new orders, a club rate of $2.50 per annum is quoted. This rate applies to subscriptions in clubs of two or more, at least half of the names in the club to be those of new subscribers.

Entered at the New York Post-Office as Second Class mail matter.

Of this issue of THE ENGINEERING RECORD 15,000 copies are printed. Total circulation for 1907 to date 672,000 copies, an average of 14,609 copies per week.

TABLE OF LEADING ARTICLES.

Architecture and Landscape Work for the Catskill Water Works.

In these days of advancing culture in the United States, the local governmental authority charged with the construction of a great system of public works has a responsibility other than to make the system as a whole and the structures in detail useful and efficient in a utilitarian way only. With additional thought and skill in design, the visible structures of masonry and earth, with their landscape surroundings, can be made beautiful—a source of pleasure as well as a means for supplying a physical need. Frequently, too, these desirable results can be obtained at slight additional cost, and cases are not unknown in which intelligence properly applied has, in satisfying esthetic demands, secured practical economies. But even if it does cost somewhat more to make public works beautiful, the expenditure, within reasonable limits, is well justified. The older communities, having met their most urgent needs for bare necessaries, can afford such investments for the enjoyment of their citizens. Indeed, judicious expenditures of this sort are not an extravagance, for besides giving wholesome pleasure to the community that builds them, and its neighbors, fine public works may become a source of considerable indirect revenue. Without doubt, several European countries attract their thousands of tourists annually—and take toll from them—not alone because of beautiful scenery, but in part ,by reason of noble and attractive public and semi-public buildings, bridges and other works.

New York City has just entered upon the construction of, probably, the greatest system of water-works ever actually undertaken, and one of the most ambitious engineering enterprises of modern days. These works will bring water a hundred miles or more from the Catskill mountains, across country of unusual scenic charm and much variety of topography. In the valleys of the mountains, where thousands of New York City's residents spend their summer vacations, the impounding reservoirs will be created. Catskill aqueduct will traverse the broad and beautiful valleys of the Esopus, the Wallkill and the Moodna; will pierce the Highands of the Hudson in crossing the main valley of that river, and will continue southward east of the Hudson through the gentler hills and dales of Putnam and Westchester counties, where are many of New York's suburbs and country homes. Along this line are some fifty gatehouses, siphon chambers and other structures suggesting the aqueduct hidden below in trench, or tunnel or embankment. Some of these buildings will occupy most conspicuous sites, commanding in several instances hundreds of square miles of territory. They cannot be concealed; they should be made attractive.

At the terminus of the aqueduct, Hill View reservoir, a covered basin, can readily become a park with broad and pleasing prospects in many directions. Near the large town of White Plains, Kensico reservoir, of approximately 40,000,000,000 gal. capacity, will become an attractive lake of very irregular outline, extending into the valleys among the hills. Its dam, a masonry wall over 2,000 ft. long, on top and 150 ft. high above the surface of the ground, will occupy a site probably more conspicuous than that of any existing large masonry dam, if judged by the number of people who will see it daily. Only 25 miles from the heart of the city, at the terminus of a proposed park system, in the midst of a populous suburban region, it is in full view, at close range, of a railway carrying thousands of persons daily to and from New York. Large aeration plants may also be included in the system, throwing numerous jets of water into the air to considerable height, and there is to be a very extensive filtration plant, which, it is to be desired, may be made more pleasing in appearance than some works of this kind have been.

What opportunities are suggested here, with no light emphasis, for the architect and landscape engineer to co-operate with the water works engineer in creating works which will be the more creditable to all the professions concerned for such a union of technically trained minds! To these opportunities and obligations the Board of Water Supply has evidently not been oblivious. With the good sense displayed in other matters which it has been the pleasure of The Engineering Record to mention the Board has engaged in a consulting capacity for the guidance of its chief engineer and his staff in the design and construction of the visible portions of the works, the services of a landscape engineer and a firm of architects of the highest standing in their respective professions. In selecting these men, it has been stated, not only was care exercised to secure skill of the highest order, but also those qualities of personality which make it possible for men to co-operate. Indeed, but slight acquaintance with the staff of the Board is necessary to convince one that this idea of co-operation is one of the most dominant notes in the policy of the commissioners and the chief engineer. Assistants who have been trained along the lines of architecture and landscape work have been engaged as members of the engineering force, so that the details of all kinds of work may be elaborated and harmonized under the immediate supervision of the chief engineer.

Such excellent results have been achieved in recent years by similar association of architects and landscape engineers with civil engineers, that the wisdom of this most recent endeavor to do something better than the ordinary in the construction of water-works can not be gainsaid. It is to be hoped that the good example of New York and Boston and some other cities will soon become the usual practice, not only for water-works, but for all public works. The recently completed Metropolitan water-works of Boston now give ample justification in their most attractive appearance for judicious regard for the esthetic sensibilities of the community and the slight additional cost which it entailed. With this successful precedent fresh in mind, this journal anticipates with confidence an accomplishment which will be thoroughly creditable to the metropolis and a cause of pride to its citizens, if the men who are now so ably directing the works be allowed to continue untrammelled in their good policies.

Problems of Motor Application.

In view of the amount of engineering attention usually given to the purchase and installation of electric generating equipment, it is singular that problems of motor application are so frequently settled off-hand by owners of industrial plants. The ability of the average well-made motor to withstand abuse is, no doubt, partly responsible for this, and another reason for the quick decisions often made as to the kind of motor selected for a given duty is found in the subdivision of motor units necessary in the great majority of installations, whether individually or group driven. Then there is the question of first cost and delivery, which is naturally important to an establishment working under conditions of forced output.

It is an easy matter in simple problems of motor application to spend more time upon the selection than the case warrants, but in the choice of motor drives where several units are required, there are some fundamental points which should not be overlooked simply because it is about lunch time and because the motor salesman has quoted a good price on standard outfits. The amount of power, average and maximum, which the machine or group to be driven will require; the prospect of more machines being added to the load of each motor; the amount and range of speed regulation necessary; the character of attendance that can be counted on; the weight of the motor unit and cost of special construction to support it, if on a wall or ceiling platform; and the efficiency curves of the motors

offered should all be carefully considered. Too few manufacturers are possessed of data showing the percentage of time different machines are idle and the variations in individual power demands at different times.

The question of motor efficiency is of much more importance than is always realized. Motor design has developed to a point where certain efficiencies may be expected in certain types and sizes of machines, but unless a motor is selected to run at or near its normal rated output the greater part of the time, the benefit of a highly efficient design cannot be had, the cost of the motor becomes unduly great for the service rendered, and the cost of power lost in the distributing system and the expense of excess current generation at the prime movers above the normal, tend to defeat its economies, which the electric drive is generally capable of bringing about if properly installed.

Occasional tests made on working installations are found to throw considerable light on the motor situation and guide future decisions as to motor selection. On account of the extremely low maintenance cost of many motors in definite commercial service, there is often an absence of accurate repair records in plants where the most minute details of engine, boiler and generator maintenance are carefully kept. A policy of charging off motor repairs, however, enables the exact cost of the electric drive to be figured in different departments, and the expense of testing the starting current, speed and power consumption of service motors is almost nominal in comparison with the value of the data. Given a motor of large capacity installed in connection with a group drive, it is most essential to find out from time to time whether it is being seriously overloaded or not, either through changes in the operating conditions at the machines or through the addition of more machine units than the motor can properly handle at the maximum rate of production.

No question is of greater importance in the applications of electric motors to commercial service than the group contrasted with the individual drive. It is not the purpose of these comments to discuss the relative advantages of group and direct driving, but to emphasize the need of going into the question thoroughly in practice. Expert advice is more necessary here than in any other phase of the motor problem. Nothing short of a careful estimate of the total annual cost of each method, taking into account the installation and purchase expense, operating efficiency of each combination, flexibility value, probable reliability and repair cost, interdependence of departments, in brief, the total power cost at the motors per unit of manufactured product, will furnish a proper basis for a sound decision in motor selection.

Sheet Piling and Earth Pressure.

There are some puzzling questions which arise in connection with sheet piling as used for both small and large excavations, especially when the latter are of considerable depth. As a matter of fact, the bracing generally employed to hold the sheeting or sheet piling in place is designed more as a matter of judgment than of exact computation. The ordinary rational theory of earth pressure is based upon an assumed perfectly dry material composed of small grains, possessing no coherence among themselves. The standard quality of earth on which is based the usual theories of earth pressure is that of a fine granular mass, whose particles are free to move over each other except for friction, these particles assuming an exterior surface slope, under normal conditions, whose tangent to a horizontal line represents the coefficient of friction. This theory results in an intensity of pressure for a mass of dry earth which increases directly with the depth as does water pressure, but at a different rate. There are few structures whose design involves the use of formulas for earth pressure which have not been proportioned upon this theory if their treatment has been of a rational character; in fact, Rankine's and other similar theories have come to be standard for this entire field of construction. Although these earth pressure theories have been criticised for various alleged defects of more or less serious nature, the latest is probably one of the most interesting attacks of this kind.

In a recent number of the "Proceedings" of the American Society of Civil Engineers, Mr. J. C. Meem has presented a paper on "The Bracing of Trenches and Tunnels, with Practical Formulas for Earth Pressures," the main features of which were stated in The Engineering Record of Nov. 2. In this paper the author has set forth certain views as to earth pressure which are based on his observations in sheeted or sheet-piled trenches. He has observed that in many new excavations both the bottom and the bottom portions of the vertical sides remain stable in place even when not supported, while in the upper parts of the same trenches the material has exhibited such a tendency to motion as to produce heavy pressures against the sustaining sheeting with its braces, the excavated material not being dry sand. He assumes, therefore, in treating the laws of pressure thus disclosed, that the greatest earth pressures are near the top of the excavation, from which place they decrease to the bottom, where they are either actually or essentially zero. This obviously is fundamentally at variance with the ordinarily accepted law of earth pressure, which makes the intensity of that pressure zero at the surface and a maximum at the bottom of an excavation, with a uniform rate of variation between.

The difference between these laws is radical, as is recognized by Mr. Meem himself. If his views are correct, practically the whole body of present and past practice in connection with earth pressures is altogether wrong, except in the case of dry, sandy material, for which he would employ the generally accepted theory of earth pressure, the law of whose variation with the depth below the surface is similar to that of liquid pressure, i. e., the intensity varies directly as the depth.

Probably every experienced engineer who has had much to do with the design and construction of structures to resist earth pressure, has recognized the familiar fact that the standard theories of earth pressure are not supposed to be more than approximately correct for other materials than dry sand. There are, however, with equal probability, very few who would be willing to postulate with emphasis that the intensity of pressure against sheet piling and its bracing decreases with the depth of excavation, becoming zero at the bottom of the latter, and acquiring a maximum value in its upper part. It is true that in almost any excavation other than in dry sand, the material in its bottom stands stiff and undisturbed for a greater or less period of time after the excavation is completed. There is nothing uncommon about that; it is a matter of frequent observation.. A damp clayey or loamy material holding considerable moisture assumes under the heavy pressure of the superposed material a stiff, dense and firm condition, which disappears only after weathering, and much weathering in some cases.

If a trench or other excavation is to be quickly completed and refilled, insufficient time may elapse for such material to lose its moisture, and so to become friable or granular behind the sheeting and produce intensities of pressure of relatively high values. This is precisely what takes place in many excavations of magnitude. Material is frequently found capable of maintaining a vertical face for a considerable time even without the support of sheeting, but the instances are rare where such faces will not soon become dry enough to lose coherence and granulate to a marked degree, and slough off or fall away if unsupported, like any dry granular material in which the maximum intensity of pressure is found at or near the bottom of the excavation. Under such circumstances it certainly would not be prudent or safe to rely upon the temporary tenacity thus disclosed to hold long in position the sides of such excavations. It is a matter of common experience to observe the weakening by dessication of vertical earth faces, nor is it so very infrequent to experience the failure of sheeting with its bracing from this kind of a cause. The matter practically reduces itself to taking chances with these excavated faces and hazard reaching the refill before the material with its reduced moisture has an opportunity to assert its capacity for lateral pressure.

More than one instance of this character has resulted in failure. Experience with excavations in general has taught the important lesson that, except in comparatively few cases of unusually tenacious material, it is safer to assume that the relatively dry granular condition may prevail sooner than anticipated, and that in general it is prudent to accept the indications of the standard theories of earth pressure, if there is much at stake. In the more difficult and dangerous saturated or semi-saturated, materials, it takes but little experience to confirm the accepted laws of earth pressure and to realize that such earth pressure theories as that of Rankine are among the valuable technical assets possessed by the engineer.

Notes and Comments.

THE DETROIT TUNNEL OPERATIONS described in this journal last week and in previous issues are so novel as to deserve a word of comment. Several projects for constructing subaqueous tunnels have been proposed in which sections of the tunnel are built on ways, launched and towed to the place where they are to be sunk, but in this undertaking the various steps are unique in their conception. The forms are first sunk, then surrounded by concrete placed under water, and finally the forms are pumped out and lined with concrete without the use of compressed air. This procedure was first proposed by Mr. W. J. Wilgus, a fact that was unfortunately not stated in the article printed last week. Mr. Olaf Hoff, of the Butler Bros.-Hoff Co., the contractors, is in personal charge of the work and has elaborated the details in a most ingenious manner in order to carry out the contract successfully.

THE ARLBERG RY. ELECTRIFICATION, the most extensive undertaking of this nature now under way, affords an interesting example of the accuracy of some of the general statements in Mr. Armstrong's valuable paper reviewed elsewhere in this issue. This road, a single-track line, is understood to have more business than any other crossing the Tyrolean Alps, about forty trains moving over it daily in each direction. This traffic has congested the line many times annually during recent years and it has become necessary to double-track the road, an enormously expensive undertaking, or to provide means for hauling heavier trains at higher speeds. By adopting electric traction the capacity of the road can be increased 50 per cent. at a far smaller outlay than that for a second track. The consulting engineer for the work is Prof. C. L. de Muralt of the University of Wisconsin, who has selected

the three-phase system for this installation, a selection practically forced by the railway authorities' drawbar pull and speed requirements, which make it necessary to develop 3,000-h.-p. with a locomotive weighing not more than 60 tons. The current will be furnished by hydro-electric stations and on the down-grades the motors on the locomotives will act as generators, returning current to the line and saving a large sum otherwise required for power, in addition to reducing heavy wear of brake rigging.

The Enormous Arch of reinforced concrete, with its clear span of 710 ft., which is the central feature of the design for the Henry Hudson memorial bridge at New York prepared by Prof. Wm. H. Burr, is the boldest bridge project for many a year. The designer has been working out the details of the plans for more than a year, assisted by the engineers of the city's Department of Bridges, and the project is now before the Municipal Art Commission for its approval. It goes without saying that the designs will receive critical study by bridge specialists everywhere, for no masonry arch approaching it in span or resembling it in design, save as a miniature resembles a large canvas, has been worked out before. At one step, reinforced concrete construction has been advanced from the very conservative works of the past to a structure that probably represents the maximum limits of practicability of the material. The computations have been conducted with great thoroughness by Mr. Leon S. Moisseiff, of the Department of Bridges, whose analytical ability is widely known, and methods of building the structure have been developed sufficiently to demonstrate their feasibility. Those critics who pronounce a hasty judgment against the design will therefore probably find that their arguments have already been examined during the progress of the studies and have been met satisfactorily.

The Excavation Records which Colonel Goethals and his staff continue to make at Panama are astonishing. The September record was a gratifying achievement, but that of October is a complete surprise. During the month about 1,844,500 cu. yd. of material were taken from the canal prism, an increase of more than 23 per cent. over the record for September. The significant fact of this accomplishment was that during October the rainfall amounted to 17.1 in., as compared with 11.9 in. in September and 11.89 in. in August. In addition to the material taken from the canal prism about 24,300 cu. yd. were removed from accessory works, chiefly the excavation for the big locks. If excavation can be carried on at this rate during a month of such heavy rainfall, what may not be expected during the season when the working conditions are more favorable? That the best excavation records obtained under Mr. Stevens have been increased more than 75 per cent. during the month of the year worst adapted for such work is a pretty good indication of progress. Another thing just as important in one sense is the excellent result of Secretary Bishop's endeavor to do away with all needless causes of discontent on the isthmus. As chairman of the Commission's committee on grievances he hears every complaint and is able to make a thorough investigation of it. By means of the "Canal Record" which is distributed free among all employees whose names are on the "gold" roll, he has accomplished wonders in producing that feeling of common interest and united endeavor essential for the best results where large bodies of men are engaged. The present situation on the isthmus is certainly one in which the American people may take justifiable pride.

The Lack of Balanced Education afforded by courses in engineering colleges is discussed at some length in the recent annual report of President Schurman, of Cornell University. These courses suffer, in his opinion, from being exclusively in the field of mathematics and physical sciences. He believes that the modern engineer, to be truly educated, needs a training broader than science and its applications. He must have the liberal expansion of mind which comes from the study of literature, history and philosophy if he is to attain the highest rank. The problem, however, of teaching all the professional subjects made necessary by the advance of engineering practice necessarily makes the curriculum of the four-year course more and more technical and less place than ever remains for any of the liberal arts. As a result, President Schurman states: "All over the country men are graduating in the engineering courses with an ignorance of literature, history and liberal arts so dense that no proficiency in science and technology can save them from the charge of being uncultured, especially when, as so often happens as a necessary result of their limited reading of literature, they are unable to express themselves either in speech or writing in correct English prose." Consequently a five-year course is suggested as the next step to be taken for improving the education of engineers at Cornell. The extra time gained by the additional year is to be given up to humanitarian subjects, in order that the graduates may receive some measure of real education as distinct from technical training. This will be considered an advance by a good many of the engineers who hold that the next great step in elevating their profession will be in the broader education of those following it. Whether, however, the suggestion of Professor Schurman to add an additional year, and preferably two years, to the present course in order to incorporate liberal arts studies along with those of a technical nature should be preferred to the requirement of a course in the liberal arts in a college as a preparation for technical studies will certainly be a matter of debate. It must be recognized that in the West where technical education is largely conducted in state-aid colleges, the requirements for admission are extremely low in the elements of history, literature and the arts. While the technical instruction in all parts of the country is on a pretty satisfactory plane, the fact remains that the instruction in academic branches as distinct from scientific branches is by no means of such a uniform character. It may be better, therefore, to keep technical training such as is given in a four-year course in an engineering college an entirely distinct thing from the education in a liberal arts course.

Municipal Repair Plants for maintaining asphalt pavements in proper condition have been a subject of considerable controversy for a number of years. For some time this journal believed that the desirability of installing and carrying on such plants was questionable in many cities, particularly those where the management of public works did not rest in the hands of technically trained officials. The experience to date with such plants has been wholly favorable, however. The city of New Orleans is one of the largest which has tried such a plant and in the last report of Captain Hardee, city engineer, the operations for the past year are stated to have been entirely satisfactory. The mechanical equipment is complete in all respects and the stone crusher has furnished a large amount of broken stone for other than pavement purposes. The asphalt machinery has been worked every day during the year except Sundays, holidays and rainy days. During the 141 working days it turned out 88,947 cu. ft. of wearing surface mixture, the largest run in any day being 1,845 cu. ft. There has been no break-down whatever. The sum of $40,307 has been spent for all repairs made to asphalt pavements during the year, while under the old rates the city would have been obliged to pay the Barber Asphalt Paving Co. $114,500 for the same amount of work. The first year's saving due to the plant is, therefore, $8,000 more than the actual cost of the entire installation.

Financial Hysterics, like the recent exhibitions in a few places, are the same strange things seen when a crowded street car bumps good and hard into a substantial truck. Before the motorman and driver are well into their controversy concerning each other's character, ability and future abode, some of the passengers will have shrieked themselves into a frenzy or have fainted away. It isn't their fault and they will be mightly ashamed of themselves afterward; but for a time they make a disturbance all out of proportion to the danger, and everybody who sees them carry on is more or less upset. It is about the same when a policeman grabs a husky pickpocket and clubs him into submission. Some people who don't know what the row is about will vociferously condemn the wanton assault on an inoffensive citizen, while the fellow whose pocket was picked will be equally mad because he has to go to the station house to get his things back. A few weeks ago some of our good financial policeman fired out of several New York banks a few men whose absence from banking circles was considered desirable. The usual crowd collected at the noise of the row and started all sorts of baseless rumors. To cap the performance, a fool newspaper reported the next day that there was trouble in a great, sound financial institution. Immediately there were hysterics; a silly, reasonless exhibition just like the ladylike variety we all regard with pity. It has scared a good many timid souls through the country, however, but perhaps, after all, it was a good thing it happened. A few of us will have our money tied up for a time in suspended banks, but we will get it out again before long. In the interim we will learn to be a little careful of our pennies, which will do no harm. For some months brash persons will not have the means to rush headlong into big enterprises which cannot stand careful investigation, and some manufacturers may have to hunt around a bit for orders instead of selecting at leisure the best of the host urgently thrust into their hands. The trouble will be repaid if Congress will take the lesson of recent events to heart, as it seems likely to do, and repair our currency system. Such a wretchedly inadequate system would long ago have brought on a slow fatal decline if the basis of our national prosperity was not so vigorous that even this powerful irritant could do no more than produce an occasional itch. The present system is just about as elastic as a dry mud pie, and not much more useful. It now appears probable that this makeshift will be supplanted very soon by something as good in its results as the systems of Great Britain and France. The trouble we have had the last few weeks has been due mainly to lack of currency, and that was caused by the inability of our rigid banking law to render any help when a few men went crazy, shouted "thief," and scared timid people into the foolish belief that their money was safer under their pillows than in the banks. The bankers in a few cities have had a hard time with their frightened depositors, but if Congress will attend to its part of the job and the people at large will refuse to get scared when hysterical persons yell "ruin," this disturbance will be cured in short order.

A Column Connection.

The Structural Features of the Singer Building, New York.

The general interest aroused in the Singer Building by the widespread stories of the work of a steeple-jack on the top of its lofty flag-staff makes it desirable to bring together the leading facts concerning its structural features, already described in detail in many articles in previous issues of this journal. The building, at the corner of Liberty St. and Broadway, covers an area of about 24,000 sq. ft., with a main structure having a uniform height of fourteen stories, surmounted by a large tower 612 ft. in extreme height above the curb. It includes the old steel frame Singer and Bourne Buildings originally ten and fourteen stories high respectively, and their additions and extensions which have been combined into a single continuous structure with fronts of about 133 ft. on Broadway and 238 ft. on Liberty St. The old Bourne Building and the old Singer Building have grillage foundations on sand, the Bourne Building addition has reinforced concrete spread footings, and the addition to the Singer Building and its great tower have concrete pier foundations carried down by the pneumatic caisson process to rock at a maximum depth of about 92 ft. below the Broadway curb.

The building is of fireproof steel cage construction of the ordinary type, except that special provision is made to resist wind pressure in the tower. It is designed for office purposes and has a two-story curved mansard roof and flat deck corresponding with that of the old Singer Building. The tower, 63 ft. square at the base, has vertical walls faced with brick and limestone. It is located near the centre of the Singer extension with the front wall parallel to Broadway and about 30 ft. back from the curb line, so that the main building has the effect of a wide base about 200 ft. high for the tower shaft. The tower contains thirty-three principal stories above the main roof, making forty-seven stories in all, and terminates in a segmental dome springing from the thirty-eighth story and finished with a flat deck at the forty-second floor, carrying a lantern about 16 ft. square and 63½ ft. high, with a steel flag-pole rising nearly 36 ft. above it. The highest office floor is the fortieth, at an elevation of 524 ft. above the curb, and the lantern balcony, 562 ft. above the curb, is the highest point accessible to the public, while the summit of the small dome is 612 ft. and the top of the flag-pole is 668 ft. above the curb.

The numbering of floors adopted in this article differs somewhat from that used in the previous articles. On the architect's plans two stories, known as the ground story and messanine story, are not numbered, therefore what is called, on the architect's plans, the first story is in reality the second story. The mezzanine story, between the thirteenth and fourteenth stories, was not numbered, so that in the present numeration the story originally designated as the fourteenth becomes the sixteenth, and all stories above it are correspondingly changed from the former designation, numerals commencing at ground level.

The structural features correspond with recent practice for steel cage office buildings and are most interesting in the provisions for wind bracing required for the 30-lb. horizontal pressure assumed on the entire vertical surface of the building. There are 58 lines of steel columns with closed rectangular cross-sections, which support the beams and girders of the various tiers on horizontal connection angles field-riveted to their top and bottom flanges. In the fourth story one of the corner columns is carried on a triple web cantilever plate girder 30 in. deep and 18 ft. long, which receives a load of about 500,000 lb. and is anchored by bearings on the under side of brackets riveted to one of the interior columns. The columns have cast-steel bases distributing their loads over I-beam grillages covering the tops of the concrete piers. Tower columns have maximum combined loads of as much as 1,637 tons and have correspondingly massive lower story sections.

The heavy wind pressure is resisted by a system of 25 vertical panels of X-bracing between adjacent pairs of columns. Four panels terminate at the sixteenth story, sixteen panels in the corners of the tower are carried up to the thirty-fourth story, and the remaining five panels, between the interior columns of the tower, are carried up to the thirty-eighth story. In nearly all cases the wind bracing consists of full-length intersecting diagonals in each panel. All of the horizontal members are made of pairs of channels back to back, and the same construction is used for the diagonal members except in the highest stories, where the strains are lighter and single channels or angles are used instead. Some of the wind-braced panels are replaced in the lower stories with knee-braces instead of full-length diagonals. In the tower, the X-braces are arranged in alternate long and short vertical panels to clear the door and window openings.

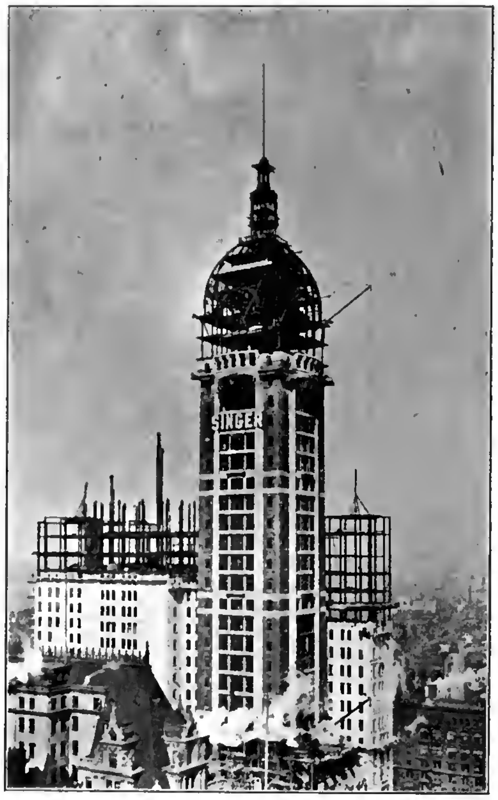
In all cases the wind braces are field-riveted to wide projecting connection plates shop-riveted to the columns. In many cases these occur on three faces of the same columns, making them extremely bulky and difficult to store or handle. The tower has 36 columns continuous through the fourteen-story building to a point 320 ft. above its roof at the foot of the dome 510 ft. above the curb.

The four center columns are continuous to the forty-fifth story about 580 ft. above the curb, where they support the light framework of the upper dome about 30 ft. higher. They have a total length of 579½ ft. each and a cross-section of 160 sq. in. at the bottom, while the others are only 499 ft. high, but have about the same cross-section. Eight of them are anchored with four 4½-in. vertical screw rods engaging pin-connected riveted links extending through the pier 40 or 50 ft. to its base, where they are secured to anchors cast into the concrete so as to develop the full weight of the pier, estimated at about 1,150,000 lb., and the enormous earth friction on its vertical sides to resist the maximum upward reaction of about 925,000 lb. developed by the overturning moment of the wind as described in The Engineering Record of May 4.

The four-story dome, 63 ft. in diameter at the base and 50 ft. high, has four hip rafters at the corner columns. Each of them is double and each part is made of a pair of curved 15-in. channels riveted together back to back. They are seated on diagonal beams in the thirty-eighth floor, and rise nearly vertical to the thirty-ninth floor, above which they curve inward to the forty-second floor, having gusset plate connections riveted between their webs for each floorbeam. They are made in two sections, field-spliced in the thirty-ninth story and connected at the fortieth and forty-second to cantilever floorbeams projecting beyond the four centre columns of the tower. In each face of the tower there are four intermediate curved jack rafters similar to the hip rafters between them.

The contract for the sub-structure was awarded September 18, 1906, and required that it should be completed ready to receive the steel superstructure in 110 calendar days. As soon as the old buildings were demolished, a timber platform 30 ft. wide was built on falsework bents from the Broadway front through the center of the lot nearly to the rear, and served for loading and unloading materials. It was provided near the middle with a two-story tower 28 ft. high, with clearance underneath for wagons, and had a 30-ft. steel extension with a 60-ft. 15-ton wooden boom at each corner commanding the entire area of the lot.

Wooden caissons of a maximum weight of 12 tons were delivered complete by wagons from the contractor's yard and were unloaded and set



Completed Tower Framework.

in place by the derrick booms, and the concrete piers were built like tall vertical shafts on their decks, before sinking was commenced, thus saving cofferdams and providing a great weight for forcing them into the excavation made later by men working under pneumatic pressure in the usual way. In this way, the thirty caissons were sunk a little below the surface of the hard pan and the excavation continued below them to rock for the concrete filling. The work was carried on continuously by two 150-men shifts in charge of Mr. Alexander Allaire, superintendent for the Foundation Company, contractors.

All of the structural steel was fabricated at the Milliken bridge shop, Staten Island, and shipped on lighters to pier No. 11 in the East River, where it was delivered on trucks to the Broadway front of the building and immediately unloaded by means of a derrick seated at first at street level and afterwards moved up with the steel work every second tier. The derrick was of special construction designed by the contractors and had a 75-ft. mast and a 65-ft. boom

of 40 tons capacity. Both mast and boom were round sticks of timber with cast-steel and forged steel fittings, and the mast was provided with connections for sixteen 1¼-in. steel guy ropes, only eight of which were used for this work. It weighed 10 tons and was equipped with ¾-in. wire-rope tackles for the hoisting and topping lifts which were rove with from nine to three parts, diminishing as the work advanced and the weight of the members decreased. The derrick was hoisted from story to story in the usual manner, first unshipping the boom and using it as a gin pole on the second floor to hoist the mast with. The entire operation required only about three hours and was accomplished by the regular force of erectors.

The steel was either assembled in final position as unloaded or was temporarily stored on the highest tier of beams until the columns and girders could be set. Occasionally bundles of small light pieces were temporarily stored on the bridge over the sidewalk. The heaviest member lifted was a 54-ft. section of one of the columns, which weighed 28 tons. All pieces were handled with chain slings. The main part of the building was erected at the rate of about two 250-ton tiers per week, and was completed up to the fourteenth story about June 1st with a maximum force of 200 men. The work was then practically suspended for nearly six weeks, and when resumed the tower was erected at the rate of four tiers in seven days, the heaviest tier weighing about 140 tons.

The erection of the tower was commenced at the seventeenth floor about the middle of July, and was completed Sept. 15th, about 2,000 tons of steel having been raised from 200 to 600 ft. during that interval. This part of the work was considerably delayed by the narrow width of the panels, which made it almost impossible to store more than one of the bulky column sections in each space, and by the awkward location of the column splices which, in order to clear the wide connection plates for the wind bracing, were placed almost midway between the floors and required the construction of scaffolds for field riveting.

View of Singer Building Tower during Erection.

After the completion of the main building up to and including the seventeenth floor, which serves as a roof deck, some of the wall columns in the Broadway front were continued from the fourteenth floor, where they terminated and the curved mansard roof rafters commenced, to the seventeenth floor at the level of the main flat roof by temporary steel columns braced in position. These carried steel girders and heavy wooden beams and planks forming a deck at the seventeenth floor level, which extended over the curved mansard roof and provided a substantial landing platform for the steel members used in the tower.

The 40-ton boom derrick was seated at this point and hoisted all steel members from trucks on Broadway, deposited them on the platform or delivered them directly to a similar derrick of 25-tons capacity that was carried up in the usual manner with the successive tiers of beams in the tower and erected the entire framework of the latter. Being located in the center of the tower the derrick mast was about 60 ft. from the Broadway front of the building and its boom was not long enough to command the trucks in the street below, hence material was hoisted at two operations as already described.

The 40-ton derrick hoisted from the street to the seventeenth floor, a little over 200 ft., in about 1½ minutes and was operated by a Lidgerwood engine permanently located on the first floor. The 25-ton derrick was operated by another Lidgerwood engine seated on the seventeenth floor and provided with steam from the boiler for their compressors. It had a maximum record of unloading and hoisting 400 tons of steel in 6 hours. The hoisting tackle for this derrick was rove with a spliced ¾-in. steel wire rope 2,500 ft. long and the lower block was provided with a 1,500-lb. cast-iron counterweight to assist it in overhauling. In its highest position on the fortieth floor, it hoisted materials from the landing platform on the seventeenth floor about 350 ft. in 3 minutes. It was moved up with every second tier of beams in the usual manner and was only out of service about 1½ or 2 hours for each operation. Each hoisting engine was provided with two gongs operated by electric buttons at their derricks, signals from which controlled all of the hoisting.

The sixteen columns in the tower were erected like those in the main building up to the base of the dome, above which the four center columns were first erected, together with their beams and girders, by the derrick seated on the thirty-eighth floor. The lower halves of all the curved dome rafters were then set in position and connected to the floor-beams and girders, bracing them with sufficient stability to maintain them until after the derrick was raised to the fortieth floor and erected the next section of the four center columns. The upper parts of the double hip rafters were then erected and their upper ends connected to the column framework of the tower, after which the intermediate jack rafters were erected, the first ones having their upper ends guyed until final connections could be made completing the framework of the dome. The derrick was not moved above the fortieth floor and in that position it erected all of the steel up to the forty-fourth floor, which is the second in the lantern and is about 47 ft. above the fortieth floor. The three last floors and the small dome extend to a total height of about 36 ft. more, and are composed of such light members that they were easily handled by breast derricks with windlasses raised by hand to the successive tiers.

Considerable delay and difficulty were experienced in the erection of the tower, dome and lantern on account of the narrow horizontal area for working and the consequent necessity of keeping the boom derrick topped up in an almost vertical position. Very great pains were taken here, as in the erection of the framework of the main building, to preserve the verticality of all columns as accurately as possible. This was accomplished by the liberal use of large numbers of wire-rope diagonals in the vertical panels between columns and floorbeams. As soon as it was erected, each column was carefully plumbed and if found at all out of vertical one, two or three diagonals were immediately attached to its upper end and adjusted by means of turnbuckles which maintained it rigidly in position until its splices and brace connections were riveted. This method was so successful that when the framework was completed to the full height of 612 ft. above the curb, the greatest deviation of the vertical columns in the elevator shaft was only ⅜ in.

There are about 220,000 field rivets, ¾ in. and ⅞ in. in diameter, which were driven with

twelve pneumatic hammers of the Chicago, Independent and Cleveland types. Air was compressed by two Ingersoll-Sergeant machines on the first floor which delivered through a 2½-in. vertical stand-pipe run to the top of the building and was provided with 2½-in. horizontal branches having ¾-in. outlets for numerous flexible hose connections at every story. Great pains were taken in fitting up, and all imperfect holes were reamed with Chicago Little Giant reamers, seven of which were provided for this job. The rivets were heated in oil furnaces provided with compressed air blast and were driven by five to nine five-men gangs who made a maximum record of 1,300 rivets in 8 hours for one gang and 2,450 rivets in 8 hours for two gangs.

The erection of the steelwork is now practically completed and the rigidity of the 6,000-ton mass is so great that no vibration has been observed by the workmen at the summit of the slender tower nearly 650 ft. above the column bases. The rapidity and efficiency of the steel erection has been largely due to the careful preparation made for receiving and handling the steel in exactly the required order and in erecting it without rehandling, the different members being swung complete to place in proper sequence without hesitation and the connections immediately made by men who were well-trained and competent to carry on the work with confidence and precision, wasting no unnecessary time and completing each operation in readiness for the next.

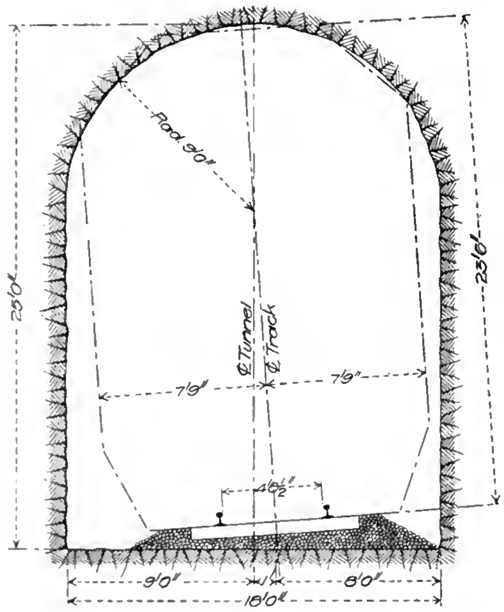
Great care was taken to maintain a constant rigid inspection of the work and of the condition of the building so that the scaffolds were always safe, the derricks in good order and no tools or materials insecurely placed or allowed to fall on the workmen below. Consideration was also had for the comfort as well as the safety of the workmen and a temporary electric passenger elevator was installed at the commencement of the work, as explained in a recent article in this journal, and its guides were extended as fast as the framework was erected especially to provide accommodations for the workmen, who were carried up and down in it to the rapidly increasing height of the building and thus saved much time and labor which would otherwise have been wasted in climbing ladders or stairs.

The steel erection is now practically completed and is entitled to the enviable distinction of two records, one for the great rapidity of construction and successful completion of a framework nearly double the height of any previous steel building, and the other for the execution of the lofty and difficult work without loss of life or a single serious accident, results which are most creditable to Mr. W. R. Waterbury, general superintendent of the steel erection for the contractors, and Mr. W. Craig, superintendent in charge.

The construction of the walls, floors, ceilings, partitions and the installation of the equipment followed as rapidly as possible after the erection of the steel work and was well advanced in the lower part of the building before the last of the many tiers of steel were in position. Heavy decks of the ordinary type were built over the Broadway and Liberty St. sidewalks and were used chiefly for storing stone and other material and for the occasional temporary accommodation of light pieces of steelwork. Underneath them elevated bridges were built to carry pedestrians while work was in progress for the vaults and sidewalks below, and two wide entrances were arranged to the interior of the building so that trucks could drive in, make a circuit and return continuously through the other as an exit without interfering.

All materials for interior construction were delivered by trucks which unloaded them inside the building, where a portion of the cement, fireproofing and other supplies was stored on the first and basement floors, but the greater part was immediately hoisted by four hod elevators to the stories where it was required. Floor construction was commenced April 15 and was carried on almost as rapidly as the steel erection, being maintained two or three tiers below the latter. All floors are made with National Fire Proofing Company's hollow tile flat arches and had Crown finish dispensing entirely with wood. Brick laying was commenced April 15th by John F. Brady & Co., and stonework for the exterior walls of the main building was commenced May 1st and for the tower August 25th. Exterior Kavanagh suspended scaffolds operated by the masons were used and all of the stone work was anchored by galvanized iron bars.

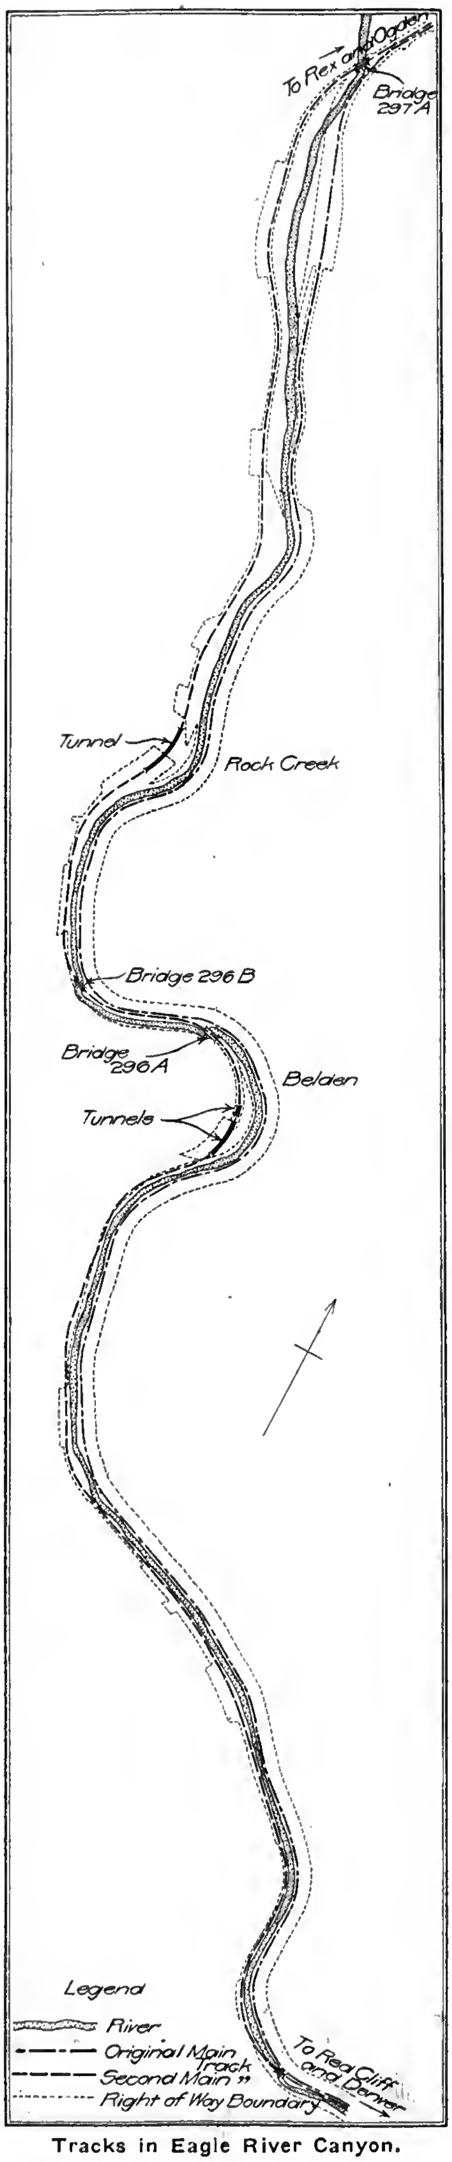
The trim is all pressed steel and the doors, window frames and sash are kalamined copper thus eliminating all woodwork except in portions of the old building. The windows in the court and up to the twentieth story of the tower are glazed with wire glass and all structural steel is protected by concrete or terra-cotta covering. The top of the building is waterproofed by the Hydrex Felt & Engineering Co. All construction was supervised directly by the architect's



Standard Tunnel Section, Eagle River Canyon, Denver & Rio Grande R. R.

office, no general contracts being awarded. Mr. Ernest Flagg is the architect of the building; Mr. O. F. Semsch, of his staff, chief engineer; Mr. Frank P. Whiting, general superintendent; Messrs. E. A. Rogers, H. J. Howell, and C. S. Heney, superintendents of the various sections. Messrs. Boller & Hodge are the consulting engineers for the structural iron, and Mr. Chas. G. Armstrong for the mechanical plant; R. W. Hunt & Co., inspectors of the structural iron; E. Kennard Thompson, inspector of foundation caissons.

PEAT-COKE MANUFACTURE by the Ziegler process has recently been started at Beuerberg, Bavaria. The peat is cut up, pressed and exposed to the air until evaporation has reduced its water to less than 25 per cent. of the whole mass. This peat is then placed in a retort for 18 hours. The coke is finally received in air-tight iron cars which are left for 6 to 8 hours to cool before they are discharged. Each retort yields during every 24 hours 8 to 10 tons of coke. The gas is passed through various tanks and towers in which the by-products are separated, and is then employed in assisting the retort process which could not even commence without the external application of heat.



Tracks in Eagle River Canyon.

Double-Track Work Through Eagle River Canyon, Denver & Rio Grande R. R.

The main line of the Denver & Rio Grande R. R. reaches the crest of the continent on the east by closely following the course of the Arkansas River from Pueblo to the headwaters of the Tennessee Fork. The main range of the Rocky Mountains is pierced at Tennessee Pass by a tunnel 2,572 ft. in length, the elevation of the highest point reached by the track being 10,239 ft. above sea level. On the Pacific slope the line follows the course of the Eagle River from its head to a confluence with the Grand River, thence down the canyon of the Grand to the mouth of the Gunnison River at Grand Junction.

The maximum rate of grade on the eastern slope is 1.42 per cent., which is also the ruling gradient between Pueblo and Tennessee Pass. The descent on the western slope is accomplished by the use of 3 per cent. gradients between Tennessee Pass and Minturn, a distance of 21 miles. West of Minturn the ruling gradient is 1.33 per cent. opposed to east-bound traffic between Glenwood Springs and Minturn, the gradient in control between Grand Junction and Glenwood Springs being 1 per cent.

Salida is a division terminal where are effected complete changes of locomotives, engine crews and train crews in both freight and passenger service. Minturn is a terminal for locomotives, engine crews and train crews in freight service, and for locomotives and engine crews in passenger service. Thus the portion of the main line between Salida and Minturn is an engine district for both freight and passenger service.

The short stretch of 3 per cent. grades between Minturn and Tennessee Pass necessitates the use of a large number of helper engines. The home of these helpers is at Minturn, to which point they return light after a trip to Tennessee Pass. This condition tends towards a congestion of traffic on the 21 miles of 3 per cent. grades, and on account of the rapid growth of both freight and passenger business, it has been found imperative to construct a second main track over a portion of the distance.

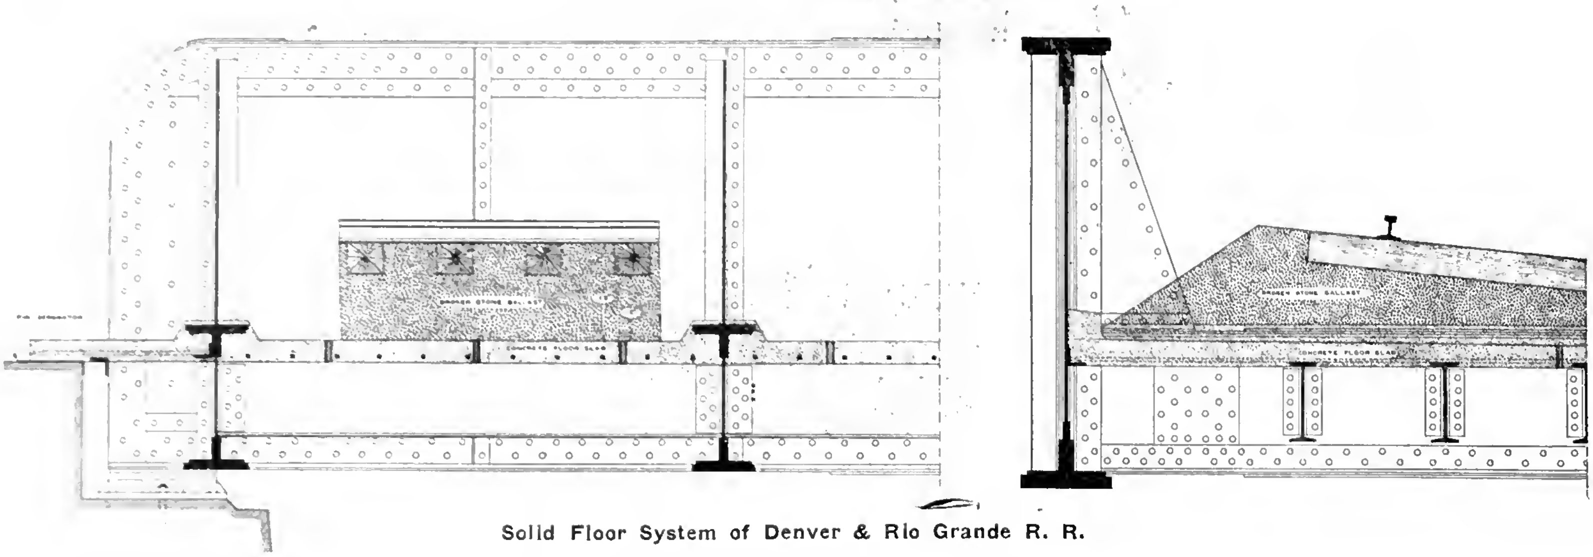
To facilitate the rapid dispatch of trains entering and leaving freight terminals the policy adopted some years ago was to construct double track for a short distance on either side and through the yards of such terminals. Hence in considering the matter of double-tracking a portion of the 3 per cent. gradient it was deemed expedient to extend the second track eastward from Rex, the easterly end of the existing double-track through the Minturn terminals, to Red Cliff, a distance of 5 miles. Perhaps, because of the peculiar topography of the country and the unusual physical characteristics of this portion of the line, a more difficult piece of double tracking could not have been undertaken.

In this portion of its course, Eagle River flows through a very narrow and sinuous canyon, in fact so narrow that it was found impracticable to parallel the old with the new track. Further complications in the existing congested condition of the canyon are occasioned by numerous patented lode and placer mining claims, a number of which are operated to a considerable extent. Accordingly it was deemed expedient to locate the line, for a greater portion of its length, on the opposite side of the river from the present track. In order not to exceed 10 deg. as the maximum curvature, five river crossings and three short tunnels were necessary in the 5 miles of line, but in this distance only three of the maximum curves were used. The tunnels and all of the bridges, except one, are on curves. The maximum gradient on the old track is 3 per cent., but this rate of grade not being continuous over the entire distance, it was therefore possible to use a maximum gradient of 2.3 per cent. on the new track. This reduction, though slight, is of especial benefit since the new track is for east-bound or up-hill trains.

As is usual in mining districts the right-of-way matters were somewhat complicated. The

Retaining Wall at Belden.

Track Location at Rock Creek.



Solid Floor System of Denver & Rio Grande R. R.

numerous claims with their surface improvements, tunnels and waste dumps necessitated rather tedious and laborious negotiations on the part of the railroad right-of-way agents. In some instances it was found advisable to construct retaining walls on the river side of the roadbed in order to provide ground space for mining operations.

The grading was performed by local Colorado contractors. An air compressing plant was installed at Belden, midway between the extreme ends of the work. From this plant compressed air was piped both ways to furnish power for the operation of air drills, which were used both in the tunnels and in the open cuts. The classification of pay quantities was as follows: Embankment, 135,220 cu. yd.; loose rock excavation, 115,315 cu. yd.; solid rock excavation, 153,705 cu. yd.; rip-rap, 2,670 cu. yd.; retaining wall, 6,190 cu. yd.; tunnel, 760 lin. ft.

The tunnels were all driven through solid rock without timbering or other lining, and are notable because of the large section, 18 x 25 ft. This large section was adopted in order to conform closely to the Denver & Rio Grande standard clearance diagram for steel bridges. Because so large a portion of the entire grading quantities consisted of rock excavation, the work was carried on through the winter months without serious inconvenience. Extreme vigilance in putting off blasts was necessary on account of the multitude of trains passing in such close proximity to the work, and the contractors are to be commended for the able manner in which the work of grading was conducted.

For the smaller drainage openings under the roadbed, cast-iron pipe and reinforced concrete box culverts were used. The river crossings necessitated one double track 48-ft. through girder, two single track 80-ft. through girders, and two single track 80-ft. deck girders. One span, an 80-ft. deck girder, occurs on tangent. All the remaining bridges are situated on heavy curvature.

The abutments were all constructed of plain concrete masonry, and, owing to the geological formation, no trouble was experienced with foundations.

The girders were designed for a reinforced concrete floor slab and track ballast, in conformity with Denver and Rio Grande Specifications for Steel Bridges, and as a result they are somewhat notable on account of their great weight. The ballast used is of the best quality of broken stone, and unusual care was exercised in order to secure a desirable character of concrete in the floor slabs.

Field riveting on bridges was accomplished by air power furnished from a flat car fitted up with a steam-driven air plant. The construction of concrete abutments and all other field work pertaining to the bridges and culverts was performed by company forces.

Denver & Rio Grande standard 85-lb. section rails 33 ft. long with plain four-bolt angle bars and flat bottom tie plates were used in laying the track. In order to easily secure a proper and uniform amount of space at the joints for variations in temperature the track was laid from Rex easterly or "up hill."

The entire work of construction was carried on without interruptions to traffic, and the new track was placed in operation for east-bound trains on Oct. 27 last.

The Union Pacific Gasoline Motor Cars.

For operation on its branch lines which do not furnish enough passenger business to be economically or satisfactorily handled with trains drawn by locomotives, and in order to give a more frequent service on other lines, the business of which will not warrant additional steam trains, the Union Pacific R. R. Co. has developed in its Omaha shops a remarkably efficient gasoline motor car.

This type of car, namely, the straight gasoline transmission, was chosen for the reason that it could be most satisfactorily operated in connection with steam freight service, and would be economical for a volume of passenger business too small even for electrical operation. Before undertaking the designs for the motor cars, a careful study was made of the various types of cars already experimented with or in use. In Europe, more headway has been made with the self-propelled car in a general way than in this country, where more attention is paid to the steam car. This is readily accounted for by the fact that the development of the self-propelled car has been largely by railway men, thoroughly acquainted with the steam locomotive and having a very limited knowledge of gas engine power.

In the investigations, two methods were available, one in which the engine transmits its power directly to the axle, and the other in which the engine drives an electric generator that furnishes current to motors connected to the axles. The latter was considered to have a number of objections, namely, additional first cost for generators, dynamos, storage batteries and controlling mechanism, and a great additional weight, loss in efficiency, and complication of electrical

Abutments for Bridges 296A and 297A on the New Second Track.

and mechanical problems. While the electrical transmission has the advantage of being able to drive more than one axle, the objections to the system so far outweighed the advantages in the opinion of the company's engineers that straight gasoline transmission was decided upon.

A four-wheel experimental car 31 ft. long, weighing about 40,000 lb., and equipped with a 100-h.-p. engine, was completed in March, 1905, and immediately put through a series of most exacting trials.

Although not intended for pulling trains, its tractive power was tested by attaching two passenger cars weighing together 112,100 lb. With this load the motor ascended a one-third per cent. grade, and also stopped and started several times on the grade without difficulty. With one car weighing 52,100 lb., it ascended a 1.6 per cent. grade at a rate of 11 miles an hour. After successfully making a trip under its own power from Omaha to Portland, Ore., and return, including the steep ascent of 27 miles on Sherman Hill, the motor went into daily service on one of the company's branch lines, 65 miles long, making the round trip daily.

As soon as sufficient experimental data had been secured through operation of this first car, and the management felt seasonably sure of the ultimate success of cars designed along these general lines, designs for an improved motor of greater capacity were worked out and up to the present time fourteen of these cars have been completed and put into operation, while there are still seventeen more to be completed during 1907.

The cars are 55 ft. long, with a seating capacity of 75 passengers. They weigh approximately 58,000 lb. They are provided with two four-wheel trucks, with 33-in. wheels, except the front driving wheels, which are 42 in. in diameter.

The car body is unique in many ways. Its rear end is semi-circular, to reduce to a minimum the air suction when the car is running, at the same time making a beautiful observation end, which is appreciated very highly by the passengers. At its front end, the sides of the car gracefully curve to a point, and the roof is curved down to the eaves, giving somewhat the appearance of the bow of an inverted boat. The object of this peculiar contour was to reduce to a minimum the air resistance when running at high speed.

In the tests made on the electric line between Berlin and Zossen in Germany, and also by the Electric Railway Test Commission, during the Louisiana Purchase Exposition, the great advantage of the wedge-shaped front end was demonstrated. These tests showed that the parabolic front offered only one-fourth the resistance that a car with a square flat end did. From the results obtained in these tests, the parabolic front end on the car would offer a resistance equivalent to 21.9 h.-p., while a plain flat end would offer a resistance equivalent to 87.5 h.-p. under the same conditions.

To secure the maximum strength in the car body, with minimum weight, and in order to have practically a fireproof car, the body is built wholly of steel. The prevailing type of roof used in wooden cars, with upper deck and ventilating sash, has been entirely discarded, and is superseded by a semi-elliptical roof, which, without sacrificing the comfort of the passengers, has been made 2 ft. lower than the old standard design. With this new tpe of roof, a car of great stiffness can be secured, with comparatively light steel posts and carlines, by uniting these parts into one piece of 2-in. channel section, extending from the side sill on one side, continuing around and down the other side of the opposite sill.

The underframe is unusually light and well braced. A single center sill is formed of an 8-in. I-beam with side sills of 6-in. channels. The body bolsters are of cast steel.

The round windows are a distinctive feature of this car, made in somewhat the same manner as the port-holes in a ship, only very much larger, and give promise of being brought into very general use in passenger car equipment in a very few years for the reason that they give an absolutely water and dust-proof window. The side wall of the car is only 2 in. through, in place of 6 or 7 in. as in the average coach, giving a more continuous view of the country to the passengers, and allowing the use of a wider seat, which increases the capacity of the car some 25 or 30 per cent.

The car is ventilated by a forced system of ventilation, fresh air being taken in at the top of the car at the front end, and distributed along the floor, the foul air being exhausted through ventilators in the roof.

The car is heated mainly by hot water coming from the cooling system of the engine, water being circulated through coils of pipe on both sides of the car. In summer, the engine jacket water is circulated through pipes under the car, and during the successive changes in temperature, the amount of water passed into the car for heating purposes is very nicely regulated.

The car is lighted by electric light or acetylene gas, the individual lamp system being used, placing a lamp over each seat, giving a beautiful clear light for reading, the light being behind an oval opalescent globe.

The interior of the car is finished in Cuban mahogany, the ceiling painted in soft colors pleasing to the eye. Comfortable upholstered seats are provided, suitable for seating three in a seat.

The engine compartment, as in all cars, is at the front, taking up about 12 ft. of space. The balance of the car is devoted to seating space for passengers. Two of the cars turned out have been built with a small baggage compartment back of the engine room. The entrance for passengers is at the side of the car, near the center, which does away with the necessity of rear-end vestibules, facilitates the loading of passengers, and when the car is running, the doors are closed and steps are not exposed to the elements.

The engines have six cylinders, connected in opposed sets of three cylinders each, so that the crank shaft receives three power pulsations per revolution. Although in general appearance the engines resemble somewhat the form used in automobiles, they are built with special reference to railroad service and the severe duty imposed upon them. The engine is located on the forward truck of the car between the bolster and the front or driving axle, and supported on the side frames of the truck. Eight spiral springs over the truck wheels carry the engine, while the car body is carried on elliptic springs under the truck bolster, thereby preventing all vibration in the engine reaching the car. The power transmission from the engine to the axle is through a 5-in. silent-running chain.

Two speeds only are used, one for starting the car, and the other thrown into commission after running about a car length. No power is transmitted through gears in the high speed, which is used 95 per cent. of the time, everything being locked, making a direct drive from the engine to the axle through the chain.

The engine is a reversible engine and can be run just as readily backward as forward. The speed of the engine is regulated by throttling the supply of gasoline, and this method has given the greatest satisfaction. Care has been used in designing inlet piping from the carbureter, to give an equal supply of vapor to each cylinder.

Compressed air is supplied through a pump driven by an eccentric on the main shaft of the engine, the air being stored in suitable reservoirs and being used for starting the engine, braking the car, the whistle, and sanding the rails. The reverse, throttle and spark advance levers are all conveniently located near the operator's post, as are also all air connections for operating the gear clutches; in fact, everything required in the handling of the car is located at either hand of the motorman. A straight air brake system is used, braking with 60 lb. brake cylinder pressure, while the main reservoirs carry from 110 to 150 lb. of air.

On the first seven cars a 100-h.-p. engine was used, having cylinders 8 in. in diameter with a 10-in. stroke. The eighth car and all cars following it are equipped with 200-h.-p. engines having cylinders 10 in. in diameter with 12-in. stroke. On a long-distance trial on the main line of the Union Pacific, a car equipped with a 100-h.-p. engine followed Overland Limited out of Omaha, running as second section of that train, leaving the depot ten minutes behind the first section. After covering 46 miles the motor car was continually held by the block of the limited train. A run of 153.6 miles was accomplished in 4 hours and 32 minutes, or 34 miles per hour. A maximum speed of 53 miles per hour was obtained.

One of the recent cars, with a 200-h.-p. engine, on Aug. 3, followed the Overland Limited out of Omaha and was held by her block continually. At Lexington, 220 miles from Omaha, the motor car was allowed to run ahead of the Overland Limited, and from Lexington to North Platte, with a clear track, she made a maximum speeds of 65 miles per hour, and went into North Platte 40 minutes ahead of the limited.

The cost of operation varies more or less with the length of the run the cars are making, and it is hard at this time to give any definite figures on operation, but the consumption of gasoline averages from 3 to 4 miles per gallon, according to the class of service and grades on line, making the cost of fuel in the neighborhood of $3.50 per 100 miles.

The original suggestion in regard to the development of a self-propelled motor car, was made by Mr. E. H. Harriman, president of the Union Pacific Railroad. Under the direction of Mr. J. Kruttschnitt, director of maintenance and operation, and Mr. A. L. Mohler, vice-president and general manager, this car was designed, built and developed to its present form at the Omaha shops under the personal supervision of Mr. W. R. McKeen, Jr., superintendent of motive power and machinery, and his corps of assistants.

A Chain and Bucket Dredge designed to raise 600 tons of material per hour from a depth of 66 ft. below water level was completed last summer for the port work at Rio de Janeiro, Brazil, according to "Engineering," London. The work on which the dredge will be used comprises 6,000 linear meters of quay wall, having a minimum depth of water alongside of 33 ft. at mean tide, and a channel 800 ft. wide and 33 ft. deep from the natural deep water. The dredge, which is named the "Affonso Penna," is 176 ft. long, 35 ft. in breadth and 13½ ft. deep. On account of the depth to which it will work and the difficulty of the material encountered, stiff clay, the ladder carrying the buckets is built very heavy. It is 130 ft. long and weighs 200 tons. The section consists of two fish-bellied girders, with both the flanges and webs braced together at short intervals by diaphragm plates. The main spur wheels which drive the tumbler of the bucket-chain mechanism are made with removable rims, which slip in case a bucket strikes an immovable object. The buckets are made very heavy and have cutting edges of high-quality steel.

Erecting Roof Trusses with a Tower Derrick.

Several years ago the steel framework of the freight shed at the Mount Royal Station of the Baltimore & Ohio R.R., Baltimore, Md., was rapidly and economically erected by a traveler which consisted of a simple 4-post wooden tower on top of which was mounted a stiff-leg derrick with a length and capacity sufficient to command all parts of the shed and assemble the different members which were temporarily braced or guyed until their final connections were made. The traveler was mounted on two flat cars furnished by the railroad company and was operated by a hoisting engine seated on one of the cars which together with the pile of old castings provided the counterweights for the derrick reactions. The traveler mast was independent of the tower post and was free to swing nearly 270 deg., thus giving a wide sweep to the boom. The traveler was run back and forth parallel with the axis of the train shed and was moved, with full load swinging from the boom, by lines operated by the capstan heads of the hoisting engine.

The traveler tower 25 ft. square and 30 ft. high was built throughout with 10x10-in. and 8x8-in. vertical and horizontal timbers and single ⅞-in. square X-brace rods in all panels, both vertical and horizontal. The corners of the vertical panels were knee-braced by planks bolted across the outer faces of the timbers. The boom was a 10x10-in. timber 50 ft. long connected to the foot of the tower and had a capacity of 5,000 lb. live load and 1,000 lb. dead load at a radius of 35 ft. The mast had a total height of 50 ft. above the boom seat and its upper end was braced with two 8x8-in. stiff legs run to the opposite rear corners of the tower. The principal stresses developed by the 6,000-lb. boom load were 6,000 lb. in the boom, 4,500 lb. in the topping lift, 5,400 lb. in each back leg, 5,050 lb. in the mast, 10,000 lb. in the front tower legs and 6,550 lb. in one of the tower diagonals. Two 6,000 lb. counterweights were required at opposite diagonals in the base of the tower and the maximum reaction there was 8,400 lb.

The overhead electric cables for the helt line railroad were carried over the site of the train shed, suspended from steel towers erected over the track. These towers consisting of four vertical posts X-braced close together longitudinally and connected at their tops by a pair of very light transverse lattice girders with clearance for train service below their bottom flanges. The cables were first temporarily supported on vertical wooden posts shown in the accompanying illustrations and arranged to permit continuous traffic with the electric locomotives. The electric cable towers were then removed by the derrick boom in advance of the erection, great care being taken to prevent men or materials coming in contact with the live wires. Later when the wires were transferred to the shed and suspended from its new roof trusses the current was temporarily cut off.

The material for the main shed was shipped direct from the bridge shops and unloaded at the site by a special boom rigged for that purpose on the rear lower corner of the traveler. With the aid of the traveler booms when necessary the members of the trusses were assembled in a horizontal plane on blocking on the ground and the splices were field riveted complete before the trusses were erected as single pieces. The erection progressed rather slowly on account of the delays due to the maintaining train service and to the danger and difficulty from the electric current in the live wires; but in some cases as many as four complete panels of the structure were erected in one day.

Tower Derrick Unloading Material and Erecting Assembled Roof Truss.

The Maryland Penitentiary has riveted roof trusses of about 50 ft. span seated on solid masonry walls 60 ft. high without openings. The material for the trusses was delivered in sections outside the building and was lifted over the walls and assembled and riveted on the ground inside the building to make the complete trusses which were erected by a wooden traveler about 60 ft. high. It consisted of a rectangular tower two panels high with the stiff-leg boom derrick seated on top at one corner and operated by a hoisting engine carried in the base of the traveler. All jack rafters and purlins were erected by the same boom and a 16-ft. cantilever working platform was extended from the top of the traveler in front for use in placing the numerous light T-bars in the ceiling. Roofs were built on two long wings of the building which were so situated that it was necessary to take the traveler to pieces after completing one roof and re-erect it for the assembling of the second roof. This was accordingly done and the steel work was rapidly erected without accident. The work was fabricated and erected by the Maryland Steel Co., Mr. C. F. Spinney, engineer.

A Sixteen-Mile Cut-off is about completed on the Baltimore & Ohio R. R. between Lodi and Nova, O., reducing the distance by more than a mile and eliminating some heavy grades and curves. This cut-off will complete the double-tracking from Youngstown to Chicago Junction.

The Hydro-Electric Plant of the Black Hills Traction Co.

By Samuel H. Lea, M. Am. Soc. C. E., State Engineer of South Dakota.

In the Black Hills of South Dakota are several streams of considerable size, which have their origin among snow-capped peaks and are fed by springs along their upper reaches, thus maintaining a constant and fairly uniform flow. These streams, in the course of their descent to the plains below, flow in narrow valleys and have a heavy fall throughout most of their length. These features are especially valuable for hydraulic power development; several water-power plants have been constructed, and others are projected on the streams among and adjacent to the Black Hills.

The Redwater River is a stream which is fed largely by springs, and which, having swift and steady flow in its channel, is but little affected by floods or freshets. It has a rapid fall along its entire course and is practically free from ice even in the coldest weather. It is, therefore, valuable as a source of power, both on account of the high power-head afforded by its rapid fall, and also because there is no danger to wheels or machinery from floating ice, as would be the case in a colder stream. This river has been utilized for power purposes by the Black Hills Traction Co., whose hydro-electric plant near the town of Spearfish, S. D., has recently been completed. This plant is a good example of modern hydraulic power construction, and it is thought that a description of it would be of interest. Before going into detail, however, a brief statement will be made concerning the use of water for beneficial purposes in South Dakota.

Under laws of South Dakota, the State has control of all the waters in the State, except navigable streams; and all applications of water to beneficial use in this State must be made under the supervision of the State Engineer. In each case of the appropriation of water a permit therefor must be obtained from the State Engineer's office. In the case of the construction of a dam and diversion works detailed plans of same must accompany the application for a permit and must be approved by the State Engineer. The writer, as State Engineer, is necessarily in close touch with all matters connected with the appropriation and diversion of water from the various streams in South Dakota, and is more or less familiar with the details of plans for hydraulic power development in the State.

Wood-Stave Pipe Line.

Typical View of Canal.

The point of diversion of the water is about 2¼ miles east of the South Dakota-Wyoming boundary; it is about 10 miles southwest of the town of Belle Fourche, in Butte County, South Dakota. The water is taken from Redwater River just below its junction with Crow Creek. The volume of water taken is about 150 cu. ft. per second; this is conveyed about 5½ miles through canal and flume to a forebay situated 4,480 ft. distant from the power house and 117 ft. in elevation above same. From the forebay the water is conveyed to the power house through a wood stave, steel banded pipe.

The power house is situated on the bank of the river, well above the ordinary high-water level of the stream at that point. The transmission line is carried across country through the town of Spearfish to Deadwood, and thence to various mines in the vicinity requiring power. The accompanying views are from photographs taken at various places along the completed work.

The dam for diverting the water into the power canal is a rock-filled log crib structure, 12 ft. wide on the top, and having an apron faced with 3 in. plank, extending 25 ft. downstream. The crest of the dam is 100 ft. long between the end cribs, giving a spillway of ample size. Anchorage to the underlying formation of clay was obtained by means of piles, driven to a depth of from 4 to 6 ft., and a row of sheet piling was driven along the upper face of the dam for a cut-off. On the upstream face of the sheet piling was placed a backing of earth, well puddled and with a broad base. The crest line of the spillway is 8 ft. above the bed of the river, and the total width of base is 60 ft. This construction has afforded satisfactory results and the dam is in excellent condition both as to water-tightness and solidity after over two years of use.

The intake has an entrance width of 16 ft., which narrows to 12 ft. at its connection with the canal. The flow of water is regulated by three valves, each 4x6 ft., placed at the head of the intake. No special precaution was considered necessary for preventing the passage of sand or silt, as the water is unusually free from floating detritus.

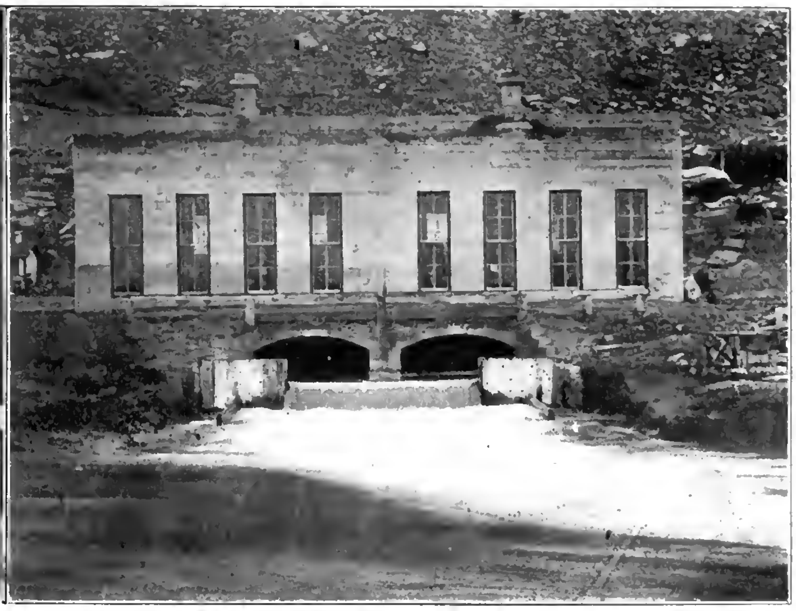
The canal is 12 ft. wide on the bottom with side slopes varying according to the nature of the material. It is designed to carry 4 ft. depth of water at a mean velocity of 2 ft. per second.

For the greater part of its length the canal was excavated in earth with side slopes of 1 to 1. Where rock was encountered the side slopes were made as steep as ½ to 1. In several places along the route where the ground was low, an embankment was made on the lower side of the canal line and the water was allowed to spread out and form a pond on the upper side. In this way considerable storage was obtained where most needed for taking care of peak loads.

At several points along the route streams and valleys are crossed and at these places the water is carried through a timber flume of rectangular cross-section. This flume rests on mud-sills spaced 6 ft. apart on banks; where openings are crossed, it is supported on pile bents, spaced 12 ft. apart, each bent containing three 12-in. piles. An interesting feature in its construction is the method used in connecting the flume with the canal at junction points. This is effected by means of a concrete apron which acts as a lining for the canal at the point of connection, and to which the flume is fastened by means of ¾x16-in. bolts at the sides and ¾x24-in. bolts at the bottom.

The forebay consists of a natural basin or reservoir into which the canal discharges. The lower end consists of an earth dam into which is built the upper end of the water conduit. Where surrounded by the dam structure the wood stave pipe is protected by a ring or covering of concrete. The entrance to the pipe line is protected by an inlet wall, with screen for preventing the entrance of foreign matter into the conduit.

From the forebay to the power house, a distance of 4,480 ft., the water is conveyed through a wood stave, steel-banded pipe 6 ft. in diameter. Just above the power house this 72-in. pipe is divided by a Y-branch into two 54-in. pipes which convey the water to two separate units. Each unit consists of a Pelton Francis turbine waterwheel, capable of developing 1,068 h.-p., which



Interior and Exterior Views of the Redwater Power Plant.

is direct connected to a 500-kw. Westinghouse generator, which runs at 400 r. p. m.

The wood-stave pipe is built of Washington fir. The staves of the 72-in. pipe are 2½x8 in.; those of the 54-in. pipe are 2x6 in. The pipes are banded with ⅝-in. steel rods, spaced according to pressure, with a factor of safety of four. A 38-in. riser is built just above the junction of the 72-in. pipe with the two 54-in. pipes, to relieve the pipe line of water ram.

The power house is a substantial masonry structure with the interior arrangement of machinery shown in the accompanying illustration. There are two main units, each with a capacity of 1,068 h.-p., as stated above, and two direct-current exciters, each having 35-kw. capacity at 125 volts. These are operated at 1,050 r. p. m., and are direct-connected by face couplings to 50 h.-p. water wheels of the same make as the large wheels. A 10-ton traveling crane is mounted on overhead runways. The governor is of a type made by the Pelton Water Wheel Co., of San Francisco, Cal. It is especially adapted to the Francis type of turbine, operating under high head, such as is used in this installation.

The transformer house contains seven 180-kw. Westinghouse water-cooled transformers, which raise the initial voltage of 440 to 24,000. The current is transmitted over a pole line a distance of 23 miles to Deadwood and vicinity for use in the mines and mills.

At a test run made at the plant in April, 1907, 1,683 h.-p. were developed on a switch board. The calculations are that the company will be able to deliver 1,200 h.-p. continuously at the end of its transmission lines.

An important factor in the efficiency of the installation, one which insures continuous service summer and winter, is the fact that about one-half of the water supply comes from Crow Creek, a stream which originates in springs less than one mile above the head works and whose water enters the canal at a minimum temperature of 46°, thus preventing the formation of ice in the canal during the coldest weather.

The company is a South Dakota corporation, owned almost exclusively by residents of the town of Spearfish. Mr. H. S. Vincent, C. E., of Deadwood, S. D., was the engineer of the company during construction, and Capt. R. M. Jones, of Denver, Colo., planned and installed the power station and equipment. Henry Keets, of Spearfish, is the president and manager of the company. To him is due the credit of promoting, organizing and financing the proposition and of carrying it to a successful completion.

When the fact is considered that all of the construction material and the heavy machinery used in this plant was hauled several miles over mountain roads from the nearest railway station, it is evident that the building of this plant in its isolated location, was an undertaking of some magnitude.

A Suspended Track Scale with a capacity of 200 tons has been installed for the Jones & Laughlin Steel Co. by the Standard Scale & Supply Co., Pittsburg. The levers are carried above the track by a steel structure, consisting of four gallows frames supported on concrete piers, which rise 5 ft. above the ground. The columns on each side of the track are braced by horizontal members and by X-bracing. Heavy knee-braces are provided between the columns, and the horizontal beams spanning the track to give transverse rigidity. The platform is 46 ft. long and its weight is carried to the scale levers on top of the steel frame by eight vertical rods. The advantage of the construction lies in the removal of the scale levers from the ground pit, where they are frequently affected by moisture and bad drainage.

Moving a Large Statue.

In the construction of the Philadelphia Rapid Transit Subway around City Hall Square it was necessary to excavate under the site of the equestrian statue of General McClellan, a tall and heavy structure, with a cut-stone base, on which was seated a heroic-size bronze statue, reaching to a height of about 25 ft. above the street and weighing about 75 tons. It was supported on an 8 x 14-ft. rubble masonry foundation, reaching about 7 ft. below the surface.

An excavation was made around the foundation to the bottom of its footing, and from it narrow tunnels were cut through the rubble masonry to receive twelve 12-in. I-beams, 20 ft. long, the outer ends of which were bolted together with separators, while the monument was still supported on the uncut rubble between the I-beams. The lower part of the monument was partly encased in wooden sheathing to protect the arrises of the stone work; wedges and packing were fitted to the upper flanges of the I-beams to provide bearing against the base of the monument, and jack screws were placed under their outer ends, reacting against timbers laid in the bottom of the trench.

The monument was lifted about 6 ft., care being taken to follow up the jacks with solid crib work piers. Ten or twelve lines of 2x10-in. planks were laid flat on the pavement, with 10-in. spaces between them, making a wide, thin grillage or distributing platform, across which were placed 12 x 12-in. timbers, 20 to 24 ft. long and 3 ft. apart on centers. At distances of about 7 ft. and 10 ft. from the street side of the center line longitudinal stringers, four in all, were laid on top of the timbers, each line consisting of two 2 x 12-in. planks in long lengths, one on top of the other breaking joints. On each pair of stringers 4 x 6-in. transverse pieces 4 ft. long were set about 18 in. apart, and occasional pieces were bolted to the stringers. On each of the two beds thus formed two ordinary 60-lb. T-rails, 30 ft. long, were laid about 2 ft. apart, and were spiked to occasional cross-pieces. The ends of these tracks projected over the excavation on each side of the monument and were supported there on cribbing.

About 20 solid steel rollers 3 in. in diameter and 30 in. long were arranged on each track placed a 12 x 12-in. longitudinal timber, 20 ft. long, with a 12 x ½-in. track plate on the lower surface to receive the roller bearings. The jack screws were simultaneous slacked off and lowered the monument about 3 in., until the projecting extremities of the needle beams took bearing on the longitudinal stringers, and the jacks were released and removed. A few of the jack screws were then set near the horizontal plane against the rear needle beam and the base of the monument, reacting against sills and inclined timbers seated on the ground, and the monument was gradually pushed forward on the tracks, the live rollers being constantly disengaged and removed from the rear and put under the front.

When the monument reached the front end of the track the second section of plank grillage was laid on the surface of the street, the ends fitted in each section, timbers were laid upon it, as already described, and a second section of track rails joined to the first. After the monument

Moving McClellan Monument on Rollers.

had advanced upon it the first section of track and grillage was removed and relaid in front, and so on until the monument had been shifted about 75 ft. to a place near the City Hall, where it did not obstruct traffic and could remain undisturbed until the completion of the subway.

At the site of the monument special bents of heavy columns and roof girders are introduced in the subway construction, and on them foundations will be built to receive the monument when it is convenient to return it by the method already described to its original position. The raising and moving of the monument was accomplished in about two weeks by a force of ten men, employed by Henry Sheeler & Sons, Chicago, sub-contractors under the E. E. Smith Contracting Co., the general contractors who executed the work on the City Hall section of the subway, under the direction of the engineering department of the Rapid Transit Ry. Co., of Philadelphia, Mr. W. S. Twining, chief engineer, Mr. Chas. M. Mills, principal assistant engineer, and Mr. Frank R. Fisher, resident engineer.

Storage Battery Cars for railway service, weighing 42 tons loaded, are reported in operation on the Prussian state railways for three short runs, the longest of which is 12½ miles.

Comparative Performance of Steam and Electric Locomotives.

At the meeting of the American Institute of Electrical Engineers on Nov. 8 an unusually valuable paper on the performance of steam and electric locomotives was presented by Mr. Albert H. Armstrong, of the General Electric Co. As a clear explanation of some of the fundamental reasons underlying the electrification of steam roads, it deserves careful study. In general, the possible saving in fuel through the adoption of electric traction does not in itself amount to enough to pay an adequate return on the investment to obtain it, and it is necessary to look for more important benefits. These are to be found, in the author's opinion, in a comparison of the characteristics of steam and electric locomotives. Such a comparison is made in the paper, which claims a superiority for the electric locomotive in general railway work, and suggests the possibility of making, with its adoption, radical changes in the methods of operation now necessary with steam locomotives.

Owing to clearances, it is seldom that a locomotive can work at more than 90 per cent. of the theoretical full stroke, and hence the maximum tractive effort at starting with lever in the corner will not be much greater than 88 per cent. of the theoretical tractive effort available with gauge pressure in the cylinders. The steam locomotive is limited as to maximum tractive effort by its engine design, and limited as to the speed at which this tractive effort is available by the capacity of the boiler to supply steam. Thus, assuming that the locomotive will give 88 per cent. of its theoretical tractive effort when starting, it is capable of providing but 80 per cent. tractive effort at a speed of 10.6 miles per hour (with the constants of the particular locomotive chosen for illustration), at which the boiler is giving its full output. Hence higher speeds can only be reached with a less cut off and a consequent reduction in mean effective pressure and tractive effort. Locomotive engines are generally designed to give their maximum tractive effort at 90 per cent. theoretical cut-off at a point corresponding to a coefficient of adhesion of approximately 22 per cent. of the weight upon the drivers; that is, at about slipping point of steam locomotives with good rail conditions. It is immediately evident, therefore, that the tonnage rating of the locomotive on ruling grade must be so proportioned that the maximum tractive effort called for will be less than the available tractive effort of the locomotive, in order to provide a small percentage, say, 10 or 15 per cent., for possible starting under maximum grade and load conditions.

On the other hand, the tractive effort of the electric locomotive is limited only by the adhesion between driving wheels and rail, and, aside from some 15 per cent. greater adhesion possible with the uniform tractive effort provided by the electric locomotive, it is possible with this type of motive power to take momentary advantage of abnormally good rail conditions or to derive full benefit from the use of sand; indeed, tests have been taken with electric locomotives showing as high as 35 per cent. coefficient of adhesion between driving wheels and rail. This point is emphasized, as with the greater tractive effort of the electric locomotive it becomes possible to give them a higher tonnage rating for the same weight upon the drivers than would be possible with steam locomotives operating over the same track profile.

The accompanying diagram was prepared by Mr. Armstrong to show a concrete case of a 22 x 30-in. steam locomotive of the simple type, equipped with 57-in. drivers, contrasted with both an alternating-current geared and a direct-current gearless electric locomotive, designed for the same tractive effort, both maximum and running, but for a higher speed. The contrast of these different speed characteristics brings out sharply the small speed variation with different tractive efforts delivered by the electric locomotives, this small variation being even more marked in the case of the direct-current gearless than in the case of the alternating-current geared motor, working at a lower iron saturation and giving a more sloping speed characteristic.

The steam locomotive chosen is typical of those in general use upon mountain-grade divisions, the tonnage rating in operation of this particular locomotive being such as to call for a tractive effort of 25,600 lb. on average grade and 33,200 lb. on the maximum ruling grade, occurring on a certain engine division, thus leaving a margin of 6,300 lb. above the demands of maximum tonnage on maximum ruling grade for starting the train from rest.

The maximum speed available at the different tractive efforts is a matter of boiler capacity, condition of boiler, quality of coal and efficiency of fireman. The first of these factors, the boiler

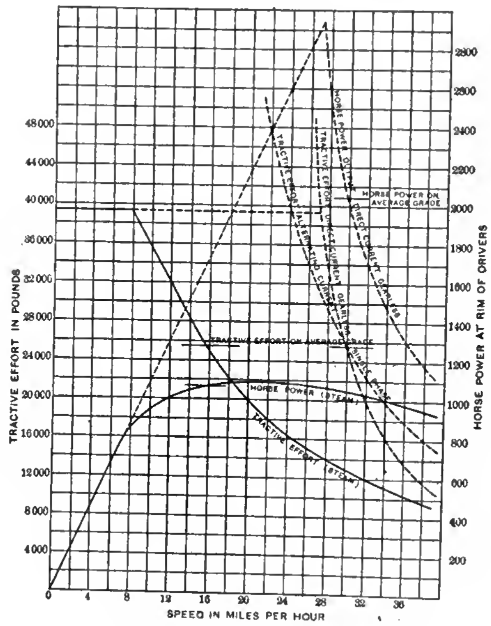


Diagram of Steam and Electric Locomotive Characteristics.

capacity, can be controlled by properly proportioning the design of the boiler to engine capacity, but there are three other factors which the locomotive manufacturer cannot control, and two of these factors constitute sufficient cause, Mr. Armstrong says, to warrant a considerable reduction in the theoretical rated capacity of the boiler. Thus, a locomotive in prime condition, carefully fired with coal of approximately 14,000 B.t.u., should be able to deliver full tractive effort at 10.6 miles per hour, but in practice it has been found that the average condition of boilers and the average firing curts the sustained boiler output down to not much more than 75 per cent. of its output under what must be considered exceptionally or momentary conditions. By sustained "output" is meant the output required while ascending the continuous up-grades on Western mountain divisions.

The locomotive characteristic in the diagram has been prepared on the basis of 75 per cent. of the possible boiler capacity, the general dimensions of the simple consolidation locomotive being as follows: Diameter of cylinders, 22 in.; length of stroke, 30 in.; diameter of drivers, 57 in.; heating surface, 3,397 sq. ft.; total weight of locomotive, 103.5 tons; weight on drivers, 93 tons; weight of tender, 61.5 tons; total weight locomotive and tender, 165 tons. This particular locomotive has been chosen for illustration, as it is the type in daily use on the mountain division of one of the largest Western roads.

Under the above conditions the theoretical tractive effort is 49,500 lb., of which 39,600 lb. is available at 90 per cent. cut-off. The contents of each cylinder is approximately 6.6 cu. ft., and, with four cylinders of steam per revolution and with steam weighing 0.41 lb. per cubic foot at 170 lb. cylinder pressure, each revolution requires 10.85 lb. steam. With 3,397 sq. ft. of heating surface there is a possibility of evaporating 6 lb. of water per pound of coal when burning 2 lb. of coal per square foot of heating surface, thus giving an available supply of 40,700 lb. of steam per hour when working boilers in prime condition at the full output, resulting from perfect firing, with good quality of coal. In practice, however, the available steam for sustained output would not be greater than 75 per cent., or 30,500 lb. per hour, thus giving full tractive effort at 46.8 revolutions of the drivers, corresponding to 7.93 miles per hour on a 57-in. driver. The "critical speed" of the locomotive is therefore 7.93 miles per hour when working at 75 per cent. of full attainable boiler capacity, and the coal consumed under such circumstances will be 4,360 lb. per hour, corresponding to 1.28 lb. of coal burned per square foot of heating surface, at which rate we would expect an evaporation of approximately 7 lb. of water per pound of coal consumed.

What might be termed the "performance capacity" of a steam locomotive may be worked out from the speed and tractive effort characteristics given in the diagram, using as a basis the 1,000 ton-miles trailing load moved per hour on a level or any gradient selected. The prevalence of 2.2 per cent. ruling grade on many Western roads perhaps justifies the selection of that figure for demonstration purposes; and the coal consumed, crew wages and maintenance charges may all be worked out from the basis of continuous operation per 1,000 ton-miles trailing load on 2.2 per cent. grade. The performance capacity obtained in this way is shown in an accompanying diagram.

Certain assumptions are necessary and are as follows: Cost of coal, $3 per 2,000 lb.; engineer, 50 cents per hour; fireman, 35 cents per hour; conductor, 40 cents per hour; three brakemen, 90 cents per hour; average mileage per locomotive per year, 36,500; total maintenance, including roundhouse charges, $5,000; maintenance per locomotive mile actually run, 13.7 cents.

The small speed variation of the electric locomotive and the fact that its motive power is separate from its unlimited source of power generation make it possible to consider radical changes in the method of moving freight, more especially on mountain-grade divisions. Steam railroading to-day is in reality steam locomotive practice, in that the speed possibilities of different track divisons are restricted to a large extent by the limitations of the steam locomotive. The only reason why it is common practice to run at very low speeds on mountain-grade divisions instead of continuing the high speeds in vogue on more level portions is because a steam locomotive cannot be built powerful enough to supply the heavy tractive effort required at any higher speeds than those now in vogue.

The one expense in train operation that is fundamental is the cost of fuel, this fatcor being influenced only by the economy of the fuel-burning plant. Other expenses, such as locomotive maintenance and crew wages, are affected entirely by the method of operation, and no radical departure from present methods is to be looked for until the coming of a type of motive power which offers possibilities not equally enjoyed by the steam locomotive. In general, it may be stated that the freight movement over mountain divisions is effected at very low schedule speeds, and the cause is evident from an inspection of the steam locomotive characteristic.

Except for the fact that curves are usually of shorter radius on heavy grades than on levels, there is no reason for the slower speed of trains, provided a type of motive power is available that is capable of supplying great draw-bar pulls at high speeds. It is just this characteristic which the electric locomotive possesses to an almost unlimited extent, and such locomotives can be built which are even more powerful and operate at higher speed than can be utilized at present.

The electric locomotive may be equipped with motors of several different types, each having characteristics best qualifying it for certain classes of work. The type to be adopted is a matter requiring full local knowledge of the conditions obtaining in each individual instance before a proper selection can be made. All three of the available motors, direct current, alternating current single-phase and alternating current three-phase, possess the one needed characteristic of great output per pound, and hence the arguments advanced for the substitution of the electric for the steam locomotive are general in character and do not apply strictly to locomotives equipped with any one type of motor to the exclusion of all others.

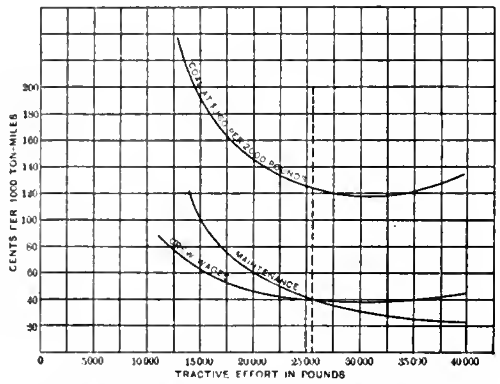
Returning to the direct comparison of the simple consolidation and electric locomotives, the diagram showing this comparison was plotted on the basis of a speed of 30 miles per hour for the electric and 15.4 miles per hour for the steam locomotive, giving in each instance a tractive effort of 25,600 lb. at the rim of the drivers. Though the electric locomotive could very readily be designed to give the same tractive effort at a higher speed, 30 miles per hour was assumed as the highest speed permissible, due to the alignment of the track on heavy grades. To plot a performance capacity curve for the electric locomotive certain further assumptions are necessary, as follows: Type of equipment, direct-current gearless motors; weight of total locomotive, 125 tons; weight on drivers, 100 tons; engineer, wages, 50 cents per hour; conductor, wages, 40 cents per hour; three brakemen, wages, 90 cents per hour; efficiency of transmission, rail to bus-bar, 70 per cent.; maintenance of locomotive, 5 cents per mile run. The train crew is so divided as to permit the location of a brakeman in the engineer's operating cab.

The cost of electrical power must in this instance be most arbitrarily assumed, owing to the widely different cost of coal, possibility of water-power, etc., obtaining in different localities. As the cost of coal for steam locomotives will also vary greatly as to price and quality, it has been assumed at $3 per 2,000 lb., and a cost for electric power of ½ cent per kilowatt-hour is based upon using the same price and quality of coal. As it is further assumed that an entire engine division of, say, 150 miles is to be electrified, it gives promise of a 24-hour load-factor of 50 per cent., and this figure has been taken. Approximating the first cost of installation of the generating station at $100 per kilowatt, and allowing 10 per cent. per year for interest and other fixed charges, the cost of power is brought up to possibly $0.0075 per kilowatt-hour at the station bus-bar. Other conditions obtaining will in a given instance modify the figures arrived at, but for purposes of demonstration $0.0075 is a conservative estimate, and such a figure is needed to compare the cost of power with the fuel item in steam-locomotive performance.

The effect of increased speed on cost of operation is clearly shown by comparing the performance capacity curves of the steam and electric locomotives.

It will be observed that the reduction in the operating expenses is effected in the two items of crew wages and maintenance of locomotives, and that the cost of fuel remains practically unchanged. This is as it should be, as the cost of fuel in the case of steam locomotives or power with electric locomotives is the only fundamentally necessary expense in train movement. Overcoming train friction and raising a train up grade against gravity represents useful work performed, and this work is accomplished at an expenditure of approximately 4 lb. of coal per horsepower-hour at the drivers with simple engines and 2.66 lb. of coal per horsepower-hour at the drivers with electric locomotives, including all intervening losses between rail and generating station bus-bar. The speed at which this work is performed, therefore, does not affect the cost of fuel or power, it being assumed that the motive power for the various speeds is so proportioned as to operate at the point of greatest economy.

While the diagrams of performance capacity indicate a certain relation among the three items of fuel, crew and maintenance expense, this is not the true relation obtaining in practical operation, for the reason that the values given in the curves assume continuous operation up-grade under the conditions outlined. Unfortunately, train crews must be paid full value per mile, whether the mile be up grade or down, and with steam locomotives there is also a considerable loss in fuel resulting from engines standing or running light, which must be also taken into account; hence, it becomes necessary to modify the figures arrived at, and for this purpose certain references must be made to current railroad practice on mountain-grade divisions, in order to arrive at the proper tonnage relations, schedule speeds, etc., obtaining in up-grade and down-grade operation.

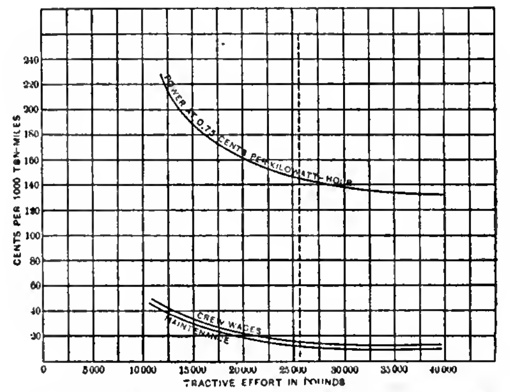


Performance Capacity of Simple Steam Locomotive on 2.2 per cent. Up-Grade.

The schedule speed on several mountain divisions is approximately 50 per cent. of the average running speed, and this figure is assumed in the following statement of cost of operating 1,000 ton-miles with steam locomotives, averaging the cost of up and down grade running. Owing to the higher schedule speed of electrically operated trains, resulting in fewer meeting points with the same tonnage handled, and owing to the absence of forced stops to take on fuel and water, etc., it is assumed that with electric motive power the schedule speed may be 60 per cent. of the running speed.

With the electric locomotive standing, or coasting down grade, there is no demand whatever made upon the generating station, and hence the only expense carried through these periods is that for train crew and a certain amount for maintenance. On the other hand, with the steam locomotive there is a considerable amount of fuel burned and water wasted when standing at sidings and when coasting. In the case of mountain railroading, with its frequent and prolonged delays, this waste may reach considerable proportions.

The following results of a carefully conducted series of tests will illustrate this point. Two test locomotives and trains were operated over a mountain division under regular service conditions, steam and fuel consumption, duration of delays, etc., being carefully noted. The total work expended up grade was 5,700 h.-p.-hr. at the rim of the drivers, including allowance for 1.54 per cent. average grade and 7 lb. per ton track and curve friction. The total water evaporated on the trip, divided by the total horse-power hours, gave a steam consumption of 36 lb. per brake horse-power-hour at the rim of the drivers. Indicator cards taken upon the engine in question at all cut-offs up to 90 per cent. showed that the greatest steam consumption did not exceed 32 lb. per indicated horse-power-hour, or 35.5 lb. per brake horse-power-hour, allowing 10 per cent. internal engine friction. Values as low as 23 lb. of steam per indicated horse-power-hour, or 25.5 lb. per brake horse-power-hour, were recorded for the average cut-off of 40 to 50 per cent. used throughout the run. A third and fourth series of tests conducted up the same grade gave similar results, except that the values were slightly higher than those quoted, showing that there was a considerable loss of water unaccounted for by indicator cards and useful work performed.



Performance Capacity of Direct-Current Gearless Locomotive on 2.2 per cent. Up-Grade.

Operating down grade, it was necessary to accomplish 1,110 h.-p.-hr., on account of the somewhat broken profile, and again the water consumption showed on two trips 57.7 lb. of steam per brake horse-power-hour, and on two subsequent trips 66.5 lb., values entirely unaccountable on the basis of useful work performed.

During all tests the usual service delays occurred, and, as the traffic on the road in question was very much congested, these delays constituted a considerable proportion of the total elapsed time. In fact, during the runs up grade the trains were in motion but 66 per cent. of the total elapsed time, and down grade the trains were in motion from 52 per cent. down to 40 per cent. of the total elapsed time. As these delays were frequent and undetermined, it was necessary to maintain full steam pressure while waiting for the momentarily expected release from the block, hence the waste of fuel and water was considerable. Averaging this waste at 400 lb. per hour, at which low rate of consumption the water evaporation would approximate 10 lb. of water per pound of coal burned, or 4,000 lb. of water evaporated per hour, and reducing the total water consumption measured by the waste losses thus obtained, the steam consumption in eight different tests up and down grade ranged 34.7, 32.4, 28.1 and 25.3 lbs., etc., water per brake horse-power-hour. These values are fairly commensurate with results of indicator cards taken, and, with the type of engine used and under the operating conditions obtaining, an allowance of 400 lb. of coal stand-by losses per idle locomotive-hour seemed not too great a value to allow, and this figure has been taken in subsequent calculations.

Locomotive performance capacity curves may therefore be plotted which will show approximately the true relation between the several items of fuel, crew wages and motive power maintenance, under the given conditions. Such curves

are given in the paper and show that in practical operation the fuel expense approaches more nearly to the value of the other items considered, instead of being greatly in excess of them, as indicated in the theoretical performance curves, showing up-grade operation only. For operation on lesser grades than 2.2 per cent. all items are reduced, and the total and subdivided comparative costs are given in the accompanying diagram and table:

Comparative Operating Expenses per 1,000 Ton-Miles of Simple Steam and Electric Locomotives; Average of Up- and Down-Grade Operation.

Grade	½%	1%	1½%	2%
Steam Locomotives.				
Coal	15 cts.	25.5 cts.	38 cts.	53 cts.
Crew	13.5 cts.	24 cts.	36 cts.	50 cts.
Maintenance	10.5 cts.	17.8 cts.	26 cts.	36 cts.
Totat	39 cts.	67.3 cts.	100 cts.	139 cts.
Electric Locomotives.				
Grade	½%	1%	1½%	2%
Power	20 cts.	35.5 cts.	50.5 cts.	66 cts.
Crew	7.2 cts.	12.2 cts.	18 cts.	24 cts.
Maintenance	3.6 cts.	6.2 cts.	9.0 cts.	11.9 cts.
Total	30.8 cts.	53.9 cts.	77.5 cts.	101.9 cts.
Saving effected by electric operation.				
Grade	½%	1%	1½%	2%
	8.2 cts.	13.4 cts.	22.5 cts.	37.1 cts.

A study of the table shows that, while the percentage saving with electric operation is approximately the same whatever the ruling grade, yet the actual money saving is much greater on the heaviest grades. As about the same investment must be made in each case for distribution system, including third-rail or overhead trolley, sub-stations, etc., the inference must be drawn that heavy-grade divisions present a more attractive field for electrification than level sections, when considered from the purely economic standpoint. There are other items of saving and other reasons for electrification which may be more or less controlling in individual cases, but it seems possible to make the broad statement that the mountain-grade division offers a particularly attractive field for the electric locomotive, and its introduction should be the means of affecting such economies in both freight and passenger transportation as to pay a satisfactory return upon the investment required.

So far, the matter has been viewed from the standpoint of comparative operating expenses for a given tonnage moved. There is another argument for electrification which may in certain instances be of a much more controlling nature. Most of our mountain roads are single track, and transcontinental tonnage has so increased as seriously to congest these mountain divisions. The heavy trains of the plains, weighing 2,000 to 3,000 tons, must be split up into units of about 1,000 tons, in order that the present steam engines, operating double and even triple, may haul them over the heaviest grades. The slow speed obtainable makes the number of trains on a mountain division large, the meeting points frequent, hence however good the despatching system employed, there will of necessity be a considerable amount of lost time introduced. Add to this the failures of motive power being worked to its limit, and there is reason for the claim that the tonnage capacity of the mountain division will be greatly increased by the introduction of electrically hauled trains.

Lest the writer be accused of unfairness in selecting the simple engine for comparison, it is proper to touch upon the economies effected with the use of the compound locomotive and also by the introduction of such coal-saving devices as superheaters and feed-water heaters.

There is a saving of approximately 20 per cent. in water consumption per horse-power with the compound locomotive, but in spite of this generally accepted saving the simple locomotive still rules the mountain division, after repeated trials of the compound. Not being an ardent supporter of either type of locomotive, Mr. Armstrong leaves the battle of the simple and compound to their enthusiasts, commenting only upon the fact that, except in the case of the Mallet compound, the arguments for the compound are based upon fuel economy only.

The latest Mallet compound, weighing 413,000 lb., is the largest steam locomotive yet built and is of particular interest, owing to the enormous boiler which such a construction permits. With a total heating surface of 5,300 sq. ft., we should expect an evaporation of 63,600 lb. of water for a short period and possibly 48,000 lb. of water continuously. With a possible evaporation of 6 lb. of water per pound of coal, this would necessitate the burning of 8,000 lb. of coal per hour, requiring the best efforts of two firemen if maintained for several hours. Assuming a steam consumption of 22 lb. per brake horse-power-hour, such a locomotive should give a sustained output of 2,180 h.-p. at the rim of the drivers, and this with a weight, with tender, of approximately 300 tons, or three times the weight of an electric locomotive of the New York Central 6,000 type, giving the same horse-power output.

The two locomotives are, of course, designed for entirely dissimilar classes of work; but it is not unfair to compare them on a horse-power basis, as it is the huge boiler of the Mallet that is remarkable, and upon this basis the selling price of the machines is approximately the same.

The comparative cost of electric and steam locomotives is generally considered as very favorable to the steam units, but reversing the usual methods and comparing the cost of the electric with that of the steam locomotive or locomotives required to replace it may reverse the relations. The electric locomotive requires no more than casual inspection, can be side-tracked indefinitely and still be ready for instant operation at full capacity, can run 24 hours without a stop, if necessary, and all these advantages and others offer a guarantee for a much greater annual mileage than is possible with its steam competitor. Then, too, compare the cost of a group of steam locomotives (no single unit could be designed to give the output) capable of delivering even 4,000 h.-p. continuously with a single electric unit of this output, and the difference in cost is not great. It may be stated broadly that for a given gross annual ton-mileage moved, the cost of steam locomotives may be even greater than the cost of the electric units replacing them.

The term "horse-power" is perhaps not fully appreciated. When the statement is made that a certain electric locomotive is rated at so many horse-power output, it does not leave the impression it should. The horse-power output of a locomotive is a direct measure of its capacity to do work, and while the tractive effort available governs the tonnage of the trailing load, it is the product of the tractive effort times the speed at which it is available, or, in other words, the horse-power output, that measures the hourly tonnage capacity of the locomotive upon which the crew expenses of the entire train depends. Hence the great claim for recognition of the electric locomotive lies in its great horse-power output, that is, its ability to carry full tractive effort or to slip its wheels at speeds two or three times greater than can be done with any steam locomotive yet built.

Superheating promises something in fuel economy, as does the introduction of feed-water heaters. Such improvements, together with the adoption of the four-cylinder locomotive, either compound or simple, must necessarily call for more expense to maintain and less reliability in operation.

As against the reduction in fuel expenses promised by the use of the compound locomotive fitted with superheaters and feed-water heaters, the electrical engineer has the great possibilities offered by regeneration of power while electrically braking on mountain-grade divisions. The amount of power saved by this means may in certain installations amount to as great a percentage of the total as is the saving effected in coal expenditure with steam locomotives by compounding and providing superheaters and feed-water heaters. Such an electrical saving is, of course, restricted to heavy-grade divisions, but the feasibility of electric braking by regeneration is unquestioned. Indeed, with three-phase induction motors regeneration is automatic, the motors being perfectly reversible and returning energy when operating down grade, with no change whatever in their connections. Other types of motors may be adapted for regeneration, with slight modifications in the control system.

All of our railway managements have felt the need of establishing a so-called express freight service, comprising a light train operating at much higher speed than is the case with the bulk of the freight movement. It is well known that the cost per 1,000 ton-miles for moving express freight is very much higher than in the case of low-speed freight. An inspection of the diagram of steam and electric locomotive characteristics illustrates the reason for this. The steam locomotive is essentially a slow-speed unit when delivering its full tractive effort; that is, a tractive effort equal to 22 per cent. of the weight upon the drivers, and high speed is only obtained at the sacrifice of tractive effort. Hence a high-speed freight train is of necessity a lighter train than could be handled over the same profile by a given locomotive, and the crew and maintenance expense is therefore large. That such a class of service is nevertheless profitable, or at least necessary, is evidenced by the continuance of the practice and the proposed introduction of electric locomotives, in effect, makes all trains fast freights, gaining the benefits of such a service, without incurring the penalty of increased operating expenses inherent to steam operation.

Mr. Armstrong does not believe that the time is ripe for the electrification of steam roads at large; indeed, the electrical enthusiasts would be hard put to it if called upon to show reason for the electrification of many branch steam lines carrying a small tonnage at infrequent intervals. There are, however, certain divisions of steam railways which, either on account of their broken profile or heavy traffic, offer an opportunity to introduce a superior type of motive power which will effect such economies in operation as to provide adequate return on the investment required for the electrification. There are still other divisions where a much desired increase in the track-tonnage capacity can only be effected by double tracking so long as the steam locomotive is adhered to as the type of motive power used. Double tracking a mountain-grade division is often a matter of enormous expense, and electrification of the single track may relieve the present traffic congestion at a moderate cost.

On mountain-grade divisions the subject of regeneration with electric locomotives should receive very careful consideration, not so much on account of the saving in power which it may effect, but rather on account of the greater safety of operation, which it guarantees by eliminating the serious defects of holding trains on heavy grades by wheel and shoe friction. No attempt has been made even to approximate the saving effected in engine supplies, roundhouse expenses, elimination of water supply, with its often attendant expensive purifying outfit, and the many items incident to steam locomotive operation. The freight-car shortage problem itself is a very serious one at certain times of the year on some roads, and as the total freight-car mileage can be increased with the higher speeds provided with electric locomotives, it should result in the saving of a considerable expense now incurred for rental of foreign cars, or even increase the gross receipts by the movement of tonnage which more available cars would make possible.

At the conclusion of Mr. Armstrong's paper, the subject was opened for discussion.

Mr. W. J. Wilgus, in a letter discussing the subject, referred to the frequent mistake of overrating the electric locomotive, but expressed the belief that for reasons of economy it had come to stay, even though the primary considerations for its adoption were not economic. Thus far electrification of steam roads has been done for the sake of convenience in operation in tunnels and doing away with smoke and noise nuisances in cities. No practical data were available for basing a change from steam to electricity on purely economical grounds.

Now, however, these data have become available on account of the operation of the two systems side by side on the New York Central, and while the expectations for the electric locomotive have been surpassed by the results, the latter have at times been quite different from the predictions.

Mr. Wilgus stated that his experience indicates that M. Armstrong's figures of cost of current at the contact shoes is too low. In determining this cost not only must the fuel and operating expense be taken into consideration, but also the cost of maintenance, taxes, structures and allied charges for the whole installation.

The experience on the New York Central shows that in maintenance and fixed charges, the electric installation is the cheaper by 19 per cent. The simplicity of the electric locomotive has resulted in a time saving in terminals of 18 per cent. over the steam locomotive, while under the newer system the daily ton-mileage has increased 25 per cent. Of the total switching in Grand Central Station, 65 per cent. with steam locomotives was dead weight, while with electric locomotives it is 54 per cent. In the regular schedule service the saving in dead ton-mileage is 16 per cent.

The total saving of electric operation over steam for the summer months runs from 12 to 27 per cent., depending on the kind of service. In addition, the smoke nuisance has been eliminated in the Park Ave. tunnel, and the capacity of the Grand Central Station has been increased one-third.

Dr. Cary T. Hutchinson, in discussing the paper, expressed approval of the views of Mr. Armstrong and Mr. Wilgus, commending the paper as the best presentation of the problem thus far made. He emphasized the fact that all electrifications now operating have been special problems, aside from the question of economy of operation. The data on electric locomotives are too uncertain as yet for economical discussion of the problem. The regeneration in running down grade with the three-phase system and the consequent fixed speed were the reasons for the adoption of this system on one of the mountain divisions of a Western railroad.

Mr. N. W. Storer emphasized the fact that increased capacity of electric over steam operation is the most important factor of the problem. Electric locomotives can haul heavier loads at greater speeds, up heavier grades than steam locomotives. These factors will count most in causing the electrification of steam roads. The latter work will go on as fast as the manufacturers can supply the equipment, for the data derived from experience are now convincing. The three-phase system, Mr. Storer believed, had a decided advantage in having a fixed speed down grade, but believed that this speed might some times be greater than the curves and roadbed would permit. The single-phase alternating current system has a higher tractive effort at higher speeds than the direct current system. The adoption of the particular system, whether direct current, single or three-phase alternating current, will depend on local conditions.

Mr. W. S. Murray agreed with Mr. Armstrong that capacity is the keynote of the problem, but believed that increase in ton-miles and ability to handle this increase are better ways of expressing it. The actual service conditions on the New York, New Haven & Hartford show a large yearly saving of the electric over the steam locomotives. The machine efficiency of the two can practically be equated and therefore eliminated from the discussion, but the difference lies in the power back of the machine equipments. The saving per year in fuel and locomotive repairs due to electric operation on the New York division will be $562,470.

Mr. William McClellan pointed out that the costs of electrification are larger than were predicted. In order to extend electric operation more convincing figures than even now available must be presented to railroad men. It is difficult to capitalize the savings of electrification due to the abandonment of coaling towers, water tanks, ash pits, and other accessories to steam locomotive operation. Not until a complete engine stage is electrically operated will full and reliable data be available. Leaving these savings aside, Mr. McClellan thought that increased capacity, especially on steep grades, was the most important advantage of the electric locomotive. A good way to approach the problem in endeavoring to convince the railroad man is to show the capacity of electric operation, and then figure the cost for the same capacity if hauled by steam locomotives.

Mr. C. L. De Muralt spoke of a short road that had rached the limit of its capacity, and was considering the addition of two more tracks at a cost of $15,000,000. By electrifying the line at a cost of $3,000,000, the same capacity with the existing trackage could be secured as by the addition of two tracks with steam operation. The advantage of the electric locomotive lies in pulling heavy loads at three to four times the speed of the steam locomotive.

Mr. C. P. Steinmetz pointed out that the use of electric locomotives did not amount to a mere substitution for steam locomotives, but a readjustment of all factors to a new set of conditions. This readjustment must be made throughout the system in order to realize the greatest advantage from the new mode of operation.

HOLLOW TERRA COTTA BLOCKS will be used for the construction of the floors, interior partitions and roof of the Pennsylvania R. R. terminal, now under construction in New York City.

The Mechanical Equipment of the North American Cold-Storage Building, Chicago.

The North American Cold Storage Co. of Chicago operates a large, modern, fireproof cold-storage warehouse, for public use, on the North Branch of the Chicago River, near the junction of that branch with the South Branch to form the main Chicago River, and a short distance from the central business district of the city. Unlike most large cold-storage warehouses, which cover a broad area and are comparatively low; with the idea of reducing losses due to radiation, this building covers a relatively small area and is very tall, protection against radiation being obtained by thorough insulation of the side walls. The building is irregular in plan, being 60 ft. wide at one end, 80 ft. wide at the other and 162 ft. long, and has sixteen stories and a basement. The structure consists of two parts, an original section and an extension that has recently been added, the two parts forming a homogenous fireproof building with uniform floor levels. The original section has a structural steel

Engine Room of the Cold Storage Building, Showing One of the Ice Machines.

frame, covered with hollow tile for fire protection, arched hollow tile floors and brick side-walls. The extension also has a structural steel frame, which is incased in concrete for fire protection, and has reinforced concrete floor slabs. The columns of the buildings are all carried on independent spread reinforced concrete footings, designed to practically float on the soft blue clay that underlies the site.

A mechanical plant in the basement of the building furnishes refrigeration through an ammonia expansion and brine circulation system for all but two floors of the building, the first and the sixteenth, and electric current for power, lighting, freight elevators and other service. This plant was designed and built under peculiarly difficult conditions, owing to the limited head room in the basement, the location of the numerous columns of the building frame, the arrangement and extent of the spread footings which carry these columns, the proximity of the river and the necessity of going below the river level to provide space for boilers. These difficulties were all overcome, however, by special design and arrangement of various features of the plant, and the latter has been in satisfactory operation since the completion of the extension of the building, three years ago.

The mechanical plant and auxiliary equipment occupy the entire basement of the building, a

44 x 45-ft. boiler room being separated from the remainder of the basement by brick walls. The floor of this room had to be placed 5 ft. below the water surface in the river, and 12 ft. below the ground level. As the soil is filled ground, black river silt and soft blue clay, provisions had to be made to prevent water entering through the walls and floors. This was accomplished by lining the bottom and sides of the pit with sheet steel, the masonry floor and walls of the room being placed inside of this steel pit.

The boiler room contains two 350 h.-p. double-drum water-tube Cahall boilers, each having 3,750 sq. ft. of heating surface and operating at a normal pressure of 150 lb. Each boiler is equipped with a Cahall chain-grate stoker having 52 sq. ft. of grate surface. These stokers are both driven by a 3 h.-p. Northern motor, mounted on a bracket on one of the columns of the building frame. The motor operates at 450 r.p.m. and is belted to the driving shaft of the stokers. A automatically by a float set at the proper height in the sump.

Steam is taken from the rear end of the drums of each boiler by a full-sweep 8-in. connection leading to a 10-in. steam header suspended from the ceiling of the engine room. These 8-in. boiler connections are each fitted with an automatic non-return valve at the boiler and a gate valve at the header. The main header extends 39.25 ft. as a 10-in. main, and then as an 8-in. main for 28 ft., a 6-in. branch being taken off at the end of the 10-in. section. The header is anchored at the junction of the 6-in. branch with it, and all connections to the steam-consuming units have full-sweep bends to provide for contraction and expansion. A Cochrane steam separator is placed on the connection to each unit.

The principal equipment in the engine room embraces two large ice machines, two engine-driven generators, two motor-driven brine-circulating pumps, two motor-driven water-circulating

Direct-Connected Centrifugal Pumps for Circulating Water.

small steam engine is also held in reserve for operating the stokers. Coal is delivered to the building in cars on a switch track at the first floor level, and is dropped from the cars through chutes leading to a firing floor in front of the boilers. The stokers are supplied from the storage piles on this floor by hand.

The boiler settings extend flush up to the ceiling of the room, the boilers being specially designed so all steam and feed-water connections could be made at the front and rear ends of the steam and water drums. Feed water is supplied to the boilers through duplicate 1½ in. connections at the front. The steam and water drums are also each fitted with an Ashton safety valve, placed horizontally in the upper part of the front end of the drums. The mud drum of each boiler is connected to a 4-in. blow-off pipe, which rises 5 ft. from the floor level of the boiler room to the level of the water surface in the river, so the sediment from the mud drum is blown up-grade. The pipe is fitted with a valve in order that it can be drained into a sump after the boiler pressure is cut off. A 2-in. vertical Kingsford centrifugal pump, with a capacity of 125 gal. a minute when running at 500 r.p.m., removes all water that reaches the sump. This pump is direct-connected to a 1½-h.-p. vertical direct-current Northern motor, which is operated

pumps, two boiler-feed pumps, together with the necessary auxiliary apparatus and connections. With the exception of one ice machine, which was in a small plant of the original part of the building, all of this equipment was installed when the new plant was built.

The new ice machine is a cross-compound condensing Corliss unit, built by the Vilter Mfg. Co. The steam cylinders are 24.5 x 36-in. and 48 x 36-in., and the ammonia cylinders are 18 and 18 x 36 in. Ammonia is drawn from a large system of condensing coils in one end of the basement and delivered to the seventh and eighth floors by this machine. The old ice machine is held in reserve for use in case the new one is out of commission.

Two double-acting 11 x 12-in. triplex Gould pumps circulate the brine through the system of refrigerating pipes. These pumps each have a capacity of 1,000 gal. a minute against the combination of a static head of 125 ft., and a working pressure of 40 lb. The static head is maintained by an open pipe extending above the highest point in the system of circulating pipes, while the 40-lb. working pressure is the maximum required to force the brine through the system. The pumps are in duplicate, each of them having sufficient capacity to operate the system under maximum service requirements. Each pump is gear-driven by a 50-h.-p. variable-speed direct-current motor, operating at 750 r.p.m. The motor shaft carries a large and a small gear wheel, either of which can be meshed with the gear driving the pump. The small driving gear reduces the speed of the pump to 50 per cent. of that given by the larger gear, and the variable speed control permits the speed of the motor to be changed from one-half to full load; the pumps can thus be operated at as low as 25 per cent. of their rated capacity.

When the extension was added to the building plans were made to install a large electrically-operated butter-renovating plant on the top floor of the building. As the equipment of this plant would require considerable power, a 250-kw. 250-volt direct-current multipolar Northern generator was provided to supply the power necessary for it and for the remainder of the electrically-operated equipment in the building. This generator, which was calculated to carry the day load, is direct connected to a 13 and 16½ x 24-in. high-duty cross-compound condensing Buckeye engine. A 125-kw. 250-volt direct-current multipolar Northern generator, direct-connected to a 10 and 21 x 18-in. high-duty tandem-compound condensing Buckeye engine was installed to carry the night load. The butter plant has not been installed as yet, however, so the 125-kw. unit is used to carry the load at all times.

Circulating water for the surface condenser which serves the steam-condensing units, and for the ammonia condensing coils is furnished by either of two 6-in. horizontal double-suction Kingsford centrifugal pumps, each driven by a 50-h.-p. 250-volt direct-current Northern motor. One of these motor-pump sets operates at 750 r.p.m., and has a capacity of 1,000 gal. per minute, the other, operating at 850 r.p.m., has a capacity of 1,200 gal. a minute. Both of these pumps draw from a 5.5 ft. circular suction well under the basement floor, which has two 10-in. inlet pipes connecting it with the river. Each of these inlet pipes carries a tee connection at the river end in which are placed vertically two 4-ft. lengths of perforated 10-in. pipe, closed at the ends with blank flanges. The perforations in these pipes consist of three ⅜-in. holes per square inch of surface. As the river carries a large amount of silt and sediment these perforations are liable to become clogged, so provisions were made to clear them. A gate valve placed on the well end of the inlet pipes is closed when the perforations are fouled and a current of air under 80 to 100 lb. pressure is forced through the pipes.

The suction pipes of the pumps are not provided with foot valves, but each pump is fitted with a 2-in. connection from the steam header which is used for priming. The discharge for the pumps is arranged so water can be delivered to the ammonia coils and thence to the condenser, or separately to the ammonia coils and the condenser. The discharge from the condenser is returned to the river.

All of the steam-consuming units, except the boiler-feed pumps, are connected to a 16-in. exhaust main, which leads to a 4.5 x 12.5-ft. Blake surface condenser, with a capacity of 15,000 lb. of steam per hour. A 20-in. Cochrane oil separator is placed on this main near the condenser. The exhaust main is also provided with a by-pass leading to a free exhaust into the atmosphere, a relief valve on this by-pass protecting the exhaust system from excessive pressures.

The condensed steam from the condenser is delivered to a tank, suspended from the ceiling of the basement, by either of two 8 x 14 x 12-in. horizontal marine wet-and-dry Blake pumps, with bronze fittings through-out. The suspended tank serves as a hot well in the boiler feed-water system. This system includes a Cochrane water purifier, a Cochrane feed-water heater and two

feed-water pumps. The condensed steam is returned by gravity from the suspended tank to the heater, or directly to either of the feed-water pumps. The make-up water is supplied to the purifier from the city mains through a tight surge tank, a valve operated by a float automatically maintaining the water level in the purifier. Make-up water can be supplied to either pump from the purifier, or directly from the surge tank. The water level in the heater is automatically maintained at one height by a valve operated by a float in the heater. The water level in the heater is also at such height that the pumps draw from the heater until make-up water is required. The heater operates on exhaust steam from the condenser pumps, the feed-water pumps and small pumps which circulate the lubricating oil used in the plant.

A complete system for circulating lubricating oil is installed. Fresh oil is placed in a metal storage tank in the engine room near the boiler feed-water heater. A small reciprocating pump draws oil from this tank and delivers to a supply line connecting with mechanical lubricators on each of the main reciprocating units. Spigots are also placed on this supply line adjacent to the other main units. The drips from all of the units are collected and delivered to a tank in the boiler room by gravity. A second small reciprocating pump draws the dirty oil from this tank and delivers it to a Turner filter over the clean oil tank.

The foundations for the various large machines in the engine room had to practically all be designed specially. The spread reinforced-concrete footings for the columns of the building frame, which are irregular in size and shape, had to be kept separate from the foundations for the machines to avoid vibration being transferred to the building. In order to accomplish this result, a joint at least 1 in. wide was made between the column footings and the machine foundations. The shape and position of the footings required parts of the different machines to be set on heavy I-beams carried over the footings by the foundations; some of these beams also had to be cantilevered over the column footings from the machine foundations. All of this intricate foundation work was done in the basement after the building was completed, the excavations being made in the soft blue clay at about the river level.

The operation of the electrical generators and of the various wiring circuits in the building is controlled from a nine-panel switchboard at one side of the engine room. This board has a panel equipped with an indicating voltmeter and an indicating ammeter, for each generator. A totalizing panel equipped with an indicating ammeter and an integrating wattmeter is also provided. Two power circuits and three lighting circuits are controlled from separate panels, each having an integrating wattmeter. The total output of the generators and the amount of power supplied to each circuit is thus always on record.

The ninth panel on the board carries steam, vacuum, ammonia and back-pressure indicating gauges and recorders, so that all information concerning the operation of the plant is available at the one board. This panel also carries two electrically-operated revolution counters, which record the number of revolutions made by the ice machines. These counters are operated by an eccentric on the shaft of the machine, which makes and breaks a circuit including a solenoid on the back of the switchboard, the solenoid having sufficient power to move the works of the counter.

All except two floors of the building, the first and the sixteenth, are cooled by the refrigeration system. The lowest temperatures are maintained on the seventh and eighth floors, where 4° and 5° below zero Fahrenheit, respectively, can be reached. From the eighth to the fifteenth, and from the seventh to the second floors, the temperatures maintained are successively higher from floor to floor, the normal temperature on the fifteenth floor being 34° Fahr., and that on the second, 32° Fahr. A total of 904,200 cu. ft. of space is thus supplied with refrigeration.

Practically all kinds of food stuffs which have to be stored in cool rooms are placed in the warehouse. Local deliveries to the building and local shipments are made from the first floor by wagons and trucks. Out-of-town deliveries and shipments are also made from the first floor to cars on a switch track at one side of the building. Four electrically-operated Otis freight elevators carry goods from the first floor to every other floor of the building. Two of these elevators are placed in separate fireproof shafts at each end of the building, the shaft connecting at each floor level with a vestibule from which doors open into the cool rooms. These elevators each have an 8 x 10-ft. platform, and a normal capacity of 4,000 lb. With a load of 3,000 lb. all of them have a traveling speed of 150 ft. per minute. One elevator at each end of the building is also arranged with a back gear so it can carry a maximum load of 5,000 lb. at slow speed.

All power and lighting wire circuits throughout the building are in conduits. The switches on the lighting circuits are in cabinets placed on the wall of the vestibule entrance to each floor from the elevators. The incandescent lamps used in the cool rooms are enclosed in a second glass bulb, thus forming an air space between the two bulbs which largely reduces radiation of heat from the lamps.

The plans and specifications for the mechanical and electrical equipment of the building were prepared by Mr. C. A. Chapman, consulting engineer of Chicago, and the equipment was installed under his direction.

Forest and Rainfall Relations have been studied for a number of years by Dr. J. Schubert, director of the meteorological section of the Prussian Forestry School at Eberswalde. The observations were made at 17 stations in the forest, on the forest edge and in the open. The forest stations showed the greatest precipitation and those in the open the least, the difference being 5.2 per cent., which is about the probability of error in the results.

Switchboard and Main Ice Machine, North American Cold-Storage Building.

Requirements for Treating Wood Paving Blocks.

A paper read before the American Society of Municipal Improvements by Geo. W. Tillson, Chief Engineer of Highways, Borough of Manhattan, New York.

During the last few years wood pavements have attained considerable popularity in this country. Whether they increase or even maintain this popularity depends upon the ability of the blocks to withstand not only the action of street traffic, but that of time and the elements.

Wood has been used at intervals in street pavements for about seventy years, but never with any permanent success, if we except the present movement. This being so, it can pertinently be asked why should any better result be expected now. The answer is that there is one vital difference between the old and the present blocks, as the former were laid in a natural state while the latter are treated chemically.

Pavements wear out or rot out. If their material will not decay, the life varies according to the traffic imposed upon them. But wood in its natural condition is subject to decay and with no traffic at all will last only for a limited time. The object of the treatment then is primarily to prevent this decay. But all wood swells when exposed to moisture and contracts when subjected to heat. But if the pores of the wood can be filled with a substance that will prevent the absorption of water it can be kept stable in size, neither shrinking nor expanding during the varying changes in the weather. The object then of the introduction of chemicals is to prevent natural decay and maintain stability in size, so that a pavement will not bulge wet nor be full of loose joints when dry.

The question, therefore, is how can these objects be attained. It is generally admitted that the best agent for treating blocks is creosote oil. When the city of Indianapolis some eight or nine years ago began to lay treated wood pavements, it required the blocks to be first thoroughly dried and then impregnated with creosote oil weighing 8.8 pounds per gallon and to an amount equal to 10 lb. per cubic foot. But it is probable at that stage of the business not enough attention was given to the character of the oil or the actual quantity used, so that the first pavements buckled to quite a serious extent. The possibilities of a perfect wooden pavement were appreciated, however, and eventually successful pavements of this character were laid.

Some time later an Eastern firm took up the matter of treating wood blocks and instead of creosote oil alone, using a mixture of 50 per cent. oil and 50 per cent. rosin, and 20 lb. per cubic foot. The first pavement of this character was laid in Boston, on Tremont St., in 1900. I quote herewith from a letter received last month from an engineer in the Boston Street Department as to its present condition.

"I have just been and looked at the wood paving on Tremont St. About three years ago the upper end, perhaps a hundred feet long, was taken up and relaid with the old blocks, with open joints about the thickness of a lath, and grouted with cement and sand, as I remember it. That portion shows wear, the joints have widened and there is some irregularity of surface. The remainder looks very well. On the part most worn, that is near the middle of the street, there is a somewhat rolling surface.

"The pavement was laid in 1900, and it has worn very well indeed as a whole and is now in good, usable condition."

This is, without doubt, the best evidence that can be obtained upon this particular kind of pavement. In 1902 a street was paved with this material in the Borough of Brooklyn, New York. In addition to the above, the specifications required that the blocks, when treated, should sink in water, and after having been subjected to a temperature of 100° F. twenty-four hours, should not absorb more than 3 per cent. of water when immersed for an additional twenty-four hours, the idea being to specify a result rather than a method only. The absorption test was considered the most important, the other being preliminary only and an indication that the proper amount of the mixture had been used. No trouble was ever experienced with pavements laid by the city under these specifications.

As the use of wood spread over the country, different specifications were adopted according to the views of the different officials. Bearing in mind the objects to be attained by the treatment, the method that will produce that result economically is the best. With the constantly increasing price of all materials used in the production of treated blocks, it is of great importance that no surplus nor unnecessarily expensive material be used. The Borough of Manhattan, New York, probably has more of this treated pavement than any city of this country, and the salient points of the specifications under which the latter portions of them was laid are here given.

(4.) The blocks are to be treated throughout with an antiseptic and waterproof mixture, 75 per cent. of which shall be creosote or heavy oil of coal tar conforming to the specifications hereinafter set forth, and 25 per cent. of which shall be rosin conforming to the specifications hereinafter set forth. All parts of each individual block shall be thoroughly treated, and not less than twenty (20) pounds of the mixture per cubic foot shall be injected.

(5.) In preparing the blocks to receive the creosote mixture, they shall be placed in an air-tight cylinder, in which dry heat, or heat produced by superheated steam, is maintained and raised to a temperature of 215° F., for one hour, for the purpose of expelling moisture; the heat is then to be increased until it has reached 285° F., this heat being maintained for a period of three hours, or until the block is completely sterilized. Application of heat is then to be stopped and the temperature of the cylinder allowed to fall for one hour, or until same has been reduced to 250°. A vacuum is then to be applied until about 26 in. is reached, and while under this vacuum the creosote mixture is to be run into the cylinder at a temperature of from 175° to 260° degrees, after which hydraulic pressure of not less than 200 lb. per square inch is to be maintained and raised until the individual blocks are treated throughout.

(6.) The creosote oil is to conform to the following specifications when tested, as follows:

(7.) The gravity at 68° F. shall be not less than 1.12. When distilled in a retort with the thermometer suspended not less than 1 in. above the oil, it shall lose not more than thirty-five (35) per cent. up to 315° C., and not more than fifty (50) per cent. up to 370° C. The oil is to be free from adulteration; it must not be mixed with or contain any foreign material.

(8.) The resin is to be solid resin obtained from pine. It is to be reduced to a fine dust by grinding and then incorporated with the hot creosote oil in a suitable mixing tank until the proper proportions are secured.

(9.) After treatment the blocks are to show such waterproof qualities that after being dried in an oven at a temperature of 120° for a period of twenty-four hours, weighed and then immersed in clear water for a period of twenty-four hours and weighed, the gain in weight is not to be greater than three (3) per cent.

(40.) Fine turnings from the block shall be placed in a suitable extraction apparatus and the oil completely extracted therefrom with ether or carbon bisulphide. The oil so extracted shall be placed in a suitable still and distilled. The portion up to 120° C., consisting of the solvent, is to be collected apart. The oil shall then be distilled up to 370° C. The creosote oil thus obtained must conform in all respects to the requirements of paragraph 39, subdivision 7.

(41.) The Engineer shall have tests and examinations made at the contractor's works of the materials and blocks proposed to be used, and reject any or all of such materials and blocks as he may consider not to be in compliance with the specifications. The Borough President shall appoint an inspector at the expense of the contractor, who shall inspect the lumber and other materials used in the manufacture of the blocks, and the treatment of the blocks; and he shall reject any of such material and blocks as he may consider not to be in compliance with these specifications.

(42.) The blocks will be carefully inspected after they are brought on the line of work, and all blocks which in quality and dimensions do not conform strictly to the requirements will be rejected and must be immediately removed from the line of work.

It will be noticed that the rosin used is only 25 per cent. and the specific gravity of the creosote oil is 1.12 which would give a weight of 9.4 lb. per gallon as against 8.8 lb. as in the original Indianapolis requirements.

In revising these specifications the writer modified them by specifying that the mixture used should contain not more than 75 per cent. of oil and not less than 25 per cent. of rosin, that pine blocks should weigh as much as water, black gum blocks 59 lb. per cubic foot and any other kind of wood at least 20 lb. per cubic foot more than the untreated. Also that the blocks should not absorb more than 3½ per cent. of water after having been dried for twenty-four hours at a temperature of 100 deg. Fahrenheit. He also changed the wordings of the clause stating the exact method of treatment by making it general in nature, so that a contractor can use any method he pleases provided that he uses the proper material in proper quantity and produces a specification block.

The words "not more" and "not less" were inserted because the author believes that with a correct proportion of rosin and oil there will be no trouble in making a block that will fill the requirements of the specifications. The weight requirement was made so as to ensure as certainly as possible that at least twenty pounds of the mixture is used. This is probably approximate only, but undoubtedly useful.

The writer was probably the person who first proposed the absorption test, and the preliminary drying was not only intended to drive off some of the contained moisture, but also to test the volatility of the oil used, and the idea was to subject it to a temperature that would produce a result equal to actual use. It was also believed that an absorption of 3½ per cent. was sufficiently severe.

In order to ascertain the present practice the writer has compiled from the specifications of the cities mentioned in the accompanying table the salient points regarding treatment and tests. The table represents the general practical differences of the cities in this country and can be considered as representative requirements.

It will be noticed that all of the specifications require creosote oil, and Indianapolis is the only one that does not require it to be mixed with something else. The Brooklyn specifications vary a little from the others in that they allowed as a substitute for resin "or any other suitable waterproofing material." One contract was laid with material other than resin, and up to the present time, although only three years have elapsed, the pavement has been satisfactory.

It should be the object of all engineers to reach the desired results in as economical a way as possible, and if 25 per cent. of resin is as good as 50 or, if none at all is necessary, it should be left out, as the addition of the resin makes quite an increase in the cost. It will be noticed also that all the cities but Minneapolis require 20 lb. of material per cubic foot, where Minneapolis calls for only 16. Of course, if 16 lb. are as good as 20, there is no necessity for putting in the extra 4 lb.

	Mixture				Tests	
City	Character	Pounds per Cu. Ft.	Specific Gravity of Oil	Kind of Wood	Weight	Absorption
Boston	Creosote oil 75 Resin 25	20	1.12	Long leaf yellow pine Southern black gum		3
Borough of Brooklyn	Creosote oil 50 Resin 50	20		Long leaf yellow pine	Greater than water	3
Indianapolis	Creosote oil	20	1.12	Long leaf yellow pine		
Minneapolis	Creosote oil 50 Resin 50	16	1.09	Long leaf yellow and Georgia pine; Norway pine; Washington fir; Tamarac		
Borough of Manhattan	Creosote oil 75 Resin 25	20	1.12	Long leaf yellow pine; Southern black gum; Norway pine; Tamarac		

It will also be noticed that, while the specific gravity of the oil called for in Boston, Indianapolis and the Borough of Manhattan is 1.12, no specific gravity is given for Brooklyn, and Minneapolis calls for 1.09. It can be said regarding the Brooklyn specifications that they were made several years ago, when the question of the oil was not as well understood as it is at present, and no wood block has been laid in Brooklyn for the past three years.

The question of the kind of wood also makes a difference in the treatment. All of the above specifications allow long leaf yellow pine; three allow Southern black gum, and the Minneapolis allow, in addition, Norway pine and tamarac, while Minneapolis also permits Washington fir. It can be easily understood that black gum, tamarac or fir, woods that contain no pitch of themselves, should require a different treatment than yellow pine. It will also be noticed that the only test specified for the blocks after they are treated is that Brooklyn requires the blocks

to be heavier than water, and Boston. Brooklyn and Manhattan require that they shall not have an absorption of more than 3 per cent. of water after having been dried for 24 hours and then immersed in water for an additional 24 hours.

The question of the specific gravity of the creosote oil is very important, and in order to learn something about the difference in the volatility of oils of different specific gravity a test of evaporation was made by the chemist of the Bureau of Highways, Borough of Manhattan, with the following result:

The experiment was carried out as follows: Approximately 50 grams of each oil was placed in an open cylindrical vessel having a diameter of 3 in. and 1¾ in. high. The oil was then subjected to a constant temperature of 120 deg. Fahrenheit for a period of 50 days, the oil being frequently weighed, as shown in the table below.

Four samples of oil were selected for these tests, two having a light specific gravity and two heavy oils. These oils when subjected to distillation had the following constitution:

No.	Specific Gravity	Creosote Oils: To 315° C Per Cent.	Creosote Oils: 315°-317° C Per Cent.	Distillate: Total to 370° C Per Cent.	Distillate: Residue Per Cent.
S— 997	1.055	82.5	8.5	91.0	9.0
S—1003	1.180	33.4	13.4	46.9	53.2
S—1008	1.065	83.1	8.5	91.6	8.4
S—1017	1.190	35.4	10.9	46.3	53.7

The amount in weight which these oils lost when maintained at 120 deg. Fahrenheit, in the number of days indicated, is shown in the following table:

CREOSOTE OILS.—Loss in Weight at 120 deg. F.

No. of Days	S-997 Sp. Grav. 1.055 Total Loss Per Cent.	S-1003 Sp. Grav. 1.180 Total Loss Per Cent.	S-1008 Sp. Grav. 1.065 Total Loss Per Cent.	S-1017 Sp. Grav. 1.190 Total Loss Per Cent.
1	13.3	6.2	10.9	3.8
2	20.2	8.1	18.2	5.7
3	26.8	10.7	24.2	7.4
6	41.1	13.3	39.1	9.9
10	53.1	16.0	49.7	12.1
15	58.9	18.1	54.4	15.0
22	63.4	19.1	59.1	15.8
29	67.0	19.6	61.9	16.2
36	69.1	20.3	64.1	16.7
43	70.9	20.8	66.1	17.3
50	72.3	21.2	67.5	17.6

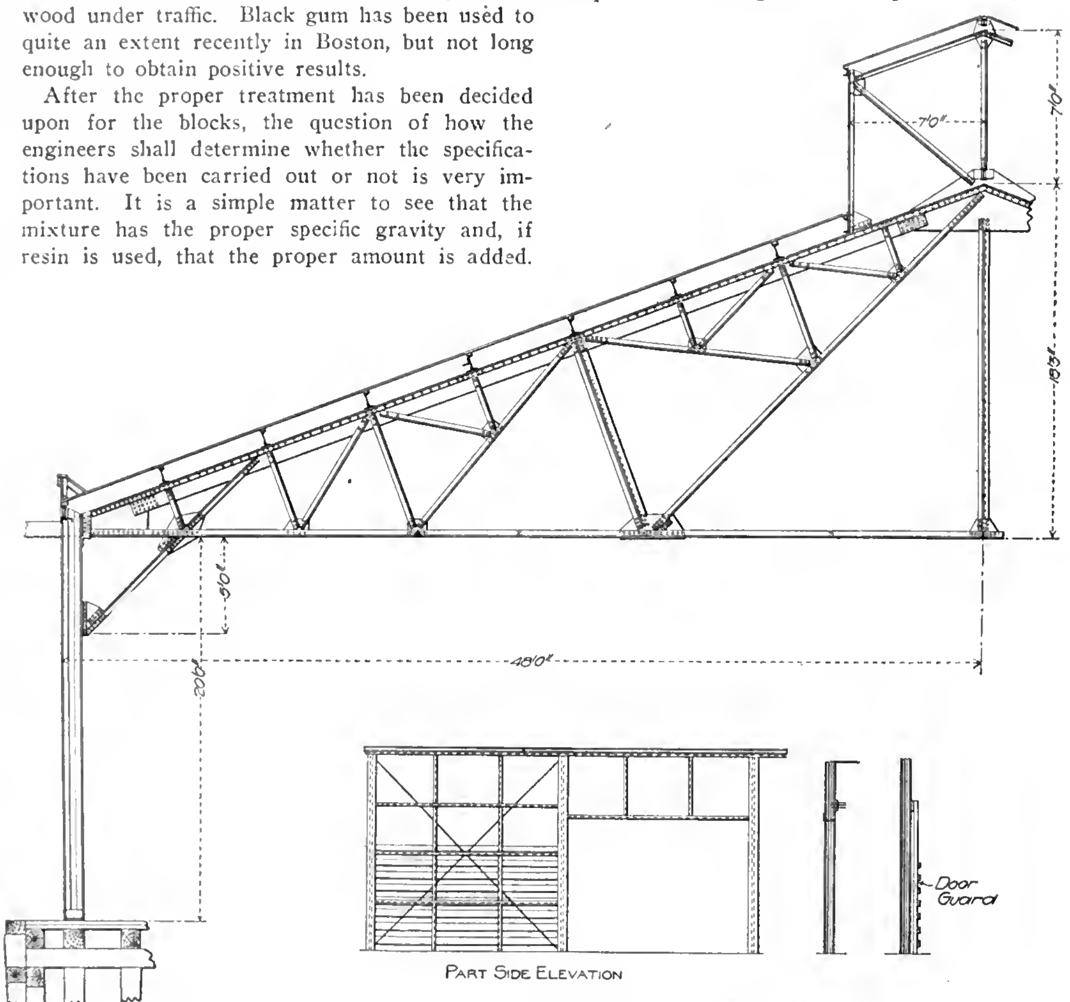
It will be noted that there is a great difference in the evaporation of the oils, both under high temperature and also the extended test of 50 days. Under the 50-day test, subject to a temperature of 120 deg. Fahrenheit, the oil with a specific gravity of 1.055 lost 72.3 per cent. of weight, while the oil with a gravity of 1.19 lost only 17.6. It must also be understood that a so-called creosote oil, with a specific gravity of 1.19, is an entirely different material from one with a specific gravity of 1.055; and it is questionable if, with the heavy oil, it is necessary to have the 50 per cent. of resin, or any at all. In fact, a great many engineers contend that the addition of the resin is injurious rather than beneficial. The object of the resin, theoretically, is as much, if not more, to preserve the creosote oil and maintain it in the blocks as it is to act as any preservative itself.

Referring to the different kinds of wood, the writer believes that it would be difficult to obtain an absorption of 3 per cent. or less with any of the non-pitch woods with so small an amount of oil as 20 lb. per cubic foot. A sample of black gum that had been kept in an office, under the ordinary temperature, for a year or more, that had been treated with 40 lb. of oil per cubic foot, was tested for absorption, under the usual conditions, and absorbed less than 2 per cent. of water.

All engineers will probably agree that the yellow pine wood of itself is the best material that can be used. But this material is growing scarcer and more expensive every year, and the government officials have been making experiments for some years, with the idea of obtaining other woods that would be equally as good, if possible. If, however, in order to get good results it is necessary to use more oil than with the pine, it might bring the cost of the cheaper woods equal to the cost of more expensive woods after both had been treated.

The 20-lb. treatment will cost approximately 45 or 50 cents per square yard for the mixture, and if an additional 20 lb. are added it, of course, increases the cost directly that amount. So that, at the present prices, with the same treatment, black gum has an advantage over the yellow pine of about 45 cents per square yard. This difference, however, might be more than overcome by the durability, or rather lack of durability, of the wood under traffic. Black gum has been used to quite an extent recently in Boston, but not long enough to obtain positive results.

After the proper treatment has been decided upon for the blocks, the question of how the engineers shall determine whether the specifications have been carried out or not is very important. It is a simple matter to see that the mixture has the proper specific gravity and, if resin is used, that the proper amount is added.



Half Elevation of Transverse Bent of Export Steel Pier-Shed.

The quantity of blocks put in the retort can be ascertained and the proper quantity of mixture used, so that the blocks will average the proper quantity per cubic foot. Of course, it will be impossible to be sure that each block has the required amount. When it comes, however, to applying the absorption test and the weight of the block, if that be specificed, another question comes up; that is, whether the blocks shall be tested at the works when they are just completed or at some subsequent time when delivered on the street, which may be some weeks or, very probably, in some cases, months. The contractors claim that the test should be made at the works and, if satisfactory, then they should be accepted at any time afterwards.

As the blocks are to be used in the streets for years, it would seem that they should be treated in such a way that they would stand the required test, even if not used for several months after having been treated, especially if heavy oils have been used and in the light of the experiment noted above. The heaviest oil lost, approximately, 18 per cent. after having been subjected to a temperature of 120 deg. for 50 days, which is an extremely severe test and one never possible to be reached on the street. If a block had been treated with 20 lb. per cubic foot and had lost 18 per cent. it would still have 16.4 lb. per cubic foot of the original mixture, which is more than the original requirements for the Minneapolis specifications. It would seem, therefore, to the writer, conclusive that the blocks should conform to the specifications when delivered on the street and not when treated.

The requirement for sinking in water, which was inserted in the Brooklyn specifications, was used more to give a quick test than for anything else, and it was found that if the pine blocks which were treated with a material that contained 50 per cent. of creosote oil and 50 per cent. of some other suitable material, almost every block that would sink in water would conform to the requirements in regard to absorption. This, however, in later experiments has not been found to be true, and, in many cases, blocks that would sink in water have not conformed to the absorption test. This may have been because the blocks were heavier originally; they did not take the treatment and absorb as much oil as the other blocks, and that when immersed in water would absorb more water. This is wholly speculative, however.

The writer believes that the question of treating wood paving blocks is one that is being investigated more at the present time than any other one kind of pavement, as he has received many inquiries regarding it during the past season. He also believes that it is a matter that neither engineers nor contractors have any positive knowledge of at the present time, and thinks it of great importance that the different cities investigating the matter should, in some way, give each other the result of their different investigations, so that in the end all cities might arrive at a good and satisfactory specification.

The question of testing the blocks is one of great importance, and it is absolutely necessary to arrive at some method of making the tests that will be as nearly positive as possible and perfectly satisfactory. And the object of writing

this paper has been, not so much to give information as to seek it and, if possible, to bring about the consummation above mentioned; that is, the getting together the ideas of the different engineers of the various cities and finally reach a result that will be satisfactory to all.

An Export Steel Pier-Shed.

The new deep-water pier for the Insular Dock Co., in San Juan Harbor, Porto Rico, is 420 ft. long by 100 ft. wide over all and has a wooden pile sub-structure and a steel superstructure. The design is of an ordinary type, and the construction is simple and is intended to adapt standard features and practice to the local conditions and the requirements for shipment. It is therefore interesting, not for novel or unusual construction, but as an example of a class of work likely to be undertaken in increasing amounts by American engineers and contractors.

The pier is located in a sheltered harbor, where there is a tide of 1 ft., and it is not exposed to unusually severe winds or to especially heavy impact from adjacent navigations. The substructure is made with yellow pine creosoted piles about 70-80 ft. long, driven through 50-60 ft. of water and soft mud to hard bottom. They are arranged in transverse bents 10 ft. apart on centers, with 23 bearing piles in each bent, all of which, except the three at each end, are 5 ft. apart. There are also two spur piles and two fender piles in each bent. The piles are capped with longitudinal 12 x 12-in. rangers, with butt joints, and 6 x 12-in. double side plates between bents. The piles are connected transversely by a pair of 6 x 12-in. horizontal ledger pieces at the top of each bent just below the longitudinal timbers. The floor is made with 4-in. transverse planks covered with 4 in. of concrete.

The 96 x 400-ft. steel shed is symmetrically located on the pier and has a height of 50 ft. 3 in. over all. It is made with 21 transverse bents, 20 ft. apart, connected with 21 lines of longitudinal purlins, two lines of longitudinal struts and nine sets of lateral X-bracing in alternate panels in the planes of the rafters. At one end of the shed there is a two-story house, two panels long, for office and administration purposes, and the remainder of the building is one story in height, with a monitor 7 ft. high and 14 ft. wide on the center line of the building, occupying 17 panels in length.

Each transverse bent has a triangular riveted main roof truss, 18 ft. 3 in. deep in the center, which is knee-braced and rigidly connected to the tops of the wall columns, 20 ft. high. The top chord or rafter has a T-shaped cross section made with a pair of 4 x 3½-in. flange angles and a 12-in. vertical web plate, to which the single and double angles forming the other members of the truss are riveted direct without connection plates, except at the feet and at the eaves. The truss members are to be shipped separate and field-riveted together in a horizontal plane on the ground and erected by derricks.

The columns have an I-shaped cross section and a horizontal base plate, bolted directly to the floor timbers. The trusses are connected by longitudinal struts at the peak and at the foot of the center vertical and by 18 lines of 7-in. channel purlins, bolted to angle clips on the top flanges of the top chord. Knee-brace plates riveted to the upper lines of purlins and to the top chords of the trusses serve also as connection plates to receive the feet of the verticals in the monitor frames at panel points. Intermediate monitor frames are connected directly to the purlins and carry three lines of 4-in. channel and I-beam purlins. All purlins have 2 x 3-in. nailing strips bolted to their top flanges to receive the 1¼-in. sheathing boards parallel to the top chords, which are covered with the ordinary tar, felt and gravel roofing.

A wooden gutter is formed at the eaves by a sort of fascia or cornice board flashed with the roofing. The eaves purlin has an L-shaped cross section made with two channels, one vertical and one horizontal, the latter serving as a frame for the siding and door casing. The fifth purlin from the eaves on each side is reinforced from end to end of the building by a 3 x 3 x ¼-in. angle riveted to the web of the channel to stiffen it for the longitudinal countenance of the lateral stresses. The lateral diagonals are 1-in. rods, with screw ends and nuts bearing on beveled washers.

The walls of the building are sheathed with corrugated iron, secured to studs and girts made respectively with 6-in. vertical channels and 2 x 2 x ¼-in. horizontal angles. The shore end is made special, with intermediate columns for the two large doors, and with an extension for a false front above the roof line. Between the one-story and two-story parts of the structure there is a special junction bent made with a horizontal 12-in. channel running across the full width of the building at the height of the eaves, 20 ft. above the floor, and supported by five intermediate columns. The side walls of the one-story part have six full-width doors, one in every third panel, with two windows above each door. In eight panels between the doors there are ⅞-in. round X-brace rods, corresponding in seven cases to the lateral bracing in the roof. In two of the center panels the diagonal bracing occurs where there is none in the corresponding roof panels.

Between the large side doors the inner faces of the columns are protected by freight fenders, consisting of eight horizontal lines of 2 x 8-in. planks, 8 in. apart, spiked to 3 x 4-in. vertical studs furred out 4 in. from the column, forming a pocket for the sliding doors. In the shore end of the building there are two large doors, two small doors and sixteen windows. At the river end there is one 14 x 16-ft. center door and one large window in the monitor. Most of the space in the side walls of the monitor is occupied by Berlin louvres, without glass. The total weight of structural steel is about 550,000 lb. The contract for the pier and shed was awarded to John Monks & Sons, New York; Mr. Richard A. Monks is the company's engineer on the dock, and Mr. John W. Ripley, engineer on the shed. The steel work was furnished by the Dietz-Waring Co., of New York.

A 1,200-Ft. Double Cableway for hauling coal and shale across a valley has been installed by Messrs. R. White & Sons, Widnes, England. There are four spans in all, the intermediate towers being 12 to 30 ft. high. The grades of the rope vary from 1 in 6½ to 1 in 2, the slope being upward against the loads. The loading terminal is about 10 ft. from the top of the colliery shaft, and a track runs from the latter to the loading terminal, sloping rapidly downward beyond the point, where the cableway picks up the cars. The latter weigh about 400 lb. each and carry a load of 800 lb. They are attached to the cableway carriers by stirrup-irons, which go under the box of the car. On reaching the discharge end they take the ground on a rising grade, exactly opposite to the arrangement at the loading end, and when on the level are automatically detached from the hauling rope. The small cars are dumped into railroad cars and sent back to the loading point on the return cableway rope. At the discharge end a tension-wheel is mounted on a trolley, which runs on a short track to take up the slack. The maximum capacity, according to "Engineering," of London, is 70 tons per hour.

The Sterilization of Treated Sewage.

At the present time there are few subjects more interesting to those engaged in research work in sanitary engineering than the sterilization of the effluents of sewage disposal works. The subject can hardly be termed one of immediate practical importance, except in a very few places, like Baltimore, where the existence of a great shellfish industry has made it obligatory to ensure an unusual degree of purification of the sewage before its discharge into Chesapeake Bay. In fact, the importance of sterilization will depend very largely on the results which may be reasonably expected from it and the cost of attaining these results, both of which factors remain to be determined. An instructive paper on the subject by Messrs. Phelps and Carpenter was printed in this journal on Jan. 19, 1907, and in the present article it is proposed to give an outline of investigations made by Messrs. Karl F. Kellerman, R. Winthrop Pratt and A. Elliott Kimberly, and described in a recent bulletin of the U. S. Bureau of Plant Industry.

Experiments upon the germicidal effect of copper were planned to include sewage effluents of different qualities, ranging from highly purified effluents from sand filters to the putrescible effluents from septic tanks. Westerville, the Boys' Industrial School, Lancaster, and Marion, Ohio, were selected for sub-stations, and a preliminary experiment upon fresh sewage was conducted at St. Mary's of the Springs, near Columbus, Ohio.

St. Mary's. St. Mary's of the Springs is a convent school of about 175 persons. The sewage is discharged into two tanks operated in series. These tanks are 10 ft. in diameter and about 6 ft. in depth to the flow line. Recent measurements indicate that the flow of sewage is in the vicinity of 12,000 gal. for a period of 16 hr., there being practically no flow after 10 o'clock p. m. The highly putrescent sewage discharges from the second tank into a small brook. It has been the daily practice of the health department of Columbus to apply copper sulphate to the sewage at the inlet of the second reservoir. The sulphate in a dry state is placed in a perforated pail, which is lowered into the liquid to a point opposite the discharge pipe from the first reservoir. The sulphate remains suspended here, exposed to the somewhat erratic solvent action of the incoming sewage; at times it is found that the entire quantity of chemical used for one day's dose is not completely dissolved in 24 hr. In making an examination of this plant samples of untreated sewage entering the second tank and of treated sewage leaving the second tank were collected at half-hourly intervals for a period of seven hours on two successive days.

From an average of 16 samples of effluent collected on two days the total number of bacteria to the cubic centimeter developing within 48 hr. at 20° C. was 5,600,000 for the raw and 65,000 for the treated sewage, giving a reduction of approximately 99 per cent. Platings of the treated effluent when incubated at 37° C. for a period of 24 hours averaged 250,000 colonies, of which 36,750, or 14.7 per cent., were acid-producing, the majority being *Bacillus coli.*

The cost of treating the settled sewage is practically the cost of chemicals and the cost of maintenance, as the construction costs for the plant are practically negligible. With copper sulphate at 6 cents a pound and a daily sewage flow of 12,000 gal., the expenditure for chemicals is 3 cents for each 1,000 gal., using 6 lb. of copper sulphate a day. The labor cost may be considered to be 25 cents a day. Similar plants applying copper sulphate in the proportion of 63 parts to the million to a sewage flow of 12,000 gal. would require about 6 lb. of copper sulphate daily, costing 36 cents a day. On an annual basis the chemical and maintenance cost would be about

$222.65. Capitalized at 5 per cent., this would represent an investment of $4,500.

For crude sewage much better results could probably be obtained by using 100 parts of copper sulphate to each million parts of sewage. For treating 12,000 gal. of sewage at this rate the expense would be 60 cents a day, or $310.25 annually, and the corresponding capitalization would be $6,200.

Westerville. The sewage plant at Westerville, Ohio, comprises two small septic tanks, which discharge, through an aerating device, onto six primary cinder filters, which in turn discharge upon two secondary filters. The plant at the present time is operated continuously, instead of upon the contact principle. The effluent from the primary filters is usually non-putrescible, but at times tends to become unstable and contains considerable crude organic matter. As the effluent from the primary filters was the more accessible, by suitable piping it was conducted through an orifice box, where the proper quantity could be diverted for the experiments with copper treatment, the excess being discharged over a waste weir.

The copper crystals were dissolved in barrels and conducted to an orifice box, where a constant head was maintained upon an adjustable orifice. The quantity of copper sulphate used in each test was based upon the computed flow of 41,000 gal. of effluent in 24 hours. At the point of entrance of the sewage effluent and the copper solution there was a small longitudinal baffle, serving to effect a thorough mixture of the chemical and the effluent. The time of contact of sewage and sulphate was slightly over one hour. It was the general practice to apply copper sulphate at a given concentration for two consecutive days.

At hourly intervals during the test bacterial samples of the sewage effluent were collected before and after treatment. Samples for chemical analyses were collected at hourly intervals, and the composite sample so obtained was subjected to chemical analysis. In addition, determinations were made in the field for free carbonic acid and for alkalinity before and after treatment.

The percentage of removal of bacteria grown at 20° C. varied from 95 to 59 per cent., depending upon the concentration of copper sulphate applied and also upon changes in temperature. The removal of bacteria developing at 37° C. was much more erratic than was the case at 20° C., the percentage of removal varying between 28 and 96 for total numbers and between 66 and 100 for acid-producing bacteria.

On the basis of treating daily 41,000 gal. of effluent from the primary contact filters, the initial cost of a plant for applying the germicidal chemical would be $70 in round numbers. Considering a satisfactory removal of pathogenic organisms to be produced by a concentration of 40 parts to the million, the daily quantity of copper sulphate required would be 13.7 lb.; the cost for chemicals would be about 82 cents, and for 2 hours' labor, 50 cents. The annual cost, with copper sulphate at 6 cents a pound and labor at 25 cents an hour, would then be $482.50. Capitalized at 5 per cent., this would represent an investment of $9,650.

Boys' Industrial School. The Boys' Industrial School is a State institution near Lancaster, Ohio, and has about 1,100 persons. The sewage is treated on 23 intermittent sand filters, which receive the crude sewage, which has been subjected only to rough screening as a preliminary treatment. The flow averages about 160,000 gal. in 24 hours. It was thought most practicable to apply the chemical to the entire effluent flow, carrying out the experiments with a view to learning the quantity of copper sulphate required to destroy coli-like organisms when the effluent was flowing at a maximum rate.

The quantity of copper sulphate applied at the beginning of the test was calculated to afford a concentration of 5 parts to the million. The rate of flow of the copper solution was practically constant at 0.75 gal. a minute, but the flow of the sewage effluent varied widely; consequently, the resulting concentration of copper sulphate showed the same variations. The concentration of copper sulphate applied was increased on each successive run until a maximum of 20 parts to the million was reached, based on a flow of 150,000 gal.

From the public health standpoint the treatment at Lancaster was more satisfactory than either of the two preceding cases. The more efficient action of copper sulphate at Lancaster is undoubtedly due to the better chemical condition of the sewage effluent, especially its greater freedom from organic matter and its freedom from carbonates.

The daily application of copper sulphate to the Lancaster sand filter effluent, with its flow of 160,000 gal. a day, would require 17.3 lb. of sulphate, and the cost of this chemical would be about $1.04 a day, based on applying 13 parts of copper sulphate to each million gallons of effluent.

The cost of constructing the Lancaster plant used in these experiments and capable of treating sewage at the rate of 160,000 gal. for six hours was $29. However, a fair estimate of the cost of a plant under practical conditions for continuous treatment would be about $92. The maintenance cost per annum on the above basis would be $1,109.50. Capitalized at 5 per cent., this would represent an investment of $22,000.

Marion. The sewage disposal plant at Marion, Ohio [Eng. Record, March 17, 1906], is a combination of septic tanks, contact filters and sand filters, handling about 600,000 gal. of sewage daily. The storage or contact period of sewage effluent and copper sulphate was determined to be about one hour. The solution was discharged at the rate of 2 gal. a minute.

At the present time the disposal plant is hand-operated in the daytime only, and it was during such normal operation that the copper experiments were carried out. From 7 o'clock a. m. until 10 a. m. practically no water is discharged into the effluent channel; hence all of the tests began at about 10 a. m. Samples were collected at half-hourly intervals.

The results of these experiments are somewhat disappointing. The degree of bacterial purification did not equal that obtained at Westerville, and, as at Westerville, a great increase in the quantity of copper sulphate applied caused but slightly increased efficiency. The chemical condition of the effluent at Marion was somewhat similar to that at Westerville, but the time of contact with copper sulphate was much shorter. As several investigators have shown, time of contact is a very important element in the germicidal action of copper, and the low bacterial removal is probably due to this factor.

The application of copper sulphate to the Marion sand-filter effluent, with a daily flow of 600,000 gal., on a basis of applying 20 parts of copper sulphate to each million gallons of effluent, would cost $6 a day for chemicals, and the cost of constructing a plant for applying the copper sulphate would be about $151. The cost of treatment annually on this basis would be about $2,920. Capitalized at 5 per cent., this would represent an investment of $58,000.

After completing the experiments with copper sulphate it was decided to experiment with the use of chlorine. In the case of certain hospitals it may be desirable to disinfect the crude sewage discharged from them, and this may be done satisfactorily by means of chlorine, without interfering with the subsequent biological phenomena of purification. Generally speaking, however, the proper function of germicides in dealing with a large quantity of sewage is that of improving the biological character of the previously chemically purified effluent. This chemical purification may be only partial, as in the case of the effluent from septic tanks, or complete, as in the case of a high-grade sand-filter effluent.

As the most inexpensive and practical source of chlorine for the experiments, calcium hypochlorite or bleaching powder was selected. This costs upon an average about 3 cents a pound, and in large quantities may be purchased for 2½ or 2¾ cents a pound. The strength of the commercial chloride of lime in bulk varies widely and, according to analyses of the commercial product purchased in Columbus, Ohio, ranges from 18 to 25 per cent. of available chlorine. The data of cost have been calculated on the basis of 2½ cents for a grade containing 25 per cent. of available chloride.

According to the experience gained at Lancaster and Marion, the preparation of the hypochlorite solution is an important feature in the successful chlorine treatment of sewage effluents. It was found that unless special precautions are taken in dissolving the bleaching powder, many large lumps which inclose chlorine remain and materially reduce the efficiency of a given weight of bleaching powder.

The method of preparation found to give the best results is as follows: A weighed quantity of bleaching powder is placed in a shallow box and covered with sufficient water to form a smooth paste. More water is then added until the heavier particles settle out, thus allowing the soluble and finely divided chloride of lime to be decanted. After decantation more water is added, the coarse lumps are broken up, and the process repeated until as much as possible has gone into solution. The importance of thoroughly mixing the chloride of lime solution and of grinding the dried chloride as fine as possible cannot be too strongly emphasized; otherwise a loss of from 10 to 30 per cent. may take place, especially in the case of low-grade bleaching powder.

Boys' Industrial School. The leading results obtained during the first series of chlorine tests at Lancaster indicated that the removal of coli-like organisms was practically 100 per cent., and the removal of total organisms, 99.8 to 99.9 per cent. In organic compounds the effluent under treatment was substantially similar to that found during the copper experiments, and the temperature of the effluent was practically at the maximum density of 4° C. In practically all instances by means of the iodo-starch tests residual chlorine was detected in the discharge after a storage of about three hours. The solution was discharged into the sewage effluent at the rate of 0.75 gal. a minute, and variations in the quantity of chlorine applied were made by changing the strength of the hypochlorite solution.

The cost of constructing a plant for treating the sand filter effluent of the Boys' Industrial School with chlorine may be taken at $92. Substantially the same plant could be used as in the case of treatment with copper sulphate. The annual cost, applying 4 parts to the million of available chlorine to a sand filter effluent flow of 160,000 gal., would be about $924. Capitalized at 5 per cent., this would represent an investment of $18,500.

Marion. The procedure adopted in the chlorine disinfection tests was substantially similar to that followed in the experiments with copper sulphate, but the rate of application of the disinfectant solution was increased to 3 gal. a minute. As the effluents from either the septic tanks or the contact filters could be diverted directly into the effluent sewer, experiments were planned with each of the three grades of effluents, from the sand filters, the contact filters and the septic tanks.

The effluent from the sand filters was first experimented with, and the quantity of chlorine applied during the three runs on the sand filter effluent was on the average 3.8, 3.0 and 1.5 parts

to the million. In the first two runs the sterilizing effect of the chlorine was sufficient to remove 98.8 and 99.7 per cent. of the total bacteria, 98.5 and 99.1 per cent. of bacteria developing on lactose-azolitmin agar at 37° C., and 100 per cent. of the acid-forming bacteria, respectively. The conclusion may therefore be drawn that Bacillus coli was not present in the treated effluent. On the third test with a chlorine concentration, on the average of only 1.5 parts to the million, the bacterial removals were 94.3 for total bacteria at 20° C., 99.2 for bacteria developing on lactose-azolitmin agar at 37° C., and 99.9 per cent. for acid-forming bacteria. The average of the platings at 37° C. in the case of the third run contained but one red colony. This, by full determinative tests, was found to be Bacillus coli. No residual chlorine was found in the disinfected sewage.

The effluent from the contact filters contained organic matter of a more putrescible character than did the sand effluent previously studied. The quantity of chlorine applied ranged from a minimum of 1.7 to a maximum of 14.5 on the first run; on the second run, from a minimum of 2.6 to a maximum of 20.4, and on the third run, a minimum of 2 to a maximum of 31.8 parts to the million. The quantity of sewage discharged varied widely at different times during the day, depending upon the amount of sewage held in the filter. At the end of a discharge the rate is very small, and during such periods, of course, the strength of chlorine applied was greatly increased.

The effect of the applied chlorine on the chemical character of the contact-filter effluent is similar to that produced in the sand-filter effluents. The average quantity of chlorine, 2.9 parts to the million, sufficed to remove 97.8 per cent. of the total organisms. The tests for Bacillus coli indicated that the contact-filter effluent contained about 20,000 to the cubic centimeter, but after treatment these organisms usually could not be detected in 0.5 cubic centimeter of the effluent.

In the second run, with an average chlorine application of 5 parts to the million, the reduction of total organisms was 97.6 per cent., that of bacteria developing at 37° C. on lactose-azolitmin agar was 99.5 per cent., and the removal of acid-forming bacteria was 100 per cent. Further, Bacillus coli usually was not found in 0.5 cubic centimeter of the treated effluent, while in the untreated effluent it was found in numbers averaging 15,000 to the cubic centimeter. The total organisms in the treated effluent were 1,600, and the total development at 37° C. was 370 to the cubic centimeter. No red colonies were found during this run.

On the third run, with an average chlorine application of 4.4 parts to the million, the total removal of bacteria developing at 20° C. was 99.8 per cent., the removal of bacteria developing at 37° C. was 99.4 per cent., and the removal of acid-forming bacteria was 99.9 per cent. The red colonies developing in the case of the untreated effluent contained 21,000 organisms to the cubic centimeter, while in the treated effluent only 3 were found. The tests indicated that Bacillus coli usually was not present in 1 cubic centimeter, although found in the untreated effluent approximately 20,000 to the cubic centimeter.

The tests for residual chlorine in the treated effluent were generally negative.

Attention was next directed to the application of chlorine to the effluent from the septic tanks. The addition of approximately 5 parts of chlorine to 1,000,000 parts of septic sewage did not suffice to effect a very material removal of either total bacteria or fermenting organisms. The total bacterial removal ranged from 36 to 88 per cent. A higher concentration of chlorine produced only a slight increase in efficiency. At the highest concentration tested the acid-forming bacteria in the applied sewage were 100,000 to the cubic centimeter and were reduced by the chlorine treatment to 51,000, showing an average reduction of 49 per cent. The indications are that with the quantity of chlorine applied the removal of bacteria is by no means as complete as is desirable. Tests for the presence of residual chlorine in the treated effluent were carried out, but were negative in every instance.

An effort was next made to learn the efficiency of greatly increased amounts of chlorine. Such information would appear to be of considerable importance in connection with the disinfection of hospital sewages at times of epidemics in cases where sedimentation alone is the only permanently available means of treating the crude sewage. To this end six experiments in the chlorine treatment of septic sewage were made, the amount of chemical applied ranging from 7.3 to 48.5 parts to the million. The experiments at these higher concentrations were conducted substantially as those already discussed.

About 25 parts to the million of applied available chlorine were sufficient to remove a substantial proportion of coli-like organisms, although a complete removal of Bacillus coli was not accomplished. In the runs in which the concentration of the applied available chlorine was increased to a maximum average of 48.5 parts to the million the removal of Bacillus coli was found only slightly greater than in the case of the application of 25 parts to the million of available chlorine. In this connection it should be noted that the suspended matter in the septic effluent increased considerably, and this probably in large part explains the low removals obtained with the increased quantity of applied chemical. Observations made during the experiments at Marion emphasize the great effect of the periodic discharge of a septic effluent charged heavily with suspended matters. At such times, no doubt, the absorption of the chlorine is very great, and presumably the organic matters in suspension in the septic effluent destroy a considerable part of the disinfectant added.

The cost of constructing a plant for treating the several effluents studied at the Marion sewage plant may be taken as $151, exclusive of arrangements for supplying water to dissolve the chloride of lime. This estimate allows for continuous treatment at a rate of flow of 600,000 gal. in 24 hours.

The cost of applying 4 parts to the million of available chlorine to the sand filter effluent is $730 annually. The total annual cost, including labor, but excluding the cost of supplying water for preparing the chlorine solution, would be about $1,620, on the basis of an effluent flow of 600,000 gal. daily. Capitalized at per cent., this would represent an investment of $29,000.

The cost of applying 5 parts to the million of available chlorine to the contact filter effluent would be about $2.50 a day, requiring 100 lb. of the chemical. The total annual cost, including labor, but excluding the cost of supplying the water for dissolving the germicide, would be about $1,640. Capitalized at 5 per cent., this would represent an investment of $34,000.

Assuming 25 parts to the million as a fair average figure for the disinfection of the septic effluent, provided the same is at all times free from abnormal amounts of suspended matters, the total annual cost, including labor, would be about $5,300. Capitalized at 5 per cent., this would represent an investment of about $106,000.

In view of the importance attached to chlorine absorption by previous investigators and the fact that a fixed relation between the chlorine and the oxygen consumed, respectively, would be of marked value in the practical control of sterilization with chlorine, it was decided to inquire into the chlorine-oxygen relation for conditions at Lancaster. Especially was this important, since a complete removal of Bacillus coli was obtained by the use of slightly less than 5 parts of chlorine to the million, and also since there was noted the presence of residual chlorine after a three-hour storage of the treated effluent.

It appears that under conditions obtaining in some experiments chlorine up to 7.5 parts to the million would be absorbed from the sewage effluent in about 45 minutes, and that chlorine in concentrations of 10 parts and over would be detected in the treated effluent at the end of four hours. Additional experiments showed entirely different results, however; in one instance, a chlorine concentration of 75 parts to the million could not be detected at the end of one hour.

In continuing at Marion the study of the absorption of chlorine by organic matter and the possible relation between such absorption and the oxygen absorption shown by the standard oxygen-consumed process, there were carried out 48 separate experiments. These experiments dealt with the question of chlorine absorption and used, respectively, sand filter effluent, contact filter effluent, septic sewage and crude sewage, each being prepared at different dilutions by the addition of tap water.

From the results of the studies the following conclusions are drawn:

(1) The ratio of chlorine consumed to oxygen consumed in a five-minute period of contact bears no constant relation to the oxygen consumed by the five-minute boiling method.

(2) The concentration of applied chlorine affects the quantity of chlorine absorbed, the absorption at a concentration of 100 parts to the million being fully double that at 50 parts to the million.

(3) Increasing concentrations of chlorine up to 250 parts to the million increase the quantity of absorbed chlorine very materially, but above this there appears to be very little increased absorption even with a chlorine concentration of 500 parts to the million.

(4) Increasing the period of contact to two hours effects but little increase in the ratio of chlorine consumed to oxygen consumed, except for the higher chlorine concentrations of from 250 to 500 parts to the million.

(5) The actual amount of chlorine absorbed in five minutes by the several liquids tested, under concentrations of chlorine of 50, 100, 250 and 500 parts to the million, ranged as follows: Crude sewage, 24 to 148; septic sewage, 41 to 160; contact filter effluent, 42 to 80, and sand filter effluent, 33 to 68.

(6) The absorption of chlorine apparently is largely dependent upon the organic content of the liquid treated, increasing materially as the oxygen consumed of the effluent increases, but not in a definite ratio.

(7) For the same concentration of applied chlorine the ratio between the chlorine consumed and the oxygen consumed appears to increase as the organic matters decrease.

(8) The readily oxidizable matter in the septic sewage studied apparently causes a rapid absorption of chlorine, increasing the chlorine-oxygen ratio, especially in the case of the lower concentrations.

A STRANGE WELL exists at Riverside Park, Logansport, Ind. An 8-in. pipe was first sunk about 80 ft. and inside it a 5-in. pipe was carried down lower. Fresh water from a limestone stratum comes up between the two pipes, while water which tastes and smells strongly of hydrogen sulphide comes up through the 5-in. pipe from a lower stratum. The sulphur water flows at the rate of a gallon a minute from the drinking fountain over the well, while the fresh water flows with a somewhat smaller volume from a pipe about 20 ft. distant. There is a similar well about 15 miles north of Cincinnati, but the latter is non-flowing.

The Proposed Dock System of Newark.

Attention was called some months ago in the Current News Supplement of this journal to the fact that steps were being taken to improve the facilities of the city of Newark for handling water-borne shipments. The project is an old one, but it is only recently that it has taken definite form. The location of the city is such that it can enjoy excellent facilities for shipping at a small expense compared with the benefit to be derived from the cost of the work. The preparation of the plans for the improvements has been entrusted to Mr. James Owen, who has made a study of the subject for many years. The plan he has prepared is shown in the accompanying diagram and the following notes are taken from his report recently submitted to Mr. M. R. Sherrerd, city engineer of Newark.

At the present time one-third of the area of Newark, known as the Meadow Section, is practically undeveloped, although the population on the higher land within the city limits increased from 10,000 to 300,000 during the last century. The manufacturing interests of the city are diversified and there is a large business between the city and New York. The city manufactured in 1905 products to the value of $150,000,000, but its exports by water were only $3,711,364. In the year ending June 30, 1907, the exports had decreased to $1,685,113, although there is no doubt that the total volume of manufactures had increased. Mr. Owen considers that it is probable that $14,000,000 of manufactured products are sent from Newark to New York for transfer into vessels.

The dock facilities of the city of New York are all occupied and an extension of such facilities has become imperative. Various methods of relief have been suggested, but Mr. Owen believes that none of them are equal to the development of docks along the Newark meadows, where railway facilities are far better than on Long Island. By developing the meadows in the manner indicated, Mr. Owen believes that Newark may acomplish the same result that Glasgow obtained in developing the River Clyde. This was changed from a sluggish shallow stream to a broad river by artificial means entirely. The value of the import and export trade of Glasgow during 1905 was over $200,000,000. In view of the desirability of a further accommodation of the trade of Newark itself and the probability of the creation of entirely new business, Mr. Owen believes that the plans submitted form a good, sound business proposition.

The diagram shows the general outline of the works. It is proposed to occupy an area one mile wide and three miles broad. In the center of this tract is the canal itself, 1,000 ft. wide and 30 ft. deep, extending from the dock line on Newark Bay nearly to the westerly end of the tract. On each side of the canal is a system of slips similar in design to the most approved dock construction of this country. The bay front outside the limits of the canal will also be developed in a similar way, and on the westerly end of the canal are a series of slips and piers for coal handling, for domestic and foreign use.

In determining the depth of the canal, the fact that the facilities must be adequate for foreign trade and foreign vessels, make at least 30 ft. desirable. It will accordingly be necessary to dredge a channel in Newark Bay for a distance of about a mile to a point where the 30-ft. depth in that body of water is attainable.

The arrangement of the piers and slips is based on a width of 250 ft. for the slips and 150 ft. for the piers. Each pier in the canal will be 1,200 ft. long. The piers on the bay front in the canal will be 1,500 x 150 ft., and the coal piers will be 1,500 ft. long. On each side of the bay front slips for transfer floats are provided for direct New York trade, or for transfer to railways not having access to the proposed development. It will be noticed that the piers are not laid out at right angles with the canal itself but diagonally, an arrangement which gives an easier access from the piers to the canal. Docks for barge accommodation are also included in the lay-out for the purely local trade from the Passaic and Hackensack Rivers and New York Bay. The total length of the pier frontage is 115,000 ft. or 22 miles, equalling the dock frontage on both sides of the Passaic River from its mouth to Rutherford.

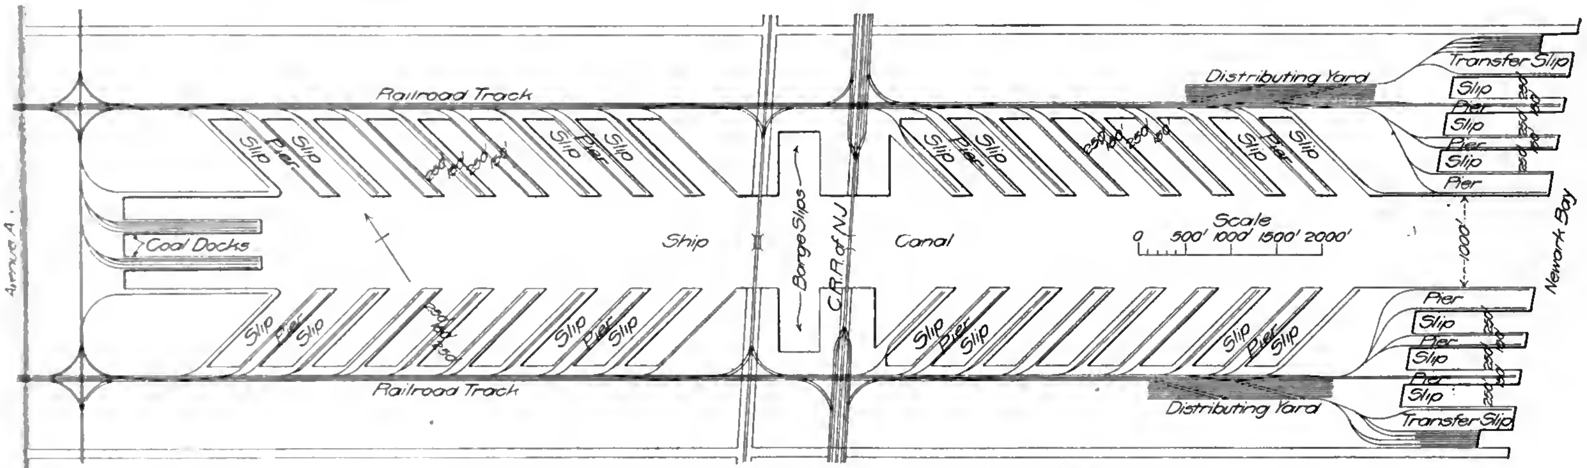
The width of the canal and the proportion of length and width of piers and slips have been settled only after careful consideration of the probable public requirements at this particular location, and from the experience of other places. The width of 1,000 ft. in the canal will give ample room for through communication in the canal and the complete handling of the largest vessel likely to enter it. The length of the piers has been determined from the experience in New York and Brooklyn and elsewhere, and gives room for two or three ordinary vessels, thus giving the greatest rental value for a minimum of expense for construction.

One of the most vital points in the whole plant is the method of communication with the country at large. There are four things to be considered, water communication, which the works are proposed to facilitate; railroad communication in all directions; trolley communication for local car service, and highway facilities for immediate delivery of freight. On the tract in question or immediately adjacent to it are the lines of the Pennsylvania, Lehigh Valley and Central of New Jersey railroads. The plan provides a system of tracks and switches with connection for one or two car tracks on each pier, so that any car at any given point can be taken to any other given point in the system, or be transferred to any of the trunk lines. Two assembly yards have also been designed, and directly connected with them are transfer slips for cars to be hauled away in any direction by water.

Two highway connections are designed as part of the system, one at the west end of the lay-out and one at the center. These highways can be constructed with tracks on them for trolley service.

In addition to the necessary strip of land required for complete access to every point of the development, it is proposed to reserve a strip of land extending nearly 1,000 ft. in width on each side of the piers and slips for future use as may be required, such as for warehouses for storage and for manufacturing plants which may find the facilities favorable for any specific industry. It is believed that this reservation is of the utmost importance in order to complete the system, and the land may be brought to grade by using the material excavated in the main channel in the bay and in the canals and slips.

The construction of these works is stated by Mr. Owen to present no difficult engineering problem. The surveys recently made show an average depth of about 10 ft. of black meadow soil and under this a deposit of unknown depth consisting of sand and clay. All the material excavated can be used to advantage in the construction of the piers and wharves, and by a judicious selection of such materials for different requirements great economy can be attained.



The Proposed Dock and Canal System on the Newark Meadows.

Concrete Fly-Wheels are reported in the "Engineer," of London, to be in use at the Zwaartkoppies pumping station of the Rand Water Board, near Johannesburg. The supply is derived from twenty bored wells, 150 to 210 ft. deep, operated in pairs, to balance the working parts of the pumps. The two wells of each pair are about 120 ft. apart. The pumps are of the plunger type, the diameters of the plunger and cylinder being 10 and 14½ in., respectively, and the length of stroke 36 in. Both pumps for each pair of bore holes are driven from one crank shaft through a gearing by an electric motor. On each shaft is an 8,000-lb. 14-ft. fly-wheel, with a reinforced concrete rim. A cast-iron boss is secured to the shaft, and into this sixteen arms, each made of 4-in. iron pipe, are screwed. Near the outer ends of the arms a ring of ¼-in. iron plate is secured with lock nuts, and around the extreme ends of the arms is fixed a second sheet-iron ring, which forms the periphery of the wheel. The space between the two rings is filled with 1:1½:3 concrete. The concrete rim is reinforced with four ¼-in. rods. The rim alone weighs about 6,000 lb. As the wheels make only 20 r. p. m., their use involves no risk of serious accident, and they are reported to have proved very satisfactory.

A Six-Span Highway Bridge at Catskill, N.Y.

A six-span reinforced concrete highway bridge, over Catskill Creek, having a total length of 450 ft. between the abutments, was finished during the past summer at Catskill, N. Y. The bridge has a clear roadway of 25 ft., a walk of 6 ft., and provision for a single street car track. Each arch has a span of 69 ft. and a rise of 8 ft. 6 in., the thickness at the crown being 16 in., and at the haunches 3 ft. 3 in. Four of the piers are 6 ft. wide, while the center pier is 12 ft. wide. All of them rise about 14 ft. from the footings to the springing line of the arch.

The spandrel walls retain a solidly tamped earth filling on which the roadway is laid. This consists of a slab of concrete paved with Catskill brick. The footwalk has a granolithic finish. The hand rail on each side of the bridge is of simple design, consisting of a rail of concrete cast in place and carried on rock-finish balusters set rather close together.

The centering for the arches was supported upon bents built without sills, the posts being cut of proper length to conform with the rock surface. Six bents were required for each span. They consisted of five 10x10-in. posts cross braced by 3x8-in. timbers. The centering consisted of five framed ribs parallel to the axis of the bridge, and carried upon the bents on wedges. The bottom chords of the centers were of 8x14-in. timbers, while the top chords consisted of three 3x12-in. boards. The framing was of 8x8-in. material. The rib carries 3x9-in. stringers placed transversely on 2-ft. centers and on them was laid longitudinal lagging of 1-in. dressed lumber in 12-ft. lengths. The timber for the centering and bents was obtained from the old bridge.

The work was started in August, 1906, and before cold weather set in the abutments, piers and three of the arches were completed. Work was then suspended during the winter until April of this year, when it was again taken up, the structure being finally finished early in July. The quantity of concrete in the structure is about 4,000 cu. yd., and the total contract price was $43,250.

Six-Span Highway Bridge over Catskill Creek at Catskill, N. Y.

The arch reinforcement consists of twisted steel rods, the longitudinal rods being of 1-in. material on 2-ft. centers, and the transverse rods of ½-in. material on 2-ft. centers. The reinforcement of the hand rail consists of two 1-in. twisted steel rods in the base and one 1-in. rod in the hand rail. The spandrel walls contain no reinforcement except immediately over each pier where two 1-in. twisted rods have been placed to prevent cracking in the railing due to settlement of the piers. The latter have no reinforcement.

The concrete for the arches was a 1:3:5 mixture, made with crushed limestone and trap and Catskill Portland cement. The railings are of a 1:2:4 mixture. All of the concrete was cast in place except the balusters, which were made at the contractors' plant in Hackensack, N. J. A Ransome mixer was used in making all of the concrete at the bridge site.

No especial difficulties were encountered in the construction of the bridge, and though the creek rises rapidly at times, the contractors were fortunate in escaping any serious floods. An old bridge which spanned the creek at this point was removed before beginning the new structure. During construction the traffic was diverted to a bridge lower down on the creek. All of the piers are founded on solid rock.

The bridge was designed and built by the F. R. Long Co., Hackensack, N. J.

An Unusual Boiler Plant is in use at the Moran ship building plant at Seattle, Wash., consisting of a battery of 12 vertical fire-tube boilers arranged in a circle around a refuse burning furnace by which they are heated. The boilers are 5 ft. in diameter by 18 ft. high and the circle is 19 ft. in diameter. The refuse burning furnace has a large conical grate. The space within each boiler constitutes the combustion chamber from which the gases pass down and thence up through the boiler tubes to the chimney, a large conical shell covering all the boiler tops and terminating in an 8 ft. stack. The refuse, consisting of slabs, sawdust and waste material from the saw mill, is fed to the furnace from a large elevated hopper, into which it is delivered by a conveyor from the mill. The entire boiler plant is easily attended by one man on each shift. The saving over the use of coal, at present prices in Seattle, is stated in the "Marine Review" to be over $100 per day.

The Artesian Water Supply of Australia.

By C. O. Burge, M. Inst. C. E.

There is such an extensively utilized artesian area in the United States that it is of interest to learn what is being done in this work in other parts of the world. Recently nearly all the inhabited parts of the Commonwealth of Australia have been blessed with ample rains, and in consequence a boom in production of all kinds has followed. In former times such occurrences there led to the extraordinary delusion that drought would never recur, and few steps were taken to provide against it. Railways were more or less rapidly pushed into the interior, forgetful of the prime necessity of giving them something to do in those almost regularly recurring periods when, as regards the inland districts especially, the rainfall was much below the average, and crops and stock suffered seriously. To any one who has once ridden over these drought-stricken plains of Australia the recollection is vivid indeed. Boundless vistas, with stunted bush and bare brown surface below, and above the prodigal sun and the brassy sky, for months unsoftened by even a fleecy cloud; skeletons of sheep all around the dying flocks, which are scarcely able to reach food or water, if either could be found; the trunks of the shadeless gum trees, gnawed for food by the gaunt rabbit, too weak to run from under the horse's feet; and all this with the deceptive mirage spreading out, in the distance, lakes of visionary water, with trees and rocks reflected in its shining surface—all these are things never to be forgotten.

The want of prevision which has prevailed so much in Australia has never existed in India, the natives to the best of their ability providing irrigation works on an extensive scale in remote ages, and the British adding to them by the magnificent works which, side by side with the construction of railways, have given an ample return for the large capital expenditure incurred. As an instance of what is here stated, New South Wales, the greater part of the area of which is subject to these periodical droughts, has practically done nothing, commensurate with its wants and capabilities, in the conservation of surface water, beyond surveying and reporting, until a few months ago, when a great scheme for the utilization of the Murrumbidgee River waters was decided upon. This will undoubtedly reclaim a large area of possibly drought stricken, though otherwise fertile, land. Victoria, though her needs are not so great, owing to a generally more regular rainfall, has been somewhat more vigorous in the past, but, taken as a whole, irrigation has been exceedingly neglected throughout Australia. The future prospects of the commonwealth, therefore, are all the more hopeful now that some substantial efforts in this direction are being made, showing that if, generally, a prosperous career has, so far, been the characteristic of the Southern Continent of the British Empire, how much more will this be the case under the newly awakened condition of its inhabitants as regards the value of water.

Among these substantial efforts are the utilization of the artesian water which has been going on for some time in Queensland and New South Wales, and, though the quantity of water from bores is insignificant, as compared with that from surface supply, and though it is limited to the artesian area, large as that is, yet a great deal has been done chiefly in the direction of watering stock. An ideal artesian basin is only to be found where the water-bearing strata dip in the middle of the area, outcropping all round at a higher level than that of the surface at the sites of the bores. Most of the artesian basins known throughout the world, however, are not of this ideal character, there being a break in the continuity of the porous outcrop somewhere, leaving a leakage, which more or less seriously draws away some of the supply otherwise released by

the bore. The great artesian basin of Australia is of this latter type, the intake beds outcropping along its eastern and northeastern sides only, while the remainder of the water-bearing formation leaks into the Gulf of Carpentaria or is hidden under the superficial deposits forming the plains of the interior of the states.

With a map of Australia before us we can easily trace the boundary of this great area. Beginning at the southwestern coast of the Gulf of Carpentaria, it runs irregularly southward to the 25th parallel of latitude, thence westerly to about 133° east longitude, thence south to the 31st parallel, along which it bears easterly, but with many indentations, to near the town of Dubbo, in New South Wales, which is the southeastern limit. The eastern and northeastern boundary, from which the chief supply comes, is roughly parallel to the east and northeast coast, about 150 miles from it in New South Wales, and over 200 miles in Queensland, joining the coast again about 100 miles from Cape York, on the eastern side of the peninsula of that name.

The greater portions of this area are in Queensland, 376,000 square miles, and in South Australia, 110,000 square miles, but in the latter it is mostly in an undeveloped and unexplored territory, while the smallest portion, 83,000 square miles, included in the area in New South Wales, is a settled, though not populous, district. The area of intake beds is about 50,000 square miles in Queensland, and 18,000 square miles in New South Wales. Victoria and Western Australia are both outside the area. Except for a strip about 100 miles wide on the eastern and northeastern side, the area is within the zone of 20 in. annual rainfall, and further inland of the 10-in. zone, and it is the character of these zones to absorb and evaporate much of the rain falling on the surface. The Murrumbidgee, the Lachlan, Darling and other rivers are much larger in the middle of their course than at their outlet, where they join the Murray, the water spreading out into lagoons between these points and being lost largely by evaporation.

To return, however, to the artesian area. This has, in the opinion of some experts, ocean outlets not only at the extreme north, as shown by the description of the area given above, but also to the great Australian Bight, to the south, but the latter view is disputed, and Professor Gregory, of Melbourne, opposes it. In his recent work, "The Dead Heart of Australia" (1906) he says: "The only available outlet is northward over a rock barrier into the Gulf of Carpentaria, or possibly eastward to the South Pacific. The fact that the main artesian basin has no regular outlet and is enclosed by a rim complete to west and south, and has only a narrow shallow lip to the north, and perhaps another to the east, shows that the deep central waters are old accumulations. The wells are the modern artificial outlets from a vast reservoir, which is almost entirely enclosed, and the waters discharged from it must have been collected during the course of centuries and probably of past millenniums. Nature has stored up a vast but probably a limited supply in a safe underground reservoir. That water, if prudently used, would probably last till Central Australia were so well occupied that it could afford to provide a more costly supply." As to leakage from the basin, Mr. Pittman, the government geologist of New South Wales, points out that any accumulation of water, underground or surface, must eventually become salt, unless it has an outlet, due to dissolution of saline matter from rocks or soil, and that, therefore, all artesian basins affording potable water must have leakage.

A recent interesting and voluminous paper on the artesian resources of New South Wales, by Mr. Percy Allan, M. Inst. C. E., M. Am. Soc. C. E., read at the University of Sydney, and the valuable annual reports of Mr. J. B. Henderson, M. Inst. C. E., hydraulic engineer for the Queensland government, enable fairly up-to-date figures to be given on this subject. The first bore in New South Wales was in 1879 on the Killara Station, between Boweke and Wilcarmia, which, though successful, was on a small scale, being only 140 ft. deep, but the owner of Kerribee Holding, near Bourke, followed with one of 1,073 ft., yielding 350,000 imp. gal. per day. The government started work in 1884, and up to the date of the latest figures there are 412, of which 41 have been failures. Of these bores, 130 have been put down by the government. The deepest bore in the state is that at Dolgelly, near Moree, 4,068 ft. deep, but the finest example, taking the flow into consideration, is the Euraba bore, in the same district, at a depth of 4,005 ft., giving a flow of 1,097,420 imp. gal. per day, the finishing diameter being 6 in. Mr. Allan gives the following average example, occurring at Rowena, near Walgett. This bore was sunk to a depth of 2,669 ft., at a cost of $11,880, having a flow of 924,990 imp. gal. per diem, which, by means of 41 miles of distributing channels, constructed at a cost of $4,051, including headworks, divisors, drops and culverts, waters 55,405 acres. The total cost was about $16,195, the benefit derived, according to experts, being about $1,920 per annum. The rate charged was equivalent to 0.022 cents per 1,000 imp. gal. The temperature of the artesian water at the bore mouth varies from about 78° to 135°, not always according to depth, but exposure to the atmosphere quickly reduces it, as a rule. However, the district being largely in the hottest part of New South Wales, the temperature of the air is occasionally higher than that of the water. The present writer once used, in the hot season, the baths at Moree, supplied by artesian water at 110°, from a depth of 2,793 ft., and could not make up his mind whether the air or the water was the cooler or more refreshing, or, perhaps metaphorically, which was the frying pan and which was the fire.

In Queensland the government was first in the field at Blackall, and there are now over 1,130 bores, of which about 11 per cent. were put down by government. Many inland towns are now supplied with water from artesian bores, among others Blackall, Cunnamulla, Aramac, Charleville and Roma. The deepest bore is that at Bimerah, which was sunk 5,045 ft., but the supply is small, while the aggregate amount of sinking for the whole state is upwards of 225 miles. The highest flow from any single well is 4,000,000 imp. gal. in 24 hours. Trouble, of course, arises from the presence of alkalis in both states, this being, according to Mr. Henderson, inimical to plant life when over 30 grains per imperial gallon are found. The mineral salts in these waters generally exceed those in the artesian supplies of America, but, on the other hand, the soil in the latter, within the districts served, is more impregnated, and the combination is frequently greater than in Australia.

It is, however, generally agreed that, with some exceptions, on account of quantity and quality, artesian water in Australia is not suitable for irrigating crops, except on a very small scale, but immense possibilities are in view from its provision for keeping stock of all kinds in good condition at all times, and in preservation of life in times of drought. A bore with a flow of 1,000,000 imp. gal. per diem, while only capable of properly irrigating some 400 acres, will provide sufficient water for stock purposes over an area of about 80,000 acres. Extending right through New South Wales, in all directions, are strips of country from half to one mile wide, reserved by the government from private sale or use, through which stock travel from one part of the state to another and feed. Where these intersect artesian country, bores are provided at the public expense, there being an average of one bore to 1,280 acres of the reserve. Including these, and summarizing, there are in New South Wales, according to latest figures, 114 successful government bores, serving 2,122,254 acres, and 257 private ones, the scope of which, if in proportion, would bring the total up to 4¾ millions of acres, the stock on which are served by artesian water. In Queensland, whether it is by ill luck or bad management, the proportion of successful to the total number of bores is much less than in New South Wales; 596 constitute the number of the former, these being mostly in private hands. The total daily flow is estimated at nearly 400 million imperial gallons. Though agriculture has been making great strides lately in Australia, the pastoral industries still are, and for many years to come will be, the chief basis of the prosperity of the commonwealth. Hence, it is interesting to know that a still only partially developed adjunct to the unrivaled wool supply of the world which she affords, is available over such a large area as that described in this article.

Book Notes.

The "Proceedings" of the third annual convention of the National Association of Cement Users is a volume of 340 pages of information of the highest value to engineers, architects and contractors. A report of the convention was published in the Current News Supplement of this journal on January 19 of this year, and it is consequently unnecessary to review the contents of the book at any length at this time. It is particularly valuable for the information it gives on the artistic treatment of concrete, waterproofing and concrete block manufacture, although many other subjects are taken up. The association is essentially one for the interchange of information relating to the practical use of concrete, and its "Proceedings" bear witness to this fact throughout. The editing of the volume has been done by the president, Mr. Richard L. Humphrey, who has eliminated irrelevant matter and repetition of ideas with much skill, thereby increasing the value of the contents to the busy reader. (Philadelphia, National Association of Cement Users, Harrison Building; $3.)

About a year ago the Minister of Public Works of France issued a set of regulations concerning the construction of reinforced concrete works. The reprints that have been made of that circular contain many typographical errors and for this reason it is rather gratifying that the first part of the important work entitled "Recueil des Types de Ponts pour Routes en Ciment Armé," by Messrs. N. de Tédesco and Victor Forestier, contains the full text of the circular and the official instructions concerning it. The regulations in question unquestionably form one of the most important indications the engineer has concerning safe design in reinforced concrete, but they are necessarily somewhat vague in many respects, so as to allow the designer an opportunity for meeting individual conditions and following personal inclinations. The object of this work under review is to explain the application of the regulations to the design of highway bridges of 4, 6, 8, 10, 15, 20, 25 and 30 meters span. In the computations for these structures, the authors have endeavored to follow the spirit of the regulations and to utilize those methods of computation which give maximum economy without entailing too elaborate calculations. The book is probably the most complete explanation of the application of such important reinforced concrete regulations that has yet been attempted. In addition, it gives all the details of a large number of computations that cannot

fail to be useful to those who desire to study the methods of design recommended by the authors. This study is much facilitated by an atlas of plates giving to a large scale the drawings of the various bridges referred to in the text. These are essentially working drawings and are executed in an excellent manner. (Paris, Ch. Beranger, 15 Rue des Saints-Peres, 25 francs.)

The attention of all interested in the teaching of mathematics in engineering schools is particularly drawn to the first volume of "A Course in Mathematics," by Prof. F. S. Woods and Prof. F. H. Bailey, of the department of mathematics in the Massachusetts Institute of Technology. This volume is the most important American outcome of the deep impression recently made by the advocates of a reform in the methods of teaching mathematics. Such instruction may be viewed from two distinct standpoints. If the purpose of the instruction is to introduce the student to mathematics as a branch of pure science, in which he may later carry on research work, the best method may possibly be different from those adapted to acquainting a prospective engineer with one of the most useful helps science has to offer him. It is generally held to-day that without any sacrifice of accuracy the methods of instructions best adapted for the mathematical classes in a technical school are those which carry forward at the same time various branches. In the old methods of instruction it was customary to finish algebra before taking up analytical geometry, to finish analytical geometry before taking up the calculus and to finish the calculus before beginning mechanics. As a result of this it was only students with good mathematical memories who were able to appreciate as fully as desirable the relations between the various branches. Such a plan is entirely abandoned in this new course, which, it should be stated, was prepared at the invitation of Prof. H. W. Tyler, head of the mathematical department of the Massachusetts Institute of Technology, and has received the benefit of his criticism. In the first volume, which alone has appeared as yet, there is an introductory chapter on methods of elmination, including the use of determinants. The student next takes up the methods of plotting functions, and is thus introduced early in his course to this valuable practical method of understanding an equation. The study of the algebraic polynomical, including the analytic geometry of the straight line, the more important theorems of the theory of equations, and the definition of a derivative comes next. This enables the student to obtain early an introduction to the principles of the calculus, which is particularly desirable. The study of the algebraic function in general is next taken up, and in doing so the student's knowledge of analytic geometry and calculus is enlarged by new applications of the principles previously stated. Simple integrations are also introduced at this time. Curves are taken up and the student is introduced to this interesting portion of analytic geometry without being confused by the idea that it relates solely to conic sections. After this, the study of elementary transcendental functions is begun and finally the year's course closes with a study of the parametric representation of curves, polar co-ordinates and curvature. It will be noticed that no work in three dimensions is taken up in this course, that being deferred for the second year. It has already been stated that the book is primarily for the use of engineering students; it may be questioned, however, whether the student who takes up mathematics as a branch of a liberal education will not find this method of approaching the subject more satisfactory than the traditional one of attacking one branch at a time. The relations between the several branches taught in undergraduate courses is so intimate that it is safe to say only a student of exceptional natural mathematical ability can acquire so good a knowledge by pursuing one branch after another as by taking them up in the way outlined by Professors Woods and Bailey. It should also be stated for the benefit of engineers who wish to review their mathematical studies that this volume will be found an excellent help for the purpose. It is clearly written, well printed and illustrated, and contains a large number of examples which will be particularly helpful, for it is a well-known fact that a thorough comprehension of a mathematical method is only possible after it has been applied in the solution of a well selected set of problems. (Ginn & Co., Boston; mailing price, $2.40.)

A book that should prove instructive to a wide circle of readers is the "Balancing of Engines," by Mr. Archibald Sharp, who has already contributed a paper on certain features of this subject to the "Proceedings" of the Institution of Civil Engineers. Some ten years ago the methods of balancing were mainly of importance to locomotive designers, but since then there is hardly any prime mover in which balancing has not become prominent. When alternating current generators came to be operated in parallel, the balancing of steam engines at once attracted general attention, and during the last two years everybody interested in automobiles knows that the most debated subject is the relative advantages of six and four-cylinder engines, which depend primarily on the balance of the two types. Up to the present time about the only volume discussing the subject in a detailed manner has been one by Prof. W. A. Dalby, and this smaller work by Mr. Sharp is consequently of particular importance. It is much simpler than the book referred to, and employs graphical methods to a greater extent than the work by Prof. Dalby; the difference in the assumptions made at the outset of the two discussions may lead the reader to believe the results in the two treatises are different, although the difference is only apparent. The volume is unusually thorough, beginning with the primary phenonoma of motion and force and the preliminary theorems in mechanics which are essential for a proper understanding of the problems and methods of balancing. The inertia forces of revolving and reciprocating masses, the inertia forces of second and higher orders, and the transverse couples due to connecting rods are discussed at length. Engines with cylinders in different longitudinal planes receive especial attention. The author then takes up in turn the kinetic energy of pistons and connecting rods, the torque on crank shafts, primary and secondary balances, and finally the displacement of engine frames due to unbalanced forces and couples. There is a special chapter on the engines best adapted for various purposes, considered with respect to their balance, and finally the author gives a forecast of the future development of large gas engines. To make the work as useful as possible to students, a series of exercises, with answers in some cases, is appended at the end of most of the chapters, some of these questions being taken from the papers set at the qualifying examinations of the Institution of Civil Engineers. Some portions of the book are entirely new, others are taken from the author's paper previously mentioned, and the author expresses his especial indebtedness to the work by Prof. Dalby. On account of the widespread interest in the subject, the appearance of a book by one who has made such a specialty of it, is particularly timely. (New York, Longmans, Green & Co., $1.75.)

Letters to the Editor.

TEMPERATURES IN BEEHIVE COKE OVENS.

Sir:—Can you refer me to any information on the temperatures in beehive coke ovens, both inside the oven and on the back of the retaining walls? I am interested in the design of a concrete oven and will appreciate any information you can give me on the subject. Yours truly,

E. HORTON JONES.

Dawson, N. Mex., Oct. 9.

[There is very little information available in the usual sources of such data concerning the temperatures of coke ovens. Probably tests to determine them have been made, but they have not been recorded for ready reference. The temperature within a coke oven of the by-product type, as shown by tests reported by Dr. Schniewind in Sydney and Mr. Hilgenstock in Germany, probably does not much exceed 1,800° Fahr. at any time during the coking operation. It does not necessarily follow, however, that this is the maximum temperature in a beehive oven. In the latter the heating gas burns under the arched roof, heats the brickwork of the roof and the heat is reflected upon the charge of coal beneath. Therefore, the temperature of the roof is very probably higher than that of the charge itself. In the same way, in a by-product oven, the gas burns in the flues, heating the coking charge by transmission through the oven walls. The heat in the flues is unquestionably higher than any temperature the coking charge itself will reach.

In a general way, it may be said that the inside of a beehive oven in full operation will be light red to orange in color, though the heat is not always so great as this. Refractory materials of excellent quality are needed for the roof of a beehive oven, but this is particularly because the hot walls are quenched by water from a hose when the coking of a charge is finished, the sudden cooling being very severe upon any quality of fire-brick as may be imagined. Concrete is manifestly bound to fail if used for a lining. Just what is meant in the inquiry by the temperature "on the back of the retaining wall" is a little indefinite. If it means the temperature at the outer surface of the firebrick lining of the oven, this is probably a low red temperature, or even hotter, depending on whether the bricks are exposed to the air or covered with masonry. In conclusion it might be said that inquiry among oven operators shows that the only way of testing a new form of construction is to build a few ovens and operate them regularly.—Editor.]

THE OCEAN PIER AT LONG BEACH, CAL.

Sir:—It is a problem of no mean proportions to build an ocean pier of any considerable length, and one that will endure, on the Pacific coast. In the first place, storms coming from the northwest, west or southwest, sweep full force against the coast, having no bar to encounter. In the next place, these storms are frequently of great violence and roll up tremendous seas against the shore line, and it takes a very solid structure to withstand their force when exposed to it. Again, there are very powerful undertows on the Pacific coast, and there are, therefore, strong submarine forces to be resisted in ocean pier construction, at the same time.

Yet, along the California coast quite a number of piers of this class are maintained. Some are designed for the handling of freight and passengers, while others are mere pleasure wharves located at popular seaside resorts. One of the most substantial and up-to-date piers of the latter class is at Long Beach, a resort that gets the great bulk of its patronage from Los Angeles and contiguous region. It was designed by, and constructed under the supervision of Mr. Howard C. Holmes, of San Francisco.

It is composed of a wharf and a double-decked approach. The wharf is 100x300 ft., while the approach is 1,299 ft. long and 32 ft. wide.

The water at the outer line of the wharf is 30 ft. deep at low tide, and both wharf and approach are supported by reinforced concrete piers, after Mr. Holmes' well-known patent. The longest cylinder pier used on the construction is 56 ft. in length, and the piers generally are driven from 10 to 18 ft. into the ocean bottom, which is composed of sand. They are all 4½ ft. in diameter, and those supporting the wharf proper are placed 16 ft. apart on centers.

The approach is built of bents, 20 ft. on centers, consisting of two 12-in. I-beams for caps, supported by two reinforced concrete cylinder piers. The stringer system supporting the main deck consists of 4x16-in. Oregon pine timbers, on 2-ft. centers, excepting under the line of posts supporting the upper deck, where 12x16-in. sills are placed to support the superstructure. The outside stringers are of 6x16-in. Oregon pine timbers, and these with all of the above-mentioned stringers, are attached to the double I-beam caps, with cross-clip and I-bolt fastenings, thus avoiding boring and framing the stringers. Both sides of the approach are lined with heavy hand rails supported by 6x6-in. posts placed 10 ft. on centers. The middle of the roadway is used for teaming; and there is a walk on either side, 6 ft. wide, for promenading and fishing.

The upper deck of the approach is 21 ft. wide and 13½ ft. between decks. The upper deck is supported by 12x12-in. posts on 10-ft. centers, having 19-ft. spans in the clear. The main cap of the posts consists of 12x16-in. timbers tenoned into the posts. The deck is sheathed with a double layer of cedar planking. The stringer system consists of 3x10-in. Oregon pine timbers, 2 ft. on centers. The outside stringers are composed of 6x10-in. timbers. The hand-rail on either side of the upper deck consists of 4x8-in. timber supported by 6x6-in. posts, 10 ft. on centers.

Ornamental braces from main posts to main caps supporting the upper deck, materially strengthen that part of the structure. The brace is in the form of a bracket built up of 4x4-in. angle irons placed back to back, the whole forming a very rigid brace, and at the same time obstructing the roadway in the minimum. The upper deck is sway-braced longitudinally with 4x10-in. timbers.

In order to make the structure as attractive to the eye as possible, it is painted throughout. The sub-structure is of a deep maroon with cylinder hoops painted black for an agreeable contrast. On the main roadway all railings and exposed woodwork are painted a rich olive green, while the hurricane deck is left dead white. At the end of the pier proper is a pavilion patterned after a Swiss chalet. In this pavilion every afternoon an instrumental concert is given at the expense of the city of Long Beach. Surrounding the pavilion are refreshment booths and space for those who desire to fish from the wharf. The wharf is also arranged for the mooring of vessels of any size.

This wharf has now withstood the fury of the Pacific gales for four years without showing a sign of weakness, although the waves sometimes break to a height of 24 ft., and the sands underlying the sea are at times plowed up to a depth of 13 ft. by the powerful undertow.

Yours truly, H. A. CRAFTS.

RELATIONS OF THE PUBLIC SCHOOL TO THE INDUSTRIAL TRADES.

Sir:—The engineering public is at the present time deeply interested in matters relating to education in industrial lines. The old time apprentice system has been worn threadbare; in fact, it has almost ceased to exist. Modern manufacturing methods tend only to the making of the specialist in machine tool operation, or in hand work. Excessive specialization has thus prevented the development of the all-around mechanic, and what is more vital still, of the broadly experienced, competent manager of men, the foreman or superintendent. Sporadic instances have appeared during the past few years where manufacturers have sought to establish effective means of giving their young employees a more general knowledge of the specific industry than can be obtained through any of the ordinary channels. Privately-maintained trade schools have bent their efforts to supplying the opportunity for those to learn who really want to learn a trade.

The public schools have assuredly been lacking in their ability to cope with the problem. The manual training school has laid the foundations for the engineering professions rather than for the mechanical trades.

With this exception, vocational training has been practically non-existant in the public schools, and even direct preparation therefor has formed a meagre part of the curriculum.

But it is now generally recognized that the concerted effort of the municipality and the commonwealth is necessary to provide what the middle, the so-called working classes, so much need, namely, education in particular trades.

It is not surprising that Massachusetts should be taking the lead in this movement. Through a Commission on Industrial Education, it is working out plans by which vocational schools may be established and maintained at the joint expense of city and state. Evening schools are already operated under these conditions.

But particularly interesting, as indicative of the trend in education, are the changes which are now being made in the school system of Boston. A radical move has been made in the reduction of the elementary school course from nine to eight years. This will provide for an earlier entrance upon industrial training.

There has been a distinct change in the ideals. Teachers are no longer to measure their success by the number of pupils that reach a certain fixed and traditionary standard of scholarship. Success will rather be judged by ability to provide work of such a nature that all of the scholars not grossly indolent can reach a satisfactory standard: To have twenty per cent. of a class fail to pass is full proof either that the work is not adapted to the class, or that the teacher is inefficient, and yet in many classes, the percentage of failure has risen to thirty-five or even forty per cent.

It is boldly asserted by the Superintendent that "if now and then a pupil should fail to do the work, it would perhaps be justifiable to say that he is not qualified to profit from high school instruction, and that he should be excluded from the school; but when twenty-five per cent. of all pupils in the high schools of the city fail to do the work required, a course of exclusion cannot be successfully defended. These pupils are as justified in demanding high school instruction adapted to their needs, as are the pupils who find it possible to do the work now offered."

Consideration is therefore being given as to how the high school needs to be modified in order to make pupils meet the present standards. Investigation has shown that out of two thousand boys seeking employment, nearly fifty per cent. would have remained longer in school could they have been taught even the rudiments of a trade.

Already a Girls' High School of Practical Arts has been established, with a course of study four years in length, with conditions of admission and graduation equivalent to those required in the regular high schools of the city. Its purpose is to give a greater opportunity for development of that type of pupil whose talents lie more in lines of doing and expression than in lines of acquisition.

The High School of Commerce is just entering upon its second year. This is definitely a vocational school, seeking to give the most effective preparation for participation in commercial life.

For many years it has been impossible to admit to the Mechanics' Art High School all of the pupils applying for admission. The facilities are now being largely increased. It is manifest that the ideals of this school will need some adjustment in order that the training may be made more definitely vocational.

It is recognized that efforts to incorporate industrial training in the elementary schools must still be looked upon as experimental. To this end changes are being made in the courses in certain districts under which certain boys will be given a much larger proportion of industrial training than is provided in the regular course.

The evening schools continue to give more or less vocational training. The teachers realize that a great many people are seeking industrial and technical instruction in correspondence schools. In fact, the Director frankly states that "the instruction pamphlets published by some of the correspondence schools on technical subjects are superior to anything I have seen in public school text books."

To rival such instruction in the evening schools, or in day schools devoted to vocational training, would manifestly entail large expenditures for equipment and maintenance. The problem is, however, simplified by the attitude of the state through its Commission on Industrial Education. In accordance with the law, and under the supervision of this Commission, municipalities may be in part reimbursed for such expenditures as they may make for the maintenance of industrial schools. This Board is instructed to consider and report upon the advisability of establishing one or more technical schools or industrial colleges, providing for a three or four years' course of extended training in the working principles of the larger industries of the commonwealth.

The Commission already expresses its belief that for pupils of fourteen or fifteen years of age, four years' instruction might be provided, so that the first two years would cover general shop instruction relative to mathematics, drawing, natural science, and English, and that the work of the last two years, or which could be gradually completed during a longer period in the evenings, or on the part-time system; meaning part of the time in the factory or shop, and part of the time in school during working hours, whether in the same day or at intervals of several days, or even weeks, by pupils who were obliged to go to work at sixteen, should give the shop instruction for particular trades. The Commission intends to provide effectively for evening pupils, and to make every effort to secure the co-operation of employers, to the end that part time courses for apprentices may be established in the proposed schools.

The efforts in Massachusett and other states will be watched with much interest, in contrast to those being made in the trades themselves, under the direct supervision of the employers. It is reasonable to anticipate that eventually the best results will be obtained through a harmonious combination of effort; the public schools laying the foundation, and the respective trades furnishing the superstructure. C. E.

Boston, Nov. 7.

LIGHTHOUSE CONSTRUCTION is being conducted under great difficulties at the Ar-Gazeck reef on the French coast near Ushant. The late Eugène Potron left £16,000 toward the construction of this light, which the government undertook to build. During 1904 the swiftness of the currents prevented more than 52 hours' work on the foundation, more than 206 hours in 1905, and more than 152 hours in 1906. During three years, therefore, only 51 days of 8 hours were available for the work.

THE ENGINEERING RECORD
PUBLISHED WEEKLY BY THE
McGraw Publishing Company
James H. McGraw, Pres.; Curtis E. Whittlesey, Sec. and Treas.
MAIN OFFICES:
239 WEST 39TH STREET, NEW YORK.
BRANCH OFFICES:
CHICAGO: Old Colony Building.
PHILADELPHIA: Real Estate Trust Building.
CLEVELAND: Schofield Building.
SAN FRANCISCO: Atlas Building.
LONDON OFFICE: Hastings House, Norfolk St., Strand.

SUBSCRIPTION RATES.
United States, Cuba and Mexico........... $3.00 a year
Canada .... $4.50 a year
Foreign subscription.......... $6.00 a year
25 shillings. 25 marks. 31 francs.
Foreign subscriptions may be sent to our London office.

NOTICE TO ADVERTISERS.
Changes in advertisements intended for a particular issue should reach the office of THE ENGINEERING RECORD on Friday of the previous week. New advertisements can be received up to noon of Wednesday of the week of issue.

NOTICE TO SUBSCRIBERS.
REMITTANCES.—Remittances should be made by check, New York draft, or money order, in favor of THE ENGINEERING RECORD.
CHANGE OF ADDRESS.—The old address should be given as well as the new, and notice should be received a week in advance of the desired change.
BACK COPIES.—No copies of issues prior to July, 1906, are kept on sale, except in bound volumes.
DATE ON WRAPPER indicates the month at the end of which subscription expires. The sending of remittances for renewal prior to that date will be much appreciated by the publishers.
CLUB RATE.—In acknowledgment of assistance rendered by subscribers in the securing of new orders, a club rate of $2.50 per annum is quoted. This rate applies to subscriptions in clubs of two or more, at least half of the names in the club to be those of new subscribers.

Entered at the New York Post-Office as Second Class mail matter.

Of this issue of THE ENGINEERING RECORD 15,000 copies are printed. Total circulation for 1907 to date 687,000 copies, an average of 14,617 copies per week.

TABLE OF LEADING ARTICLES.

Back-Lash in Engineering Education.

President Schurman's call for a broader training for engineers, upon which brief comment was made last week, ought to arouse active interest and should lead to reforms. To put the matter plainly, a four-year technical course taken from the datum plane of the ordinary collegiate admission requirements fails to put the graduate where he ought to be. Modern science has expanded so rapidly that the best training of the engineer demands more time than is now comfortably available for it. And at present the difficulty is becoming every year more serious. There is a strong feeling among thoughtful educators that for a man to make the best of himself he must have something more than mere technical details in his college course, and the available time is scant even for these details, as the courses are generally arranged. President Schurman's remedy is boldly to increase the length of the course, taking five to six years for it instead of four. Two other ways leading to similar results are open; first, raising the admission requirements; or, second, making the technical course proper essentially post-graduate as Harvard University has done in the case of the Medical School. All these roads lead to practically the same point, a substantial increase in the total time required for a thorough engineering education. It does not seem probable that those who are to be educated will take kindly to the proposition, which will start the young man in independent work at the age of twenty-five to twenty-seven, instead of at twenty-three or so.

Technical education has, as a rule, been built up from the earlier non-technical work in no very systematic way. Courses have been piled one upon another until the aggregate has become burdensome. And going back of technical training, the same kind of unsystematic, time wasting aggregation, bad even if carefully done, burdens the earlier years of preparation. Before adding one or several years to the total, would it not be wise to go down the line and eliminate the back-lash in the mechanism so that the student can be pushed steadily forward, on a piston lift as it were, instead of being pried and jacked up over the present irregular and rather rickety falsework? In the lower schools it is hardy too much to say that indirection reigns supreme. Solemn-visaged "educators" prate by the hour about "natural methods," quite forgetful of the fact that a very large part of the intellectual advance of the human race is due to its success in improving upon these methods. The sad result is that, almost from the beginning of school life, the victim is being dragged over roundabout paths. Nowhere is this tendency more conspicuous than in the study of mathematics, the foundation of engineering. Two or three years of school time are wasted, for example, in pottering over utterly useless ramifications of common fractions. How often does the practical (or theoretical) engineer for instance, have to add 7119/1153 and 419/831, or reduce 0.114 71/79 to its vulgar terms? All the common fractions needed in any proper arithmetical work could be taught the boy of average intelligence in six months of schooling—for the rest leave it to the symbolic treatment of algebra later.

Algebra, which is the basis of all higher mathematics, should be brought into action as soon as its methods direct to the path of least resistance. Why waste brain energy in doing arithmetical "stunts" when algebra was devised for the especial purpose of making them needless? And, similarly, why deal in the further study of algebra with problems which belong fairly in the domain of trigonometry or analytical geometry or calculus? Such indirect methods are not even defensible as mental discipline, since the effort put upon them could be better spent in acquiring facility in attacking the same problems by more practicable routes. Analytical geometry and calculus are not difficult save as they demand facility in algebra, and were a really modern and scientific course in practical mathematics laid out the student, without spending an extra hour of time, would reach college with the elements of these branches thoroughly ground in and with the ability to pick the right method for the problem in hand as instinctively as he would grab the right club out of his caddy bag. As it is in mathematics, so is it elsewhere. If boys learned English grammar instead of wandering through the devious bypaths of so-called "language lessons," there would be fewer complaints of the incapacity of college students to write intelligently their mother tongue. Even more objectionable and time-wasting than these zig-zags along the path of learning are the gay excursions up educational blind alleys. If boys parsed more sentences and painted fewer pansies, learned more history and less rum-and-nicotine physiology they would come up as engineering freshmen with less need for apologies.

There is at least a year of worse than useless educational back-lash, even up to the time when the boy reaches the so-called high school. Here more trouble awaits him. As a rule, the teachers in these upper grades are competent and hard-working, but incapacitated by being cramped between the pressure of the college above and the wallow of the educational theorists below. There has been in the last two or three decades so large an increase in the elective possibilities of college entrance requirements that the demands upon the preparatory schools are very severe. The desire for so-called "enriched" courses, a species of effervescence from the grades below, has put many a stumbling block in the straight path through to the college, and the resulting deficiency in essentials often throws up upon the college a burden of training properly belonging in the preparatory school. The net result is that the student enters upon his serious work about a year behind time, and has then too little time for both a general and a technical training. The first step toward broadening and strengthening the technical courses is the expurgation of tommyrot from the lower schools and the alignment of the preparatory schools for straightforward serious work, such as is done by the better German gymnasia. When this is done there will be a material increase of available time in the university. A broader course there is highly desirable, as President Schurman says. If the time set free in the manner just indicated is not sufficient for such broadening, an extra year may have to be added, but a year saved and well utilized ought to bring about a great change for the better. It would certainly be a step of dubious expediency to lengthen the university course without an attempt to strengthen its foundations.

The Modern Highway.

It has become generally recognized, both at home and abroad, that our highways, as they have been constructed in the past and even the best macadam roads of to-day, will not withstand, without rapid deterioration, the concentrated motor traffic to which they have been subjected since the advent of the automobile. The necessity for some radical change which shall involve an improved method of construction or the introduction of some means of protection and preservation is so apparent that the subject is receiving very general attention. But a short time ago in France the Minister of Public Works was authorized by the Cabinet Council to take the initiative in calling an international congress to consider the maintenance of roads suffering from motor traffic and for devising some means for adapting them to the new conditions which they must meet, and an equal interest has been taken in the subject in England. Massachusetts, always a pioneer in such directions, has devoted much attention to the problem of the protection of its elaborate system of highways and parkways, and what has been done there has been watched with the greatest interest. No one has recently gone over the Revere Beach Parkway, a stretch of three and a half miles in the suburbs of Boston, without remarking on its excellent surface and entire freedom from dust. In the same way the manner in which the dust has been suppressed

on Commonweath avenue and on the park roads under the Boston Park Department, by the application of oil emulsions, has attracted attention. As to the cost of these undertakings, and that of their maintenance, there has been a great curiosity, which has been recently satisfied by the facts given in a series of papers presented last week before the quarterly meeting of the Massachusetts Highway Association in Boston, an abstract of which appears on page 570 of this issue. These data are of extreme interest to all who construct, maintain or use our roads, and they speak for themselves, but there are one or two points to which particular attention should be drawn. The very startling fact is announced and confirmed by several observers in Massachusetts that a macadam road of the best form of construction when subjected to motor traffic will last, at the most, when unprotected in any way, but two years, while, under less favorable conditions, near Lynn, a mile of almost perfect roadway had to be resurfaced after a year. The importance of the problem of maintaining the highways of that commonwealth is, therefore, apparent, even if the state of affairs is not as serious in other localities in regard to which as complete data are not available.

That something can be done to prevent the destruction of macadam roadways by the application of tar and similar substances, and at a cost which is not prohibitive, is very convincingly shown by the data in regard to the Revere Beach Parkway and the macadam roadway in Lynn. The cost of the treatment of the former averaged but 7.3 cents per square yard in 1907, while the maintenance of the work of 1906 averaged, for the entire surface, only 3.5 cents. At Lynn, the cost of tarring was 8.7 cents. With greater experience and with better facilities for working, this will, no doubt, be reduced. The results are such as to encourage further trials. Data in regard to the further cost of maintenance, after two or more years have elapsed, will be looked forward to with much curiosity.

It is of interest to note that roads with gravel surfaces are pronounced more satisfactory for motor traffic than macadam as constructed in Massachusetts, that such roads are more susceptible to treatment with oil, and that gravel or even sand is regarded as superior to crusher screenings as a covering for the tar after it is applied to the road. In France, it must be remembered, sand or the sweepings from the road itself, as it is cleaned before the tar is put on, is the material in use, although it is not spread until at least twenty-four hours after the tar to permit of its absorption. The Massachusetts practice of following up the tar at once with screenings cannot be the best unless the application is so thick that it is sufficient to work up through the screenings under traffic, and such an amount was suggested by one of the speakers.

Massachusetts has done nothing, however, in the way of tar macadam, with the exception of a small experiment of three or four hundred yards in Watertown, and data are sadly needed as to the value of this form of roadway. As properly constructed in England, especially with slag and crude coal tar on the Thames embankment, it has given some satisfaction. Recent experiments in this direction in New Jersey will be watched with care, and will, perhaps, enable us to determine whether the treatment of the broken stone for the second course and for the surface with tar before it is rolled will repay the additional expense involved. It certainly gives the road more elasticity and makes it, to a certain degree, more waterproof.

Another very striking point brought out at the meeting is the great relative economy attained by the Boston Park Department by the use of oil emulsions, as compared with water, in suppressing dust on the park roads, the saving being in the neighborhood of 50 per cent., or $333. per mile, while a distinct binding effect is observed in the surface, as the oil accumulates from the numerous sprinklings.

The papers read at the meeting are a most valuable contribution to the problem of the protection of our roadways and the suppression of dust, and are worthy of very careful study on the part of our road engineers.

The Conservation of Water.

The California case reported a fortnight ago in The Engineering Record, wherein the right of the State to regulate the use of artesian wells was affirmed, awakens a train of thought of serious import. The day is not far distant in which the water supply for the purposes of power and irrigation must be conserved with no small degree of care, and the privileges of individuals must be subordinated to the welfare of the community. In the arid portions of our country long strides have already been taken in this direction. It is hard for those who dwell in a well-watered region to realize how vital is the issue. Those, however, who have seen deserts in California or Navada or Idaho turn at the magic touch into marvellous gardens understand the significance of the decision just rendered. Fancy the situation were all the world arid save for the help given by the mountain snows and a few precious showers. If the ingenuous speculations of Professor Lowell be true, the inhabitants of Mars must have a code of water laws more complete than anything for which this planet can furnish a symbol. It may take well nigh measureless time for the earth to lose its water vapor, molecule by molecule, but the time is already in sight when the diminishing coal supply and the extremes of flood and drought due to denudation will combine to demand action for self-preservation.

One of the features of the California case was the attempt to defy the authority of the State by hiding behind the poor overworked misconstrued Fourteenth Amendment. It furnishes a strange example of an enactment made within the memory of the jurists who interpret it to serve a specific purpose, which they and all men understand, and which has been applied chiefly not to the protection of the grievously oppressed, but to the bare use of individual or corporate adventurers halted by the arm of the Law in attacks upon the rights of the community. In this instance, fortunately, a decision of the United States Supreme Court furnished a precedent directly applicable and affirming the rights of the community in subterranean water by whomsoever the overlying strata might be held. The common rights in "great ponds" and in navigable streams seem also to be beyond the grasping reach of individuals, and the common interest of riparian owners in other streams has been over and over confirmed by statute. It may be pertinent to go a step further and to inquire how far a man is at liberty, for his own private gain, to damage his neighbor's water supply. Has a perverse holder of land the right to injuriously deprive his neighbor of the natural flow of the stream? To press the question home is the holder of a portion of a watershed not liable for the use he makes of it if that use injures others, and is not the State well within its rights in restricting such injurious use? In the case here considered the Judge stated, "it is settled law that all property is held subject to the exercise of the police power," and this power has been repeatedly exercised to protect all those things in which the community has a contingent interest.

In the case of the water supply for power or irrigation, such interest has been clearly and fully recognized. Would it not be well within the proper powers of the State to prevent such indiscriminate denudation of the watershed as would injuriously affect the natural flow of a stream? The questions of fact in such a case may be somewhat intricate. In some instances denudation is permanent unless checked by deliberate reforestation, in others the effect is temporary and the damage is in part naturally repaired. Yet the situation to-day is a serious one, taking the country as a whole, and it is certainly pertinent to inquire whether there is not some more prompt and effective way of preventing irreparable damage than by creating forest reserves. It seems to be well established that the value of forest lands is enhanced by careful management, and not a few large owners of such lands are working them with due regard to the future. If cutting is done in accordance with the principles of sound forestry, the damage to forested watersheds is negligible and the situation may even be improved. It looks very much as if there were a fair opportunity for the State to step forward and say to those holders of forest lands who misuse them: "You shall not so deal with your holdings as to damage the rights of the community to the natural flow of its streams, any more than you are at liberty wantonly and injuriously to divert these streams where they pass over your holdings." The State of New York has done well at last to conserve its public lands and hydraulic rights. Why should it hesitate to prevent damage to these rights by the misuse of private lands? Forestry laws cannot be regarded as confiscatory, but only as regulative, and in the existing state of affairs they seem absolutely necessary to the future welfare of the community, which, however neglected by individuals, it is the duty of the State to guard.

The Proposed Henry Hudson Memorial Bridge at New York.

The proposed Henry Hudson Memorial Bridge as a masonry structure with its main feature a reinforced concrete arch of 710 ft. clear span is one of the boldest ideas of modern engineering. It was described in the Current News Supplement of the last issue of The Engineering Record. While it is not impossible that some of the minor architectural features of this new design may be criticized, it scarcely seems probable that such dignified, graceful and structurally effective plans for this great memorial bridge will fail of approval of the Art Commission. It does not often happen that the natural features of a location afford such a remarkable opportunity for a monumental bridge as do the surroundings at Spuyten Duyvil, and although various types of structures may harmonize with the setting of the bridge site, there can be no question that the masonry arch is one of the best. The massive dignity of the masonry arch, simply treated so as to give well-balanced and graceful proportions, combines both beauty of outline and structural force. The Bridge Department of the city has therefore acted with sound judgment and good taste in adopting a homogeneous composition of the masonry type, after being convinced of its structural practicability for such a large span.

The monumental character of masonry construction has been fully recognized for centuries, but never before in such a striking manner. The topography at the chosen crossing of Spuyten Duyvil valley affords an opportunity for giving the main arch a relatively great rise, which permits the use of a much longer span than would otherwise be feasible. It has been assumed by some engineers that the limit of length of an arch of masonry of any kind is about reached in

existing structures; in fact, it has been assumed in some cases that it would not be feasible to build even a reinforced concrete arch of a materially greater span than about 350 ft. In reaching this conclusion, the influence of a great rise has obviously not been sufficiently recognized. The 220-ft. clear span of the Cabin John bridge held for many years the primacy of length, then came two European masonry spans of 275 and 295 ft., followed closely by the 256-ft. concrete arch in Philadelphia. Apparently no engineer has satisfied himself that far longer spans of stone and concrete arches than those mentioned were entirely practicable where the local conditions afford the required rise.

It would probably be quite feasible to construct a granite arch of the span and rise found in the proposed Henry Hudson Memorial Bridge, but such a structure would be enormously heavy and prohibitively costly. A thoroughly effective combination of steel and concrete, however, makes the design of this 725-ft. span, from center to center of springing joints, a matter of ready computation and relatively low cost. The basis of such an important problem in design is obviously to combine the steel and concrete so as to develop completely the supporting capacity of the former. As indicated in the description of the plan published last week, it would seem that the most effective feature of the design of the main arch as a structure is the manner of distributing the steel throughout the great reinforced concrete rib. Each unit of four steel angles is thoroughly latticed to form a steel column in itself, and all units are so tied and braced together throughout the entire mass as to constitute not only an effective steel rib, but also a continuous interior banding of the concrete, so as to enhance largely its resisting capacity. This latter feature is in its effect the same as that which governed the design of the compression members of the Thirty-Ninth Street Building from which this journal is issued. The principle of binding together a mass of concrete and thus increasing its carrying capacity by an artificial system of steel running through all parts of it, and at the same time creating thereby a perfect column effect with that steel, is essentially new and in the highest degree effective. It gives to the resulting combination of materials the toughness or tenacity of steel construction with the ordinarily low percentage of steel in reinforced concrete, and permits the use of concrete under the most advantageous conditions yet devised for that material.

The criticism has been made by a New York newspaper that the great arch of this new plan is too experimental to satisfy the requirements of assured safety in such a public work. A 725-ft. arch is certainly unprecedented, but so is any advance on what has hitherto been accomplished. While the proposed construction is bold, it is based upon tried details and processes, and is only an adaptation of proved materials and procedures, established by successful use in actual construction, to a structure whose dimensions exceed those of any masonry bridge already built. It is not in any sense experimental. The general type of reinforced concrete arch has already been employed time and time again, and there is no substantial reason whatever why it should not be employed in this special instance, to which it is so eminently adapted. Reinforced concrete has now been so extensively and successfully used for so many years that its permanent place among the best structural materials available to the architect and engineer is conclusively assured.

The Bridge Department has proceeded with wisdom in providing for four subway tracks below the roadway floor. A rapid transit route has already been tentatively laid out with a view to using this structure, and it is bound to become a part of one of the rapid transit routes to the north of Manhattan Island. It would be a grave mistake to build this bridge without ample provision for subway tracks and the additional cost involved, whatever it may be, is more than justified, it is demanded for a pressing public need. The main architectural treatment of the plan is excellent, to the engineering eye, in that it is simple and dignified. This observation is particularly applicable to the provision made for the subway tracks. In fact the whole project is thoroughly monumental in character and, if executed, will probably rank among the finest public works of the present time.

The Time Element in Industrial Efficiency.

Efficiency of production depends upon many factors. The cost of material, the expense of transportation within the plant, cost of power and of labor must all be cut to the lowest point consistent with reliable and prompt service if the work of the establishment as a whole is to be effective to the maximum pitch possible with each particular combination of men and equipment. In the power plant a single bad leak in a high-pressure main carrying superheated steam nullifies the economy of the best boilers and engines, and in the industrial plant, where power is but one element of production cost, failure to keep the stock moving from process to process invites an economic waste that may easily be several times as important as the exact make of turbines or gas engines qualified to produce a kilowatt-hour on the smallest coal consumption. The sense of proportion was never more needed in the conduct of large industries than to-day.

It would be idle to deprecate efforts to solve any single problem of production economy. A dollar saved at the coal pile is as valuable as a dollar saved in labor otherwise wasted, but the largest leak should be stopped first. A case in point is found in the years of study given by engineers to the perfection of prime movers, generators and switchboard appliances in the face of the complex uncertainties of the boiler plant. The day has come when the cutting off of half a pound of coal per kilowatt-hour by the scientific study of boiler installations, relations of draft and grate design to fuel quality, and the frequency and manner of firing is considered of even more importance than the reduction of one or two pounds in the steam consumption. Both ends of the plant now stand a fairly even chance of receiving proper study by order of progressive executives. The parallel in the large industrial plant follows in the enlargement of the engineering staff's analytical duties to cover the entire range of production from the storehouse to the side track. In some plants a separate development may be needed to study the problems of production efficiency, but whatever be the form of the organization, there is no doubt about the value of technical methods in the analysis of processes, including both graphic and tabular records.

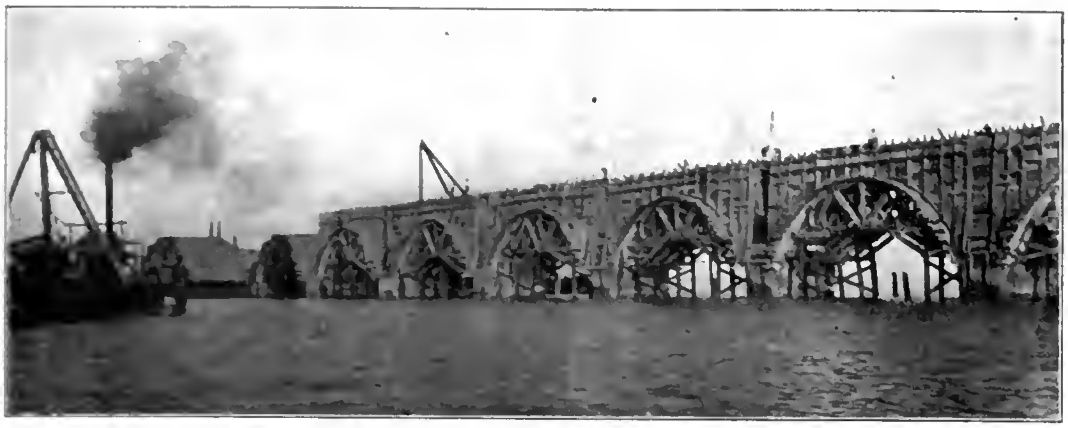
In approaching the general problem of production betterment from the standpoint of the engineer, the time element will often be found the most indefinite of all the factors which enter manufacturing cost. Cost of material and power, as well as administrative, sales and general expenses and fixed charges in the investment may be accurately ascertained; and the cost of labor will be known fairly closely with first-class accounting. A surprising absence of accurate data as to the average time each process and handling of the stock ought to require is very generally felt by the investigator in this field, however. Personal opinion will advance estimates enough from department heads, but there is rarely the same careful tabulation of processes by minutes and seconds, allowing for reasonable steadiness of application on the part of the employee, that there is, for example, in the collection of power costs per department and per piece handled.

It is easy to argue that stop-watch tests on separate processes give little indication of the continuous rate of production which may be expected from a shop force occupied in the manufacture of duplicate parts of machinery, and there is no question that a more intense rate of production will be expected if the results of stop-watch tests alone form the data from which output rates are to be established. On the other hand, the stop-watch test sets a limit, and if averaged over a long series of operations will be of great assistance in additions of separate departmental periods, taken in conjunction with counts of pieces turned out per day or week. Space forbids the extended pursuit of this theme, but the fact remains that the stop-watch test sufficiently repeated by the engineer investigating economy of production has in numerous instances brought to light conditions of surprising inefficiency at some stages in the manufacturing cycle, particularly in the fields of inter-department transportation and assignment of the product to its proper place at the machine tool. It is certainly no more arbitrary to establish an average time in which a piece of work instantly repeated should be turned out by machine tools and transferred from one department to the next over a fixed course than it is to settle the maximum turning speeds of a given tool steel in the high-speed lathe for a fixed quality of stock. The attention given to forcing production by the adoption of high-speed tools, the rebuilding or replacement of machine frames for heavier strains, the use of abrasives in place of cutting tools and the perfection of hoisting facilities are all moves in the direction of time economy, which affects both labor, cost and works capacity.

More accurate registration of time cards is desirable in many plants, for experience at the bench and tool clearly shows to every close observer the opportunity for gross inaccuracies to enter here. In a plant devoted to the manufacture of a single product, the time card presents less chance of serious average error, but in an establishment where the work varies in type, as in the manufacture of boilers of different styles, a time card error of 15 minutes multiplied among several caulkers or riveters is a point worth rectifying at the prevailing prices of skilled labor. The actual sum in a particular case may be small, but the point is to secure the most accurate figures of cost per job consistent with the conditions, eliminating every readily apprehended error. Closer bids can be made for this quality of data.

Aside from the attractiveness of time-saving through careful study of the legitimate duration of separate processes and the shortening of these when feasible, enforced by proper supervision, there accrues from such investigations valuable knowledge of the capacity of departments to handle rush orders. When the delivery is the deciding point on a contract, the ability to figure production times without a heavy estimated margin for contingencies may be worth the cost of several years' routine observation of production rates from the analytical standpoint.

The Conservation of Natural Resources, which is so generally recognized as an important national problem, will be discussed next May at the White House. The President has invited all governors of States, members of Congress and the Inland Waterways Commission to meet then for a consideration of the subject from every point of view.



Spandrel-Wall Forms in Place

THE LONG KEY VIADUCT.

Description of a Two-Mile Reinforced Concrete Railway Viaduct.

By Wm. Mayo Venable, Division Engineer, Florida East Coast Ry.

The first and longest of the viaducts on the Key West Extension of the Florida East Coast Ry. is approaching completion. All of the piers are in, and there remain but a few arches and the filling in of the space between the spandrel walls in a part of the structure before trains can be run over it. This work, it is expected will be finished in time to allow trains to run to Knights' Key by Jan. 1, 1908. The actual concrete work will be finished about the last of November.

The Long Key viaduct is unique. It carries the railroad across an opening between Long Key and Conch Key, where the water varies in depth from 9 to 17 ft., and the tide flows from the Ocean to the Bay or the Bay to the Ocean with a velocity of from four to six miles per hour under ordinary conditions of weather, and with vastly greater velocity during storms or high winds. The velocity under severest conditions is difficult or impossible to compute, for the water from the Bay is actually picked up by the wind when a hurricane visits this region, and carried in the form of spray so swiftly that it cuts the face of a person exposed to it, and a man cannot look against it.

A storm of this character, blowing from the side of the Bay of Florida, occurred during the construction of the viaduct in October, 1906. There were then in place a number of piers, but no arches. All cofferdams and falsework were demolished, but the piers remained intact, justifying their design as capable of resisting the greatest possible attack that can be made upon them from the side of the Bay. From the Southeast, or Ocean side, the exposure is greater, the water being deeper. A liberal allowance has been made for the greatest possible wave that may come across the channel that lies between the keys and the reef, which interposes between the shallower waters about the viaduct and the Atlantic Ocean.

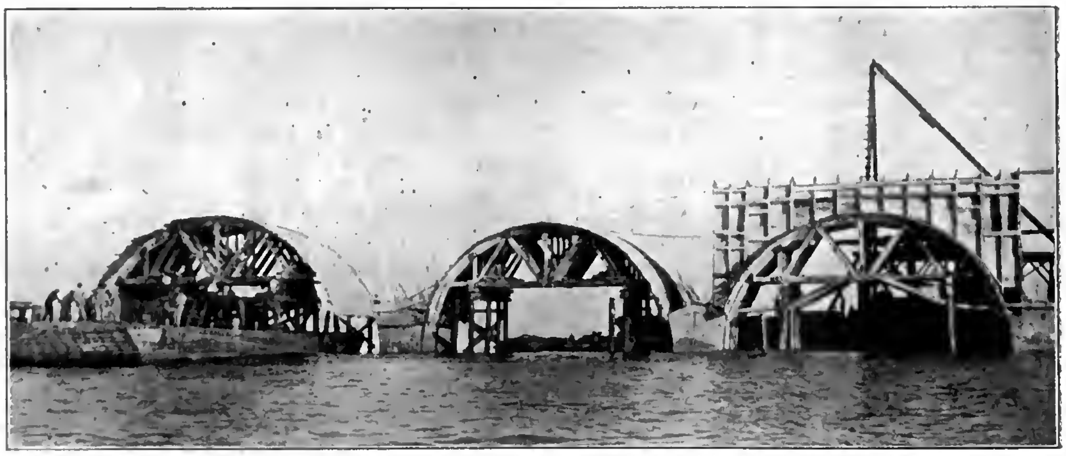
The top of the viaduct is 30 ft. above mean low water. The structure consists of a series of one hundred and eighty concrete arches, heavily reinforced with steel rods, with soffits of semi-circular section. The radius is 25 ft., making the full span 50 ft. from pier to pier, and the height above mean low water 25 ft. Spandrel walls are built on each side of the arch, and rise to a height of 5 ft. above the soffit. Between these walls the space is filled with sand and marl dredged from the vicinity of the viaduct.

The bottom is a coraline rock, encrusted with a surface of harder material, somewhat like that which forms around a geyser. For the most part the bottom was comparatively clean, but in places it was covered for several feet in depth with a deposit of marl and sand. When the crust, which varied in depth from 4 in. to more than a foot, was broken through, softer material was encountered, which, though requiring blasting for its removal, was comparatively easy to penetrate with a drill, or even allowed of driving piling in the ordinary manner.

The situation and the conditions being unique, the methods adopted were likewise peculiar to this work and this locality. It was decided in the first place to conduct the work with a floating equipment, in spite of the obstacles of tide and the possibility of storm during a part of the year. All supplies and materials were of necessity brought to the work by water, and the facilities for storing them as well as using them had to be provided. Most of the supplies were brought to the work from Miami, Fla., a distance of more than eighty miles, by stern-wheel steamboats of the Mississippi River type, a number of which were bought by the company at the inception of the work. Piles and lumber came from the same port. Broken stone was brought in schooners all the way from New York, discharged at Knights' Key dock, constructed for the purpose of receiving such materials at Knights' Key, where boats drawing 19 ft. of water may be unloaded. From the dock the stone was conveyed to the work on barges, towed by the stern-wheel boats, the haul being about twenty miles. A considerable quantity of broken stone was unloaded into the water in a favorable location and reloaded for use later. Gravel for concrete in piers and seals was brought from Mobile; cement from Germany and New Jersey; sand from Bears' Cut, near Miami. Thus a very wide area was tributary to the construction.

The method of placing the piers, while simple, was perhaps the most interesting and unique feature. The piers were of sufficient section to carry the thrust of the arches, to which they were firmly anchored by the reinforcing steel, so that they were inseparable from the superstructure. The reinforcing of the viaduct consists of two sets of ¾-in. Ransome rods, one set imbedded in the concrete near to the soffit and passing from pier to pier, and the other set imbedded in the outer portion of the arch and likewise extending from pier to pier. These two sets of rods are properly spaced and held the right distance apart by spacing rods, which likewise add some strength to the structure. Considerable steel is also used in the spandrel walls, both to prevent them from forming surface cracks and to make them add to the strength of the structure as a whole. As an additional precaution against several of the arches being demolished in case one should be destroyed by any accident, every fifth pier is made thicker than the others. The reinforcing not only joins every pier to the adjacent arches, but it is so disposed as to join all arches and piers in one continuous structure, so that any shock delivered to the viaduct at any one point would be transmitted to a number of piers. There are no breaks or hinges in the structure from one abutment to the other, a distance of about two miles.

The method of placing the piers, to return to the subject of construction, was unique. Briefly stated, it consisted of lowering cofferdams to the rock bottom, the cofferdams being open at both top and bottom. Within the cofferdam after it was lowered and the bottom cleaned of sand or marl, was deposited through pipes a layer of concrete from 2 to 5 ft. in depth, according to the depth of water. This concrete was allowed to set, and the cofferdam pumped out to allow the placing of the form for the pier, and the subsequent work of concreting the pier. As the cofferdam sometimes rested upon marl or sand when first lowered, and sometimes rested on clean rock, and as there was a strong current, due to the tide, which changed direction while the preparation of the pier for sealing and the sealing were in progress, considerable trouble was encountered in executing this work, especially at the commencement, when the best methods had to be discovered. An attempt will be made to describe these processes with sufficient detail to make them understood in a general way, and to indicate some of the difficulties.



Placing Arch Centers and Spandrel-Wall Forms.

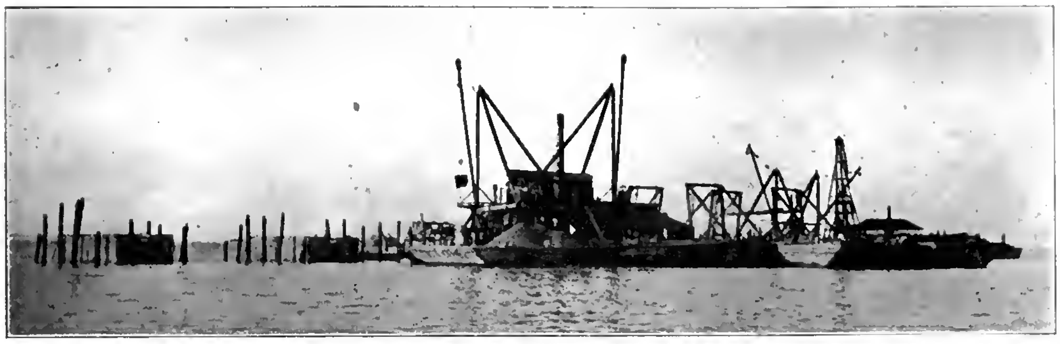
It was contemplated to anchor the piers to the bottom, either by blasting into the bottom or by driving piling into it to take up the shear that might be imposed between the base of the pier and the rock bottom, which was often quite smooth, though uneven. Of these two methods that of driving piling was preferred, although it was not definitely known before the work was undertaken that it would be found practicable. It had the advantage of not disturbing the hard crust of the bottom, of requiring less material,

and of leaving a bottom easier to clean of loose material. It was found practicable, and piles were driven by a floating driver for every pier as well as to support the arch centers for every arch. Many piles for mooring purposes were also put down, and a number for temporary docks and other incidental structures.

The method of driving piles was as follows: A steel shaft, some 25 ft. long and 6 in. in diameter, was provided at one end with an enlargement to form a punch 8 or ten in. in diameter. The other end of the shaft was fitted with a socket to take a short piece of piling as a buffer between it and a steam hammer. This punch was swung upon the pile-driver, and was placed in position in the leads at each point where a pile was to be driven. It was then driven into the rock by the steam hammer, from one hundred to five hundred blows of the No. 1 Vulcan hammer being required to secure a penetration of from 3 to 6 ft., according to the hardness of the rock. In some places it was found impossible to secure over 18 in. penetration, this being insufficient to support a pile. In other cases, though such were rare, after one or two blows of the hammer the punch would fall 6 to 12 ft., as if it had broken through the crust into a cavity. Holes like these, when encountered, were found to be of very small section, as the punch placed only a foot or so from a position where it fell after being struck might refuse to be driven more than a foot or so. They appeared to be pipes in the coral bottom, filled with nothing but water.

When the desired penetration of punch was secured, the punch was withdrawn from the hole, a process by no means easy until special rigging was made for it. The form of the punch also was an important factor in the ease with which it could be withdrawn. The pile was then placed in the hole prepared for it, and driven home with the driver, requiring from twenty to fifty blows. Many of the piles were cut to proper length before being driven and driven with a follower, so that they did not show above water until the cofferdam was lowered around them, sealed and pumped out for the pier work.

The cofferdams were made of four pieces,—two sides and two ends, constructed so that they could be taken apart at the corners by the removal of long pins. Each piece was composed of timbers lagged with pine planks 4 x 8 in. by 16 ft., and calked with oakum. The four pieces were assembled by a derrick on a barge, which, with a companion barge, was called the catamaran. The corners were made tight by canvas held across the uncalked joints by nailing strips. The completed cofferdam was then run out on timbers between the two barges, raised by blocks so as to swing free from the timbers and allow of their removal, and then lowered to the bottom in the proper place. It was then anchored in place by pull jacks and chains fastened to the guard piles or arch bent piles around it. Six jacks were used for each cofferdam.

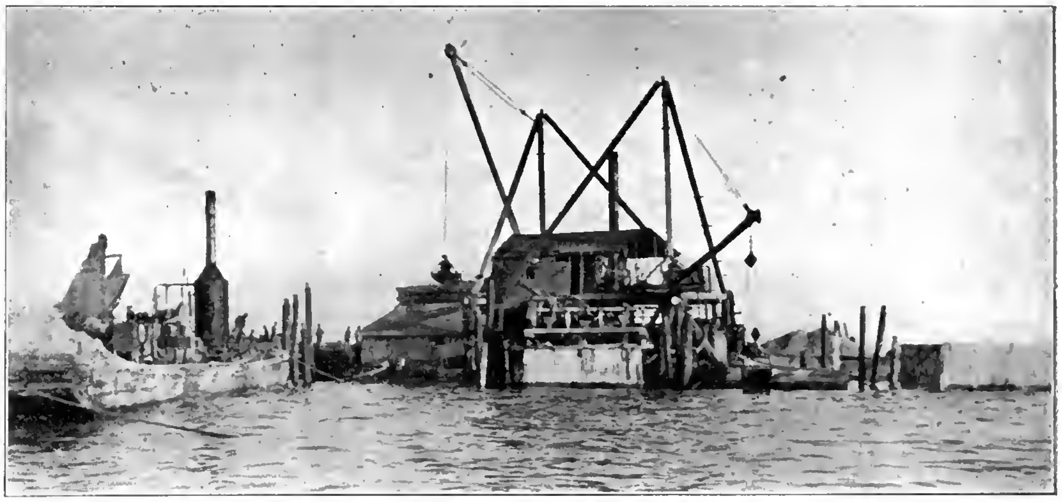


Plant Ready to Place Concrete in Sealed Cofferdams.

When lowered in place, the cofferdam was protected against the tide washing underneath it by lowering sacks of sand around it, or by dredging sand to bank up around its bottom, when this was practicable. Its interior was then cleaned on the bottom by pumping out any marl, sand or seaweed with a centrifugal sand pump, after the material had been loosened by jetting. Failure to properly close the bottom against the tide, or washing away of the protecting sacks at the turn of tide, which sometimes occurred in spite of precautions, resulted in washing out a part of the cement from the seals subsequently placed. With the proper closing of the bottom of the cofferdam the greatest difficulty was experienced.

The sealing was done through three 8-in. galvanized iron pipes, mounted on a car which ran on a track placed on the cofferdam. Each pipe was provided with a hopper at its upper end, and mounted in such a manner that it could be readily raised and lowered by two men who were charged with that duty, so as to feed the concrete to the bottom without allowing the water to enter the pipe during the process of sealing. This was very hard work, and required skill and conscientiousness on the part of the men. Lack of skill in placing the concrete resulted in inferior sealing, owing to the concrete being deposited in such a way as to wash out a portion of the cement. The concrete itself, for seals, was mixed in the proportion of one and a half parts of cement to two of sand and four of gravel, and allowed to set an hour after mixing before being shoveled into the hoppers. All of the mixing was done by machine.

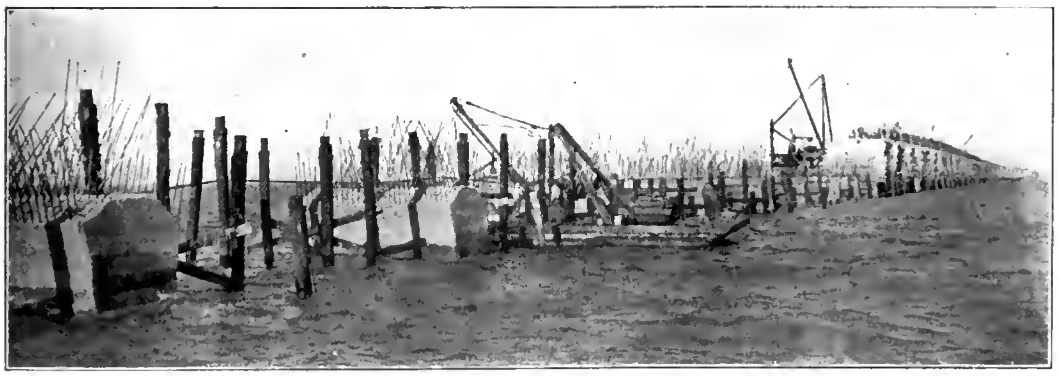
At the beginning of the work seals were allowed to set three days before the cofferdams were pumped out to place the pier forms; but later only two days were required. When pumped out, the cofferdams allowed men to descend, cut off the piles projecting through the seal at the proper height, place the pier form and the reinforcing rods. The concrete was then placed by one of the work-barges equipped for this purpose. It was mixed in the proportions of one part of cement to two of sand and four of gravel.



View during the Sealing of a Cofferdam.

The work-barges employed for concreting were especially designed for this work. They contained a concrete mixer, with hoppers for sand and gravel, and two derricks, one for hoisting material into the hoppers and one for removing the concrete from the mixer to the work. These derricks were mounted with their bases about 16 ft. above the deck, and they had booms 50 ft. long, so that they were capable of placing the concrete wherever it was wanted, in piers or any part of the superstructure. They were likewise equipped with pumping outfits and electric light plants, for the work of concreting proceeded both by day and by night.

A few days after a pier was concreted the cofferdam and forms were removed, and at any convenient time thereafter the work of placing the arches was undertaken. This work on the arches was practically independent of the work on the piers, and was conducted with different men, different barges, and to some extent dif-



Finished Piers, with Anchor Rods for Arch Reinforcement.

ferent materials. While in the piers only German cement was used, in the superstructure either German or American cement was permitted. The hesitation about using American cement in the piers was on account of doubt as to its ability to resist the action of salt water. The arches were concreted with a mixture of one part of cement, three parts of sand and five parts of broken stone.

In the arch-work the first step was the placing of the center. The centers, of which thirty-three were used in the construction of the entire one hundred and eighty arches, and left in good condition at the end of the work, were first assembled in the place where they were first to be used; but thereafter they were floated forward intact and placed for the arches by the use of jacks. After the centers were placed the spandrel wall forms were erected. These were made in panels, there being sixteen inner and sixteen outer panels to each arch. The panels were re-used many times, but they did not have the lasting qualities of the centers, being much damaged in removal. A small section of the spandrel wall form over each pier was built in place each time.

The concrete was placed in the arch ring and the spandrel wall at the same time, being commenced over a pier and carried out on each side thereof over the adjacent arch centers. Thus, an arch ring would be built in two operations, the first consisting of placing the concrete from one pier to a point about one-third of the distance around the arch ring, and the second beginning at the other pier and completing the other two-thirds of the arch. The place where these two operations formed a joint was selected so as to secure the least deflection of the forms during the placing of the concrete due to the loading. The method was very successful.

The spandrel wall forms were removed at any convenient time after the concrete had set, it being the policy to remove a form only at the time that it would be needed ahead, so as not to encumber a barge with it until it was needed. The arch centers were left in place thirty days, to insure complete setting before loading. Thus a less number of spandrel wall forms was required, but these were in constant need of repairs.

After the forms were removed the space between the walls was cleared of all litter except such concrete material as spilled into it during the process of concreting. This material was used to bank about the drain tile that was placed in the top of the pier to drain the space between the walls. Thereafter the space was filled with marl and sand, material readily available in the vicinity, and at a portion of the viaduct so located that it could be dredged and deposited in place with a single operation of a clamshell bucket. But for most of the viaduct it had to be dredged in one place and barged and rehandled into place between the walls. Some experimenting was done to determine the suitability of this material for this purpose, with gratifying results.

The handling of this work, many miles from any city, and far from any labor market, as well as from any depot for machine supplies, was in many respects more difficult on account of the isolation than the physical obstacles. The force employed on the viaduct varied from five hundred to eight hundred men after the work was under way. These men were for the most part recruited in New York, that is the laborers, many of the skilled men coming from other places. Quarters and subsistence had to be provided, and transportation from the camp to the work each day. The towage of the barges of material to the machines that were to use them was in itself a considerable problem, as was the acquiring and maintaining of a plant of such peculiar character, intended for use a short time only. The fact that this viaduct is itself but a part of a road containing equally unusual and difficult construction in other places, all under the same management as regards construction, and dependent upon the same transportation facilities, introduced elements not ordinarily met in equally heavy construction.

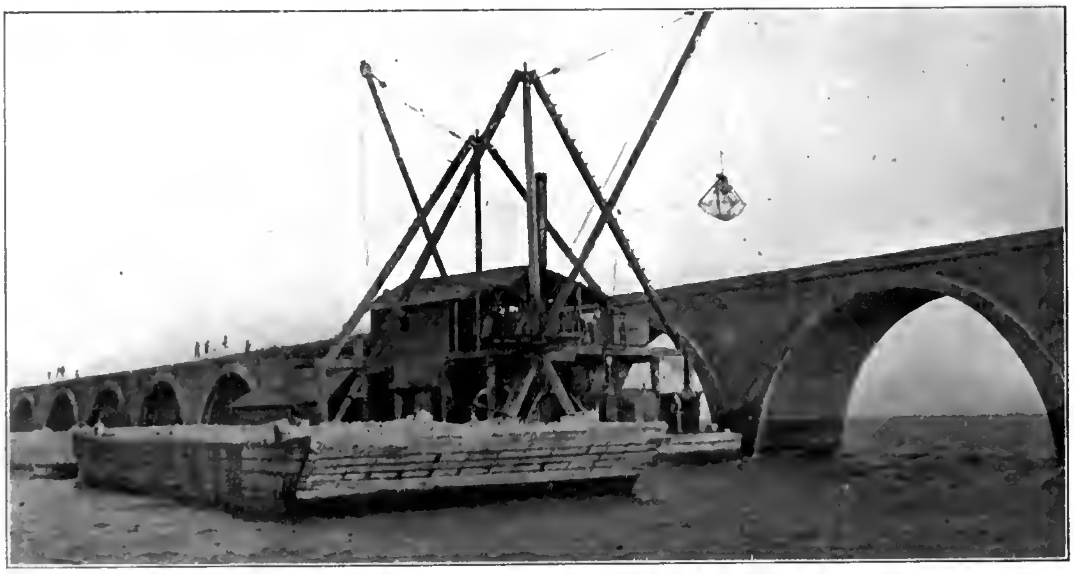
The camp provided was in a picturesque grove of cocoanut trees on the Southwest end of Long Key, formerly known as one of the worst places for mosquitoes on the Keys, but converted by clearing and some draining into a delightful spot.

Long Key Camp, Seen from the Water Tank.

The land is but slightly above mean high water, and at times portions of it have been overflowed; but it has been kept in perfect sanitary condition, and no sickness has been known to originate there. Water for domestic use is brought from the Everglades, and is most pure and wholesome. Before railway communication was established in October, 1907, water, like everything else, was brought by boat, but now it is brought in tank cars. A well organized subsistence department, with headquarters in Miami, supervises the issue of food supplies over the whole of the road and procures the necessary skilled help in that department. At Long Key there is a bakery with a capacity of one thousand loaves of bread a day.

View of the Camp from the Viaduct.

As all know, the enterprise is the peculiar interest of Mr. Henry M. Flagler, and owes to him its inception and the means of carrying it into execution. In execution, his interests are represented by Mr. J. R. Parrot, Vice-President of the Florida East Coast Ry., and the constructing engineer, Mr. J. C. Meredith, who has immediate charge of all matters, both of design and construction, of the extension from Miami to Key West. The writer's connection with the work is as division engineer, in immediate charge of the Viaduct construction. He took charge in this capacity in September, 1906, at which time a few piers had been placed, but no arches. Mr. M. F. Comer is general foreman, having been connected with the construction work from its start.



Work-Barge Placing Filling between Spandrel Walls.

The Filtration of the Croton Water Supply of New York.

On March 28 of last year Mr. I. M. de Varona, chief engineer of the Department of Water Supply, Gas and Electricity of New York City, submitted to the Commissioner of the department a report reviewing previous recommendations for the filtration of the Croton water supply and advising the construction of filter beds above the roof of the eastern basin of the Jerome Park reservoir. In order to settle definitely the practicability of the plan, a further appropriation was made at Mr. de Varona's request, in order to make more complete studies and plans than the previously available funds permitted. Messrs. Rudolph Hering and George W. Fuller were retained as consulting engineers, Mr. William B. Fuller was appointed engineer in charge of filtration and a staff organized under his direction. An examination of all possible sites for filters showed the decided superiority of Jerome Park to all others, and plans for works there were developed in a general way, described by Mr. de Varona in a report about a year ago. Since that time the work has been completed, and last week he submitted his final report.

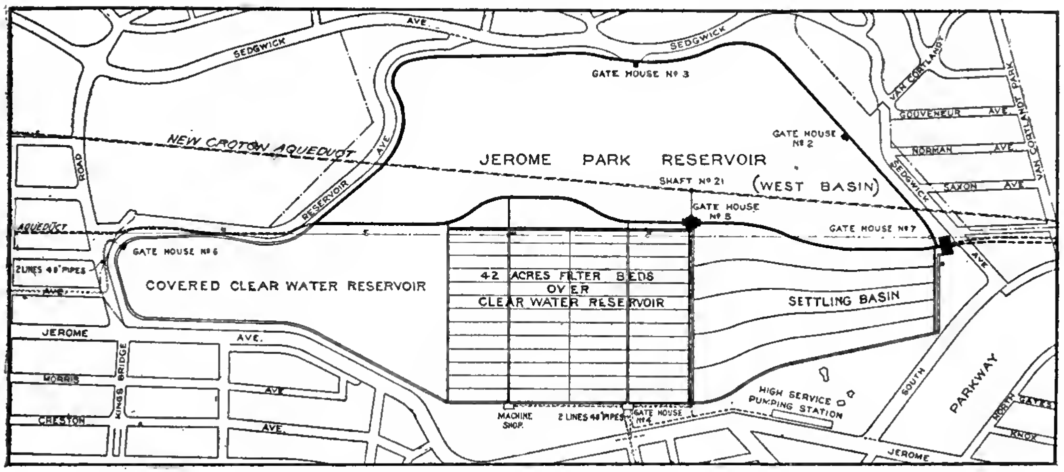
The research work on which the decisions were based in part was conducted at two testing stations. One was built by the Department to furnish information concerning the best rate of filtration of the Croton supply, and the other was constructed by private parties to demonstrate the value of the ozone treatment.

The Department's station essentially consists of sedimentation basins 10 ft. deep, 71 ft. by 25 ft., arranged by baffles in a series of compartments to represent as desired a period of sedimentation of from 4 to 60 hours. The filters consist of two rectangular beds, each about 15 by 30 ft., and having an area of about 1/100 of an acre. The filtering medium consists of about 26 in. of Cow Bay sand, having an effective size of 0.21 mm. and a uniformity coefficient of 2.62. The sand layer is supported by four layers of graded gravel of an aggregate depth of 16 in. Beneath these gravel layers are tile pipes to convey the effluent to the outlet, where the rate of filtration is governed by means of a series of calibrated orifices. The filters are equipped with gauges and indicating apparatus for recording all necessary data. A laboratory and set of coagulating devices are also provided, together with an adequate staff for operating the plant, securing samples and making analyses as directed. The laboratory building is about 18 ft. by 42 ft., and is located over and at the westerly end of the filter and sedimentation basins. The analytical work included both bacteriological and chemical analyses, as well as the ordinary tests to record the color and turbidity of the water before and after treatment.

The contractor for the testing station got the various devices in working order in March, 1907, since which date the tests have been carried on practically without interruption.

Just to the west of the experimental station the United Water Improvement Co. of Philadelphia erected a frame building and placed therein the necessary apparatus for a demonstration of their method of water purification. Work on this building began in December, 1906, and the first ozone was made on Jan. 12. Ozone was first used in the sterilizing tower Jan. 31. Essentially their method consists of the introduction into the water to be purified of a mixture of air and ozone, whereby the organic matter present is oxidized and bacteria killed.

Their plant consists of a mechanical filter of the Hungerford type, which treats water for the removal of its turbidity. The water so treated is then pumped to the top of a 38-ft. stack, 22 in. in diameter, and flows downward through the stack, while in the opposite direction there rises a mixture of air and ozone, admitted to the bottom of the stack by a special strainer or spreader. Reaching the bottom of the stack the water flows into a vertical pipe and rises to nearly the top of the stack, in order that the stack may be kept at all times full of water. The amount of water, air and ozone may be varied to meet the special conditions of the applied water.



Plan of the Proposed Filter Plant for the Croton Water Supply, New York.

The air is first cooled by passing through a refrigerator, to remove its moisture, as dampness causes trouble in the ozonizer. After this first refrigerating process, the cooled air is drawn into the ozonizer of the H. Blanken system, where, by means of an alternating current of 10,000 volts, 60 cycle, a portion of it is transformed into ozone. From this ozonizer the mixture of air and ozone is drawn by a compressor and forced into a pressure tank, from which is supplied the upward current of air and ozone in the sterilizing stack.

Aside from its magnitude, the Croton one differs from the majority of filtering projects, Mr. de Varona states, in that it deals with water supply from very large impounding reservoirs and not with the water taken from a muddy river, into which flows the sewage of various communities above the intake. The Croton water is distinctly easier to filter than many other supplies now being filtered in this country, except, perhaps, the supplies at Reading, Pa., New Haven, Conn., and a few other small plants. Some filters for water drawn from rivers, containing considerable sewage, silt and clay, have been generally operated at the rate of from two and one-half to three million gallons per acre daily, but carefully conducted investigations at the Lawrence Experiment Station of the Massachusetts State Board of Health, and at Cincinnati and New Orleans, and practical experiences at Reading, show that double those rates are entirely feasible for water less impure and, in fact, the investigations above mentioned, combined with the experience at Springfield, Mass., and at Zurich, Switzerland, show that a rate of ten million gallons per acre is feasible, provided the water is given a proper preparatory treatment. In the consideration of the Croton filtration project, much attention has been given to the use of a high rate of filtration from the view point of economy and efficiency, as judged by an adequate removal of disease germs, color, turbidity and objectionable tastes and odors.

A ten-million gallon rate per acre, as compared with a five-million gallon rate, obviously means a great reduction in the construction cost, which, in the present case, is represented by the difference between estimates of $7,600,000 for the higher rate and $11,500,000 for the lower rate. Many of the pipes and appurtenances would not be affected by these rates, but the filters themselves would be only one-half as large if the higher rate is feasible. The rate of filtration does not materially affect the quantity of water filtered between cleanings of the sand surface or the time required for a single cleaning, as the frequency of cleaning is inversely proportional to the rate of filtration. In other words, a higher rate means that a filter is out of service for a much greater portion of the time for purposes of cleaning and a much greater reserve area of filtering surface is required with the ordinary method of draining the water from the sand layer, scraping off the surface layer of clogged sand and filling the filter again before starting. For a project as large as that for the Croton supply, this reserve area of filters to compensate for the periods when the filters are out of service for cleaning is of much importance and has caused a careful study to be made of the improved methods of cleaning the filters.

The better the quality of an unfiltered water, the easier and cheaper it is to filter and the higher is the permissible rate of filtration. Studies have been made along this line to ascertain the benefits of sedimentation with and without the aid of coagulants as a preparatory treatment for filtration.

Forty-five runs were made prior to the preparation of the report on the filters of the experimental station, with different rates of filtration, different periods of sedimentation and different kinds of application of coagulants, covering all possible conditions. The results of these experimental runs show that, with adequate preparatory treatment by sedimentation and coagulation at those times when the water in the aqueduct is very muddy or highly colored, rates of filtration up to ten million gallons per acre daily are thoroughly safe and feasible for a well designed filter plant operating upon the Croton water.

Within the limits of three to ten million gallons per acre daily, there was no measurable difference in the bacterial, chemical or physical quality of the effluent or any substantial difference in the volume of water filtered between cleanings, due to the rate of filtration. The initial loss of head increased in direct proportion to the rate of filtration, and with a ten-million gallon rate approximated one foot with a medium fine sand.

Sedimentation did not ordinarily prove to be of assistance during the period of these investigations, but undoubtedly there are times, especially in the winter and early spring, when the amount of mud or turbidity in the water will be sufficient to make sedimentation a distinctly helpful adjunct to the filtration plant. During these tests the bulk of the suspended matter in the water was due to algae growths, and these did not subside to any very great extent.

Studies were made both in the laboratory and in the operation of the basin and filters as regards the need and best manner of coagulating the Croton water. It was found impracticable to remove the color and other matters from the Croton water by the aid of lime and sulphate of iron unless applied in quantities prohibitively expensive. Sulphate of alumina in quantities averaging

about one grain per gallon would effect a decided improvement in the quality of the filtered water for about eight months during the average year. During the remaining four months of an average year this treatment would be unnecessary. The cost of this coagulant would average about $1.10 per million gallons, and for this application a sedimentation basin will be provided, holding at least seventeen hours' flow, in order that the bulk or larger portion of the coagulated matter may be deposited before reaching the sand beds. The entire elimination of the coagula by sedimentation cannot be accomplished, nor is it desirable, and a considerable quantity of very tiny particles of alumina hydrate would pass from the sedimentation basin to the filters, where it would be removed at the surface of the sand layer.

After the filter got in normal condition, in April, the quality of the effluent regularly has been satisfactory as regards freedom from bacteria, turbidity and vegetable tastes and odors. The color or vegetable stain has been removed to an average extent of about 25 per cent. This removal would leave a noticeable color in the effluent for some eight months during the average year, and at times the discoloration would be very pronounced, when the water received no treatment other than by sedimentation and by filtration, as provided under our plans as already outlined.

In accordance with the adopted rate of ten million gallons per acre, it is entirely practicable with 42 acres of sand filtering surface to filter the present nominal carrying capacity of the two aqueducts, namely, 400 million gallons daily.

In the course of the investigations it was of the utmost importance to determine the most effective and economical method of washing and cleaning the sand, and for this purpose repeated trials were made of the Brooklyn method, successfully employed in a small scale under Mr. de Varona at the filter beds in Hempstead and Forest Stream, which offers some advantages over the usual method by scraping the sand, removing it, washing it and replacing it in the filters; and numerous trials have also been made of the Blaisdell machine for washing the filters without removing sand or throwing the filter beds out of commission.

The Brooklyn method consists essentially of allowing the water above the sand to drain until a depth of only about one inch remains above the sand surface. Outlets just above the sand surface are then opened and water is applied at one end and allowed to flow across the bed, the direction of flow being guided in these experimental filters by boards set on edge in the sand layer. As the water flows over the surface of the sand the layer is raked by men standing upon the sand surface. The depth of water flowing over the sand during this raking operation is about two inches. The raking and flow of water are continued until the water leaving the filter is practically clear. Water is then applied in the usual way and filtration resumed.

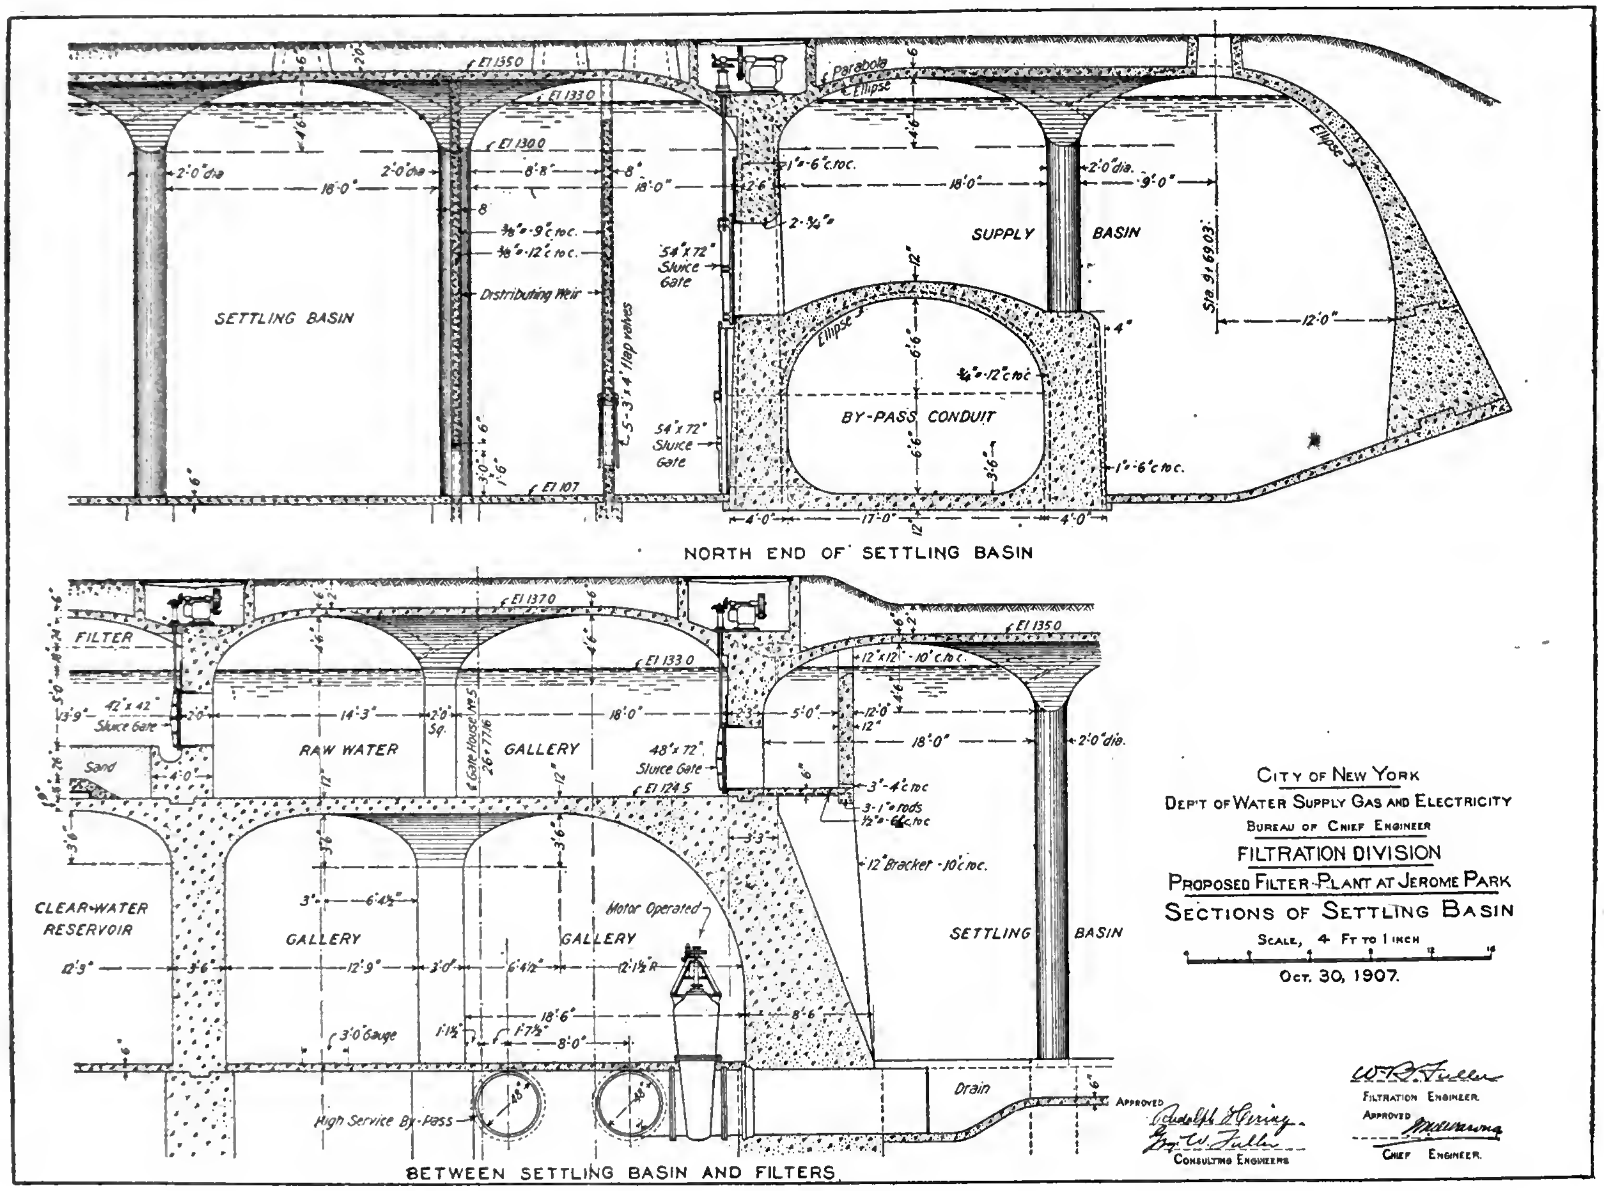
The Blaisdell machine, as here proposed, consists essentially of hollow revolving rakes incased in an inverted box, the whole apparatus being submerged and moved by suitable machinery from one end of the bed to the other. In its operation water is forced through the rake teeth into the sand layer, to be cleaned, to any desired depth, while the rakes revolve, and the dirty water is pumped from the enclosed box. If this machine be used there is no need of draining and refilling the filters or removing the sand.

The results obtained from these trials show that either the Brooklyn method or washing by the machine are cheaper than the method hitherto adopted of scraping the sand, washing it and replacing it. The filters have been so designed that either the Brooklyn method or washing by the machine can be adopted for a sand layer with a comparatively uniform size of grain.

Owing to its efficiency in destroying germ life without injuring the water, ozone has for some time been favorably and extensively discussed in this country and abroad, as a possible adjunct of filtration, and some small plants have been installed and at times operated in Europe, but not with favorable results. The drawbacks hitherto to the adoption of ozone have been the unreliability of action and prohibitive cost of operation.

The United Water Improvement Co. made a proposal to install an experimental ozone plant at Jerome Park, claiming that whereas the usual production of ozone by other methods had not exceeded 16 grains per kilowatt-hour, with their new ozonizer they could readily obtain 85 grains of ozone per kilowatt-hour, thus bringing the cost of the process within practical limits. They also claimed that the system of a silent electrical discharge in their ozonizers absolutely secured continuity of action and reliability of operation.

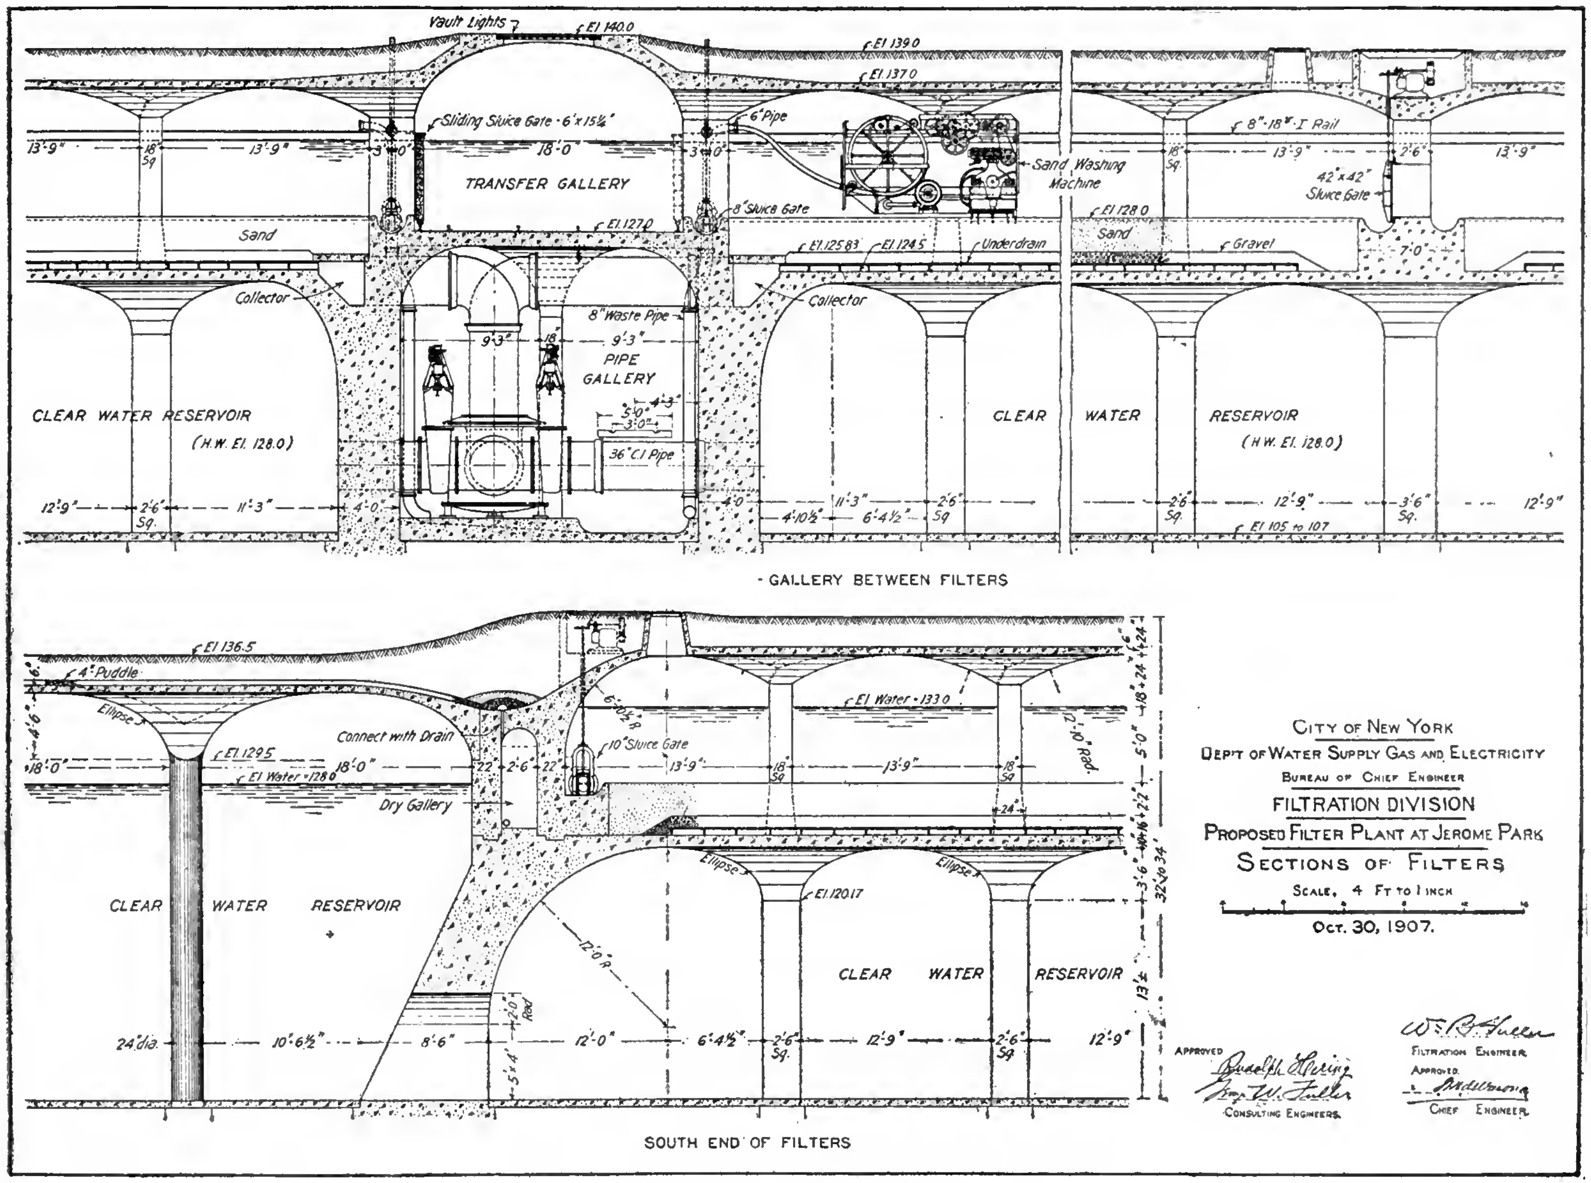
Permission was given to this company to install, at their expense, a plant for the purpose of testing the merits of their method, the experiements for that purpose being, under the terms of the agreement, conducted under the immediate direction



Sections of Settling Basin for the Proposed Filter Plant for the Croton Water Supply.

and supervision of Mr. de Varona and his staff. After the completion of their preliminary tests, he was officially notified by the company that the plant was ready for his tests, which were conducted from May 7 to May 31, 1906, after which date no further tests were made and the company ceased to operate the plant, and have been ordered to remove the same in accordance with the agreement.

The experiment showed that of the current used, about one-quarter was consumed by the refrigerating machine, one-quarter by the transformer and ozonizer and one-half by the compressor. It appeared that the color might be reduced from about 15 to about 5 and bacteria from about 100 to about 7, by the use of about 3,500 grams of ozone per million gallons, with an expenditure of about 800 kilowatt-hours. With electrical energy costing 2½ cents per kilowatt-hour, it appeared that under the conditions of the experiments the process was costing about $20 per million gallons, of which perhaps $5 represented the cost of ozone and the other $15 were chargeable to drying the air and pumping it into the water. During the whole time that the plant was in operation, it did not run a single day without stopping, a fact of itself sufficient to demonstrate the impracticability of using the proposed method of ozone purification as an adjunct of the filtration plant, regardless of its cost.



Sections of Filters and Clear Water Reservoir for the Proposed Filter Plant for the Croton Water Supply.

The conclusions reached from the thorough and detailed study of this matter and the practical results obtained at the experimental stations, are summarized by Mr. de Varona as follows:

The eastern and unfinished section of the proposed Jerome Park reservoir, on which work was suspended about two years ago, which has an area of 135 acres, affords the most favorable site for the location of the filter plant. (See illustration.) The marked advantages of this site over all others, especially in cost of construction and operation, were fully discussed in his report of Oct. 3, 1906.

The proposed plant is to have a capacity of 400,000,000 gal. a day, which is equal to the nominal capacity of the two existing aqueducts, and about 85,000,000 gal. in excess of the present average daily consumption.

The proposed site has been excavated approximately to grade. The filter plant consists of a settling basin on the northern section, covering about 37 acres, the filters consisting of 102 filter beds covering about 48 acres of the central section, with an effective area of 42 acres, and a clear water reservoir which occupies the southern portion of the site, covering about 46 acres. The clear water reservoir extends also underneath the filter beds.

The water is now delivered at the Jerome Park reservoir through the new and old Croton aqueducts, the height of the water line in the latter being 3½ ft. lower than in the former. It is proposed to raise the water in the new aqueduct 1½ ft. above its present hydraulic grade, thus bringing it about 9 in. above the intrados of the crown at Jerome Park, and under these conditions the aqueduct will deliver about 310,000,000 gal. per day.

The water to be delivered through the old aqueduct, 90,000,000 gal. per day, will be lifted 5 ft. to deliver it to the filters. The water from the aqueducts will enter the west basin of the Jerome Park reservoir, the high water line of which will be kept at an elevation of about 133. and will be supplied to the filters through a distribution chamber from which it will flow to the settling basin over a weir about 600 ft. long, thus making a very even distribution of water into the settling basin.

The method of delivery through both aqueducts, as above stated, has been adopted not only to facilitate the design of the filter plant, but to secure the great additional advantage of allowing, when necessary, bringing the whole Croton supply, even at its maximum, after the watershed has been fully developed, through the new aqueduct, and to use the old aqueduct for whatever additional supply may be temporarily furnished from up the State before the completion of those works. The importance of this feature will be readily appreciated.

Under the proposed plan, the high water line on the clear water basin will be at an elevation of 128, so that 325,000,000 gal, of filtered water can be delivered at the Central Park reservoir with the latter full, and 75,000,000 gal. more through pipes already partly laid or about to be laid, without reducing the pressure either south of the Harlem River or in The Bronx.

Whenever it may be necessary to use a coagulant for the reduction of color, it will be added just before the water enters the distributing chamber.

The settling basin has a capacity equivalent to about 18 hours' flow and is divided into five compartments, any one of which can be shut and independently cleaned. The basin is about 1,200 ft. long and the velocity of water is only from

10 to 20 in. per minute. At the southern end of the settling basin the water passes over a gathering weir and enters a raw water distributing conduit extending 1,200 ft. long across the entire end of the filters. This water is allowed to enter the filters by means of sluice gates connecting directly with the filter space above the sand. There is no raw water piping of any description and the opening of these gates floods the entire 42 acres of filter plant above the surface of the sand, which will therefore present the appearance of a large pond. The filters are placed on groined arches above the clear water reservoir and are built of concrete, each filter being 0.4 acre in area and consisting of three bays, each 410 ft. long. The filter medium consists of 25 in. of sand supported by 9 in. of graded gravel, which, in its turn, is supported by a system of tile underdrains leading to the pipe gallery. The pipe gallery consists of a dry tunnel dividing the clear water reservoir, in which are placed the controllers for regulating the rate of filtration.

Above this tunnel the gallery will be flooded with water, and this portion may be used for transferring the washing machines from one bed to another, if it is decided to clean the beds with the machines. If the Brooklyn method of cleaning is adopted, the apparatus required will be floated along the transfer gallery to the beds, as required.

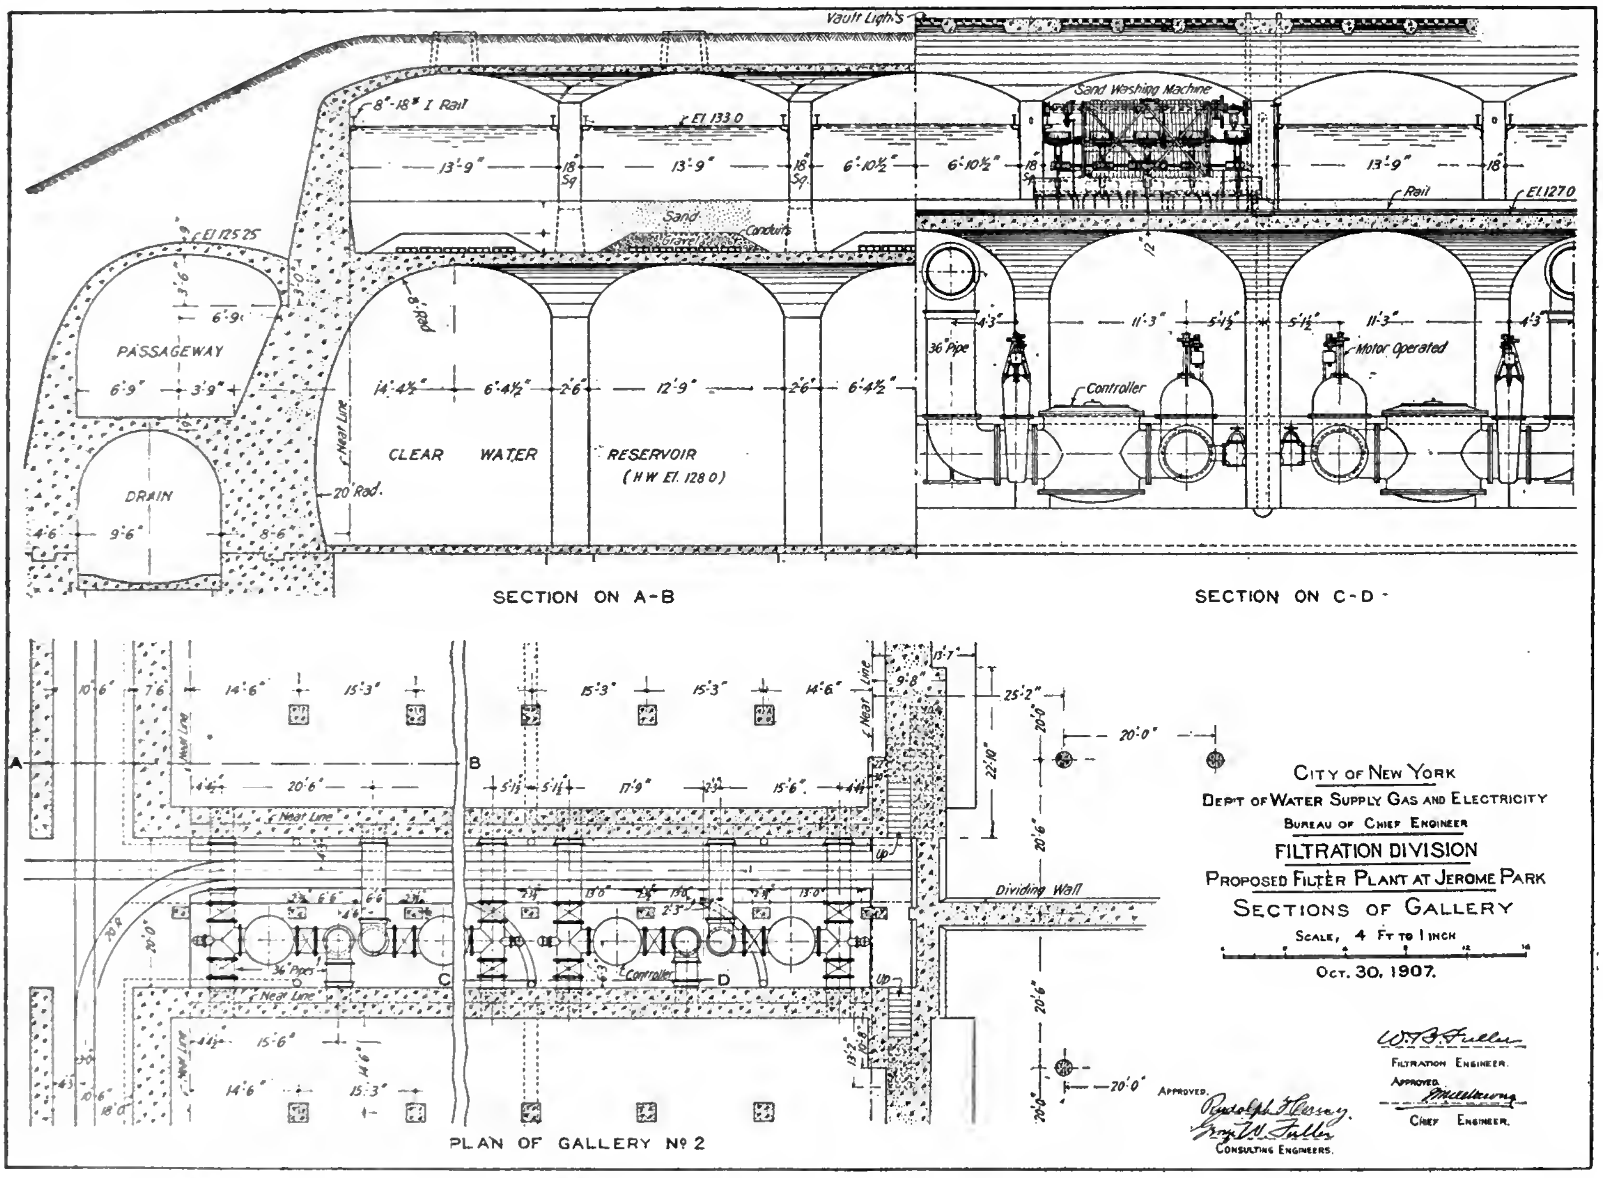
The clear water reservoir occupies about 46 acres at the southern end of the plant and is covered with groined arches. It has a capacity of 575,000,000 gal., including the basin under the filters, and the total storage capacity of the compensating basin, settling basin, filters and clear water basin is 1,785,000,000 gal. Advantage is taken of the two conduits in the present dividing wall of the reservoir to circulate the filtered water from the different divisions of the clear water reservoir, and also to bypass any of the clear water reservoirs if it is necessary to do so. These conduits convey the filtered water to a gate house, whence it is distributed to the city. The filters will be supplied with lines of rails on which a machine may be run, if desired, for the purpose of washing the sand, and each filter has also been designed so that the beds may be cleaned by the Brooklyn system, discharging into a drain connected with the city sewers.

At the end of one gallery there will be a distributing gate house and above this a chemical and bacteriological laboratory for the proper regulation of the plant. At the end of the other gallery there will be a machine shop for repairs to the mechanical equipment of the plant.

It is not proposed to cover the Central Park reservoirs, the use of which at present, Mr. de Varona states, causes a loss of pressure, because they will be abandoned for regular use when the Hillview reservoir is completed, and until then pipes can be laid from the Jerome Park reservoir sufficient to provide for the distribution for considerable less money than it would cost to cover the Central Park reservoirs, and these pipe lines will always be needed for the general distribution system. It is not proposed to cover the west basin of the Jerome Park reservoir, but to use it as a compensating reservoir, allowing the unfiltered water from the aqueducts to enter and circulate in this west basin before it enters the settling basin and filters.

The cost of the filter plant and covering of the reservoirs has been computed from detailed drawings at $7,600,000, which was the figure given in Mr. de Varona's previous report. In order to provide, however, a liberal allowance for contingencies, he deems it advisable to add about 12 per cent. to the above figures, making the total estimated cost $8,500,000.

The cost of maintenance has been estimated at $2.50 per million gallons, including expenses of operation, administration, laboratory, care of grounds, lighting, repair gangs and depreciation, but exclusive of interest and sinking fund charges.



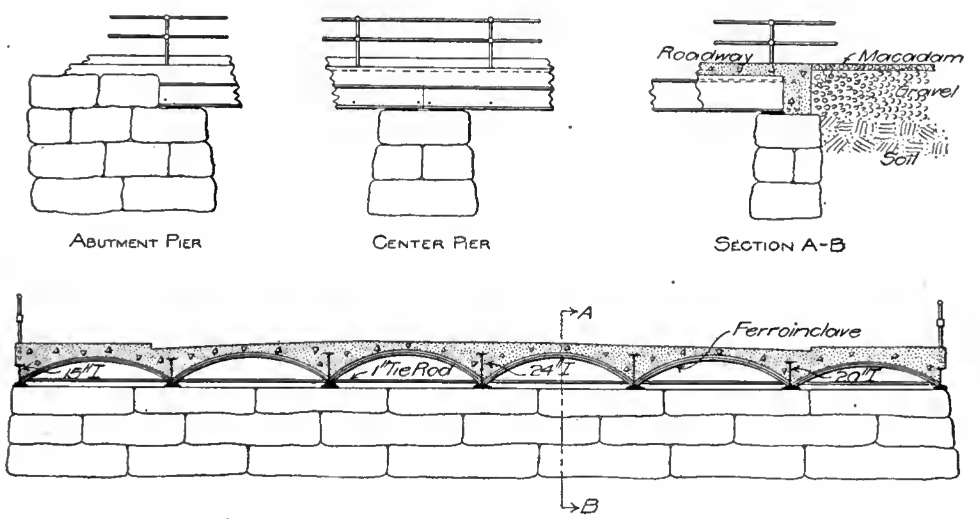
Sections of Pipe Gallery, Filters and Clear Water Reservoir for the Proposed Filter Plant for the Croton Water Supply.

Grade Change on the Canadian Pacific Railway.

The Canadian Pacific Ry. is building a new stretch of track on the west side of the summit of the Rocky Mountains, between Hector and Field. The present line is on a 4.4 per cent. grade and has a maximum curvature of 12 deg. Four miles of this track will be abandoned when the new line, 8¼ miles long, is completed. The new alignment has a maximum grade of 2.2 per cent., compensated, and a maximum curvature of 10 deg. The features of the new work are two loop tunnels, both on 10-deg. curves, and a 1.6 per cent. grade. One of them is 2,800 ft. and the other 3,200 ft. long. In each case, according to "The Canadian Engineer," the upper line crosses the lower immediately above the portal of the lower entrance to the tunnel, thereby doing away with an overhead bridge crossing. The rock excavation will be 400,000 cu. yd.

A Simple Highway Bridge.

The details of a very simple type of highway bridge recently constructed at Fort Plain, N. Y., are shown in the accompanying illustrations. There are two spans in this bridge, each of about 20 ft. These consist of I-beam stringers having curved Ferroinclave sheets sprung between their lower flanges. On top of the sheets was placed a mixture of 1 part of Portland cement to 2 parts of sand to a thickness of about ½ in. above the tops of the corrugations of the sheet, and then concrete mixed 1:2½:5 was laid to the required depth. After the concrete on the upper side had been put in place, the Ferroinclave was coated on the under side to a thickness of ⅜ in. with a mixture of 1 part of Portland cement, 3 parts of sand and half a part of hydrated lime. It will be seen that this type of construction is substantially that used for arched floors. The advantage of it for this particular bridge was that the work could be easily and quickly erected without the use of any centering, the Ferroinclave sheets themselves acting as centering. In order to drain the roadway, the slope was taken care of by increasing the thickness of the concrete upon the upper side and, in the gutters, pipes were run through the Ferroinclave sheets on either side at fixed intervals and the concrete on the upper side was placed around them, thus giving down spouts through the bridge itself. The bridge was built by the Brown Hoisting Machinery Co., Cleveland, Ohio.



A Simple Highway Bridge.

The Iron Ore Resources of the United States.

The iron ore resources of the United States are discussed in a report by Mr. E. C. Eckel, of the U. S. Geological Survey, which states that the Lake Superior District is assumed to have from 1,500,000,000 to 2,000,000,000 tons, and that this supply is being drawn upon at a rate which will pretty well exhaust it by 1950. The workable iron-ore reserves above the 1,000-ft. level in Alabama, Georgia, Tennessee and Virginia are estimated to contain 1,850,000,000 tons of red ore and 725,000,000 tons of brown ore. Adding to these quantities the ores at deeper levels in the four States and also the red and brown ores which occur in Maryland, West Virginia and Kentucky, and the magnetic ores of the other Southern States, it is considered probable that the total Southern ore reserve will amount to very nearly 10,000,000,000 tons, or about five times that credited to Lake Superior. These figures are issued to disprove the widely quoted assertion made in Sweden to the effect that the whole world has only 10,000,000,000 tons of iron ore which is yet unmined.

The Density of Pavements.

The importance of the density of a pavement as an influence on its durability was discussed in some detail by Mr. J. W. Howard in a paper read at the recent convention of the American Society of Municipal Improvements. It is particularly important, he pointed out, in all composition pavements, laid in monolithic or sheet form, such as asphalt and bitulithic. That which is densest is to be preferred, he stated, as is shown by the fact that the natural bituminous limestone or rock-asphalt pavement of Europe is denser, closer-grained and more durable than many, but not all, of the artificial asphaltic sandstones which are the principal asphalt pavements laid in American cities.

Density and consequent longer durability reduce the cost of maintenance, which in the end is the greatest cost because maintenance goes on forever. Asphalt mixture pavements, composed of sand, limestone dust and asphalt cement, too often lack density and are porous, according to Mr. Howard. In such cases they do not resist traffic nor weather as well as if they had the maximum density possible with proper mixture and compression. The bitulithic pavement he considers an example of concentration of as much mass as possible into a given space. It aims to assemble crushed stone so that there is a minimum of voids and it approximates the original solid stone from which the crushed stone is obtained. The density of the composition of bitulithic pavements combined with the density of hard stone used he considers as probably the principal reason for the degree of success which that special pavement has attained.

The same reasoning Mr. Howard applies to all other kinds of pavements, different bricks, different woods, and the like proposed for paving streets. Each kind of pavement, granite block, bitulithic, asphalt, and the others, is suited to certain kinds, locations and characters of streets. The knowledge of the comparative densities of these different materials, shown by tests in definite figures, helps determine what kind of pavement to use for individual streets and further helps determine which one of many granites, bricks and composition pavements offered is best for use in each case. Requirements of minimum density for each kind of pavement should be inserted in all specifications, he asserts, in order to help secure, in conjunction with other and usual requirements, the best possible pavements.

Two types of density are discussed by Mr. Howard. The first is the density of the pavement, including its voids, which he regards as the most important because it is of the actual pavement laid. It is the weight per unit volume of the given material, and can be expressed in pounds or as specific gravity of the pavement, dried before testing and with air but no moisture in the voids of the specimen. This density may be called volume-weight. The second density is the specific gravity of the materials of which the pavement is composed, exclusive of any voids present in the pavement.

To illustrate the two densities, one of the finished pavement and the other of the material, entering into the pavement, Mr. Howard mentioned certain Baltimore bitulithic pavement made of crushed stone so graded in sizes and assembled by mixing that a very small percentage of the volume is unfilled voids. He found a specific gravity of a large piece cut from the pavement to be 2.69, whereas the solid stone of the same kind as the crushed stone in that pavement had a specific gravity of 2.96. The pavement has about 9 per cent. less density than the stone which is its principal element. The first is the specific gravity or density of the pavement as laid, the second is the specific gravity of the stone used in that pavement. The asphalt pavements of the United States, as laid, vary in density as specific gravity between about 1.90 to 2.24, whereas the density of their main elements, sand and limestone dust, exclusive of voids, is between about 2.60 and 2.70. These pavements are therefore 15 to 25 per cent. less dense than their principal mineral elements. The requirement in specifications for some wood pavements, that the blocks when dry must at once sink in water, is a crude way of requiring that the wood must have a certain degree of density. It is better to express this by definite figures.

Valuable deductions at once follow, Mr. Howard says, from knowing the volume-weight of the pavement, including voids, and the density of its materials excluding voids. The density-grade (or percentage of density) and the void-grade (or percentage of voids) of a pavement can be found. The density-grade d is obtained by dividing the volume-weight w of a pavement by the density or specific gravity s of the materials of a pavement. This is the percentage of the pavement which is solid mineral matter which should be as large as possible. The void-grade v, obtained by subtracting the density grade from unity, which is the percentage of voids in the pavement, which should be as small as possible. For example, in the Baltimore bitulithic pavement referred to, $w = 2.69$, $s = 2.96$, $d = 91$ per cent., which density grade means that 91 per cent. of the pavement is solid stone, and $1 - d = v = 9$ per cent., which void-grade means that 9 per cent. of voids exist between the broken stone, which volume or space is filled with fine dust and bituminous cement. Asphalt, brick, wood and other pavements can have their density-grades and void-grades determined in the same manner.

Moisture in the University and Municipal Libraries at Ghent, Belgium, was so great that some parts were entirely abandoned, but it seems probable, according to U. S. Consul W. P. Atwell, of that city, that a new method of drawing humidity from walls (which he does not describe in his report on the subject) will make these rooms serviceable. The official experiments began July 14 and were completed Aug. 14. The hygrometrical degree of the air in the room, of approximately 1,200 cubic meters, where the different experiments took place, was 83° on July 13. At that time a strong moldy smell was found to exist. The greater part of the wall was covered with saltpeter, while the floor or pavement was almost continually wet. On Sept. 13, after testing the new system thirty days, the hygrometer was found to have lowered from 83° to 60°. The walls had become completely dry, and the saltpeter and smell had disappeared. The pavement was dry and remained so, while prior to these experiments it had always been moist.

Lowering a Large Pneumatic Caisson with Screw Rods.

The west river pier for the four-track Schuylkill River Bridge of the Philadelphia Rapid Transit Co. was built with a 20 x 80-ft. wooden pneumatic caisson, sunk 40 ft. to rock through water 16 ft. deep and a mud and silt bottom. On account of obstructions in the river and the long distance in which it would be necessary to tow it, it was considered undesirable to build the caisson in the usual manner on shore and launch and float it to position, and arrangements were made for constructing it vertically above its required position and lowering it to place under control.

As its location is adjacent and nearly parallel to the city bulkhead wall, the latter was utilized for a portion of its support and carried part of the working platform, on which materials were received and stored and part of the work was done. A pile platform about 42 ft. wide and 127 ft. long was built parallel to the bulkhead wall and about 58 ft. in the clear from it. This consisted of 17 transverse bents of four and six piles each, which were capped with transverse timbers and supported a deck of 4-in. plank.

The space between the platforms was bridged by 12 x 12-in. timbers, on which a working platform was placed, and the wooden caisson was built to a height of 10 ft., including the deck, and was calked and completely finished. Six heavy forged steel flat hooks were then attached to the cutting edge equidistantly on each side of the caisson, and their upper ends were pin-connected to vertical 2½-in. rods about 24 ft. long, close to the outer face of the caisson. The rods were threaded full length and fitted with nuts engaging steel bearing plates on the tops of 12 x 12-in. timbers about 3 ft. long, through which the rods passed with clearance. These timbers were seated transversely on the top flanges of pairs of 20-in. I-beams, 30 ft long, supported at each end, just beyond the vertical rods which passed between them, on four lines of longitudinal 20-in. I-beams, supported close to each side of the caisson by six timber cribs up to a height of about 7 ft. above the deck of the working platform.

Scaffold planks parallel to the caisson were seated on the lower flanges of the transverse I-beams, making working platforms for pairs of men, with 6-ft. wrenches, who first turned up the nuts on the long vertical rods sufficiently to raise the caisson, which had an estimated weight of 180 tons, and released the 12-in. transverse bridge girders on which it had been erected. These were removed, and then the men, working simultaneously by signal, slacked off the nuts, one revolution, or ½ in., at a time, until in about 12 hours the caisson was lowered 16 ft. In this position the south end of the caisson rested on timber cribbing in the foundation of an old pier of the wooden bridge formerly occupying this site. The caisson was sufficiently embedded in the mud at this end to permit the application of air pressure, which enabled men to enter and cut away the obstructions under the cutting edge, while the other end of the caisson was suspended about 10 ft. above the bottom. After the obstructions were cut away the nuts were slacked still farther, until the screws were relieved of all stress, and their connected hooks were lowered free of the cutting edge and disengaged from it, after which hooks, rods, I-beams and cribbing were all removed, and the caisson was sunk through soft material to rock by the usual methods. To facilitate handling the heavy wrenches a line was tied to each near the head and made fast to the screw 2 or 3 ft. above it. This safeguarded the wrench from being dropped and was of material assistance in carrying its considerable weight every time that it was released from the nut and moved back and turned for a fresh grip.

Lowering Pneumatic Caisson for West Pier.

East Pier Caisson Suspended from Girders.

The caisson for the east river pier of the same bridge was built nearly one year later in substantially the same manner as above described, and was then towed to the site and sunk in the usual way between guide piles. After this caisson was completed on its movable transverse girders it was suspended much as already described from overhead transverse I-beams, which in this case were seated directly on top of the cribs, without intervening longitudinal girders. This caisson weighed about 180 tons and was lowered about 12 ft. in 10 hours by a force of 36 men.

The piers were designed and built under the direction of the engineering department of the Philadelphia Rapid Transit Co., Mr. W. S. Twining, chief engineer, and Mr. Chas. M. Mills, principal assistant engineer. The work was executed by John Monks & Sons, New York.

An Elliptical Dome, 119 ft. on the major axis and 80 ft. on the shorter axis, was built about 1729 for the Church of Madonna di Vico at Vicoforte in Piedmont. Its existence was forgotten by architects until it was brought to their attention by an American traveler, Mr. L. M. Rossi. He was so charmed with this unusual edifice that he has written a book concerning it which the Macmillan Co. has recently published.

Tests of Track on the Pennsylvania Railroad.

Reports which have recently appeared concerning certain tests the Pennsylvania R. R. has been making on the West Jersey & Sea Shore R. R., near Clayton, N. J., have created an entirely erroneous impression. It has been stated that the company was racing steam and electric locomotives, with a view to determining the speed capacity of each type. The Pennsylvania R. R. has other, more accurate and much less dangerous, methods of testing the speed of locomotives than trying them out in such a manner as this. Furthermore the types of electric and steam locomotives which have been used in these experiments were not designed for speed.

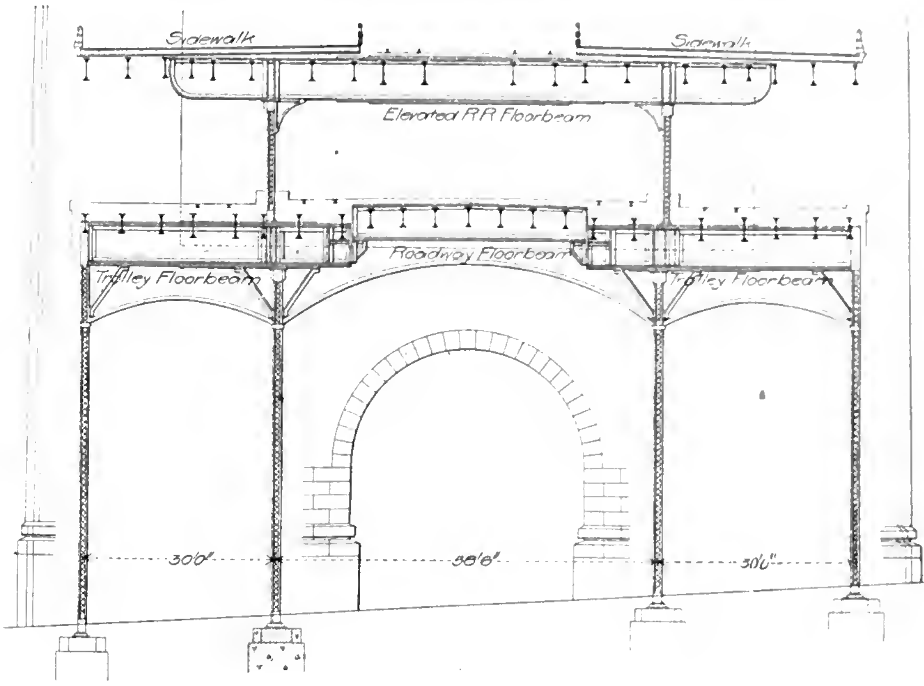
What the company is doing is this: Experience indicates that the operation of electric locomotives, owing to their lower center of gravity, has an effect upon the track different from that due to the action of steam engines. In order to ascertain the exact nature and extent of this pressure upon the rails the Motive Power Department has devised the apparatus which is being utilized at Clayton. A stretch of track about 166 ft. in length has been equipped with rails and cast steel ties, designed and made especially for this purpose. Instead of attaching the rail to the ties by spikes, a special form of block has been substituted which allows a slight movement of the rail as the engine goes over it. This movement registers the force with which the flanges of the wheels strike or press against the rails.

It is expected that a large number of experiments with this apparatus will show the company quite accurately what the effect is of either steam or different types of electric locomotives, moving at different speeds over either straight or curved track. Necessarily, to make these tests, the engines must move at different speeds. An electric apparatus has been devised to measure the precise amount of time elapsing while the different locomotives pass over this 166 feet of track, in order that in computing the effect upon the track the exact speed attained may be known. The steam and electric locomotives, however, go over the track at different times, and there is no element of contest as to speed between the two types. The matter of speed is purely incidental to the main purpose of the tests, which is to enable the company, in planning its electric installations in New York, to design a track so safe as to be absolutely secure against any form of locomotive that may be utilized.

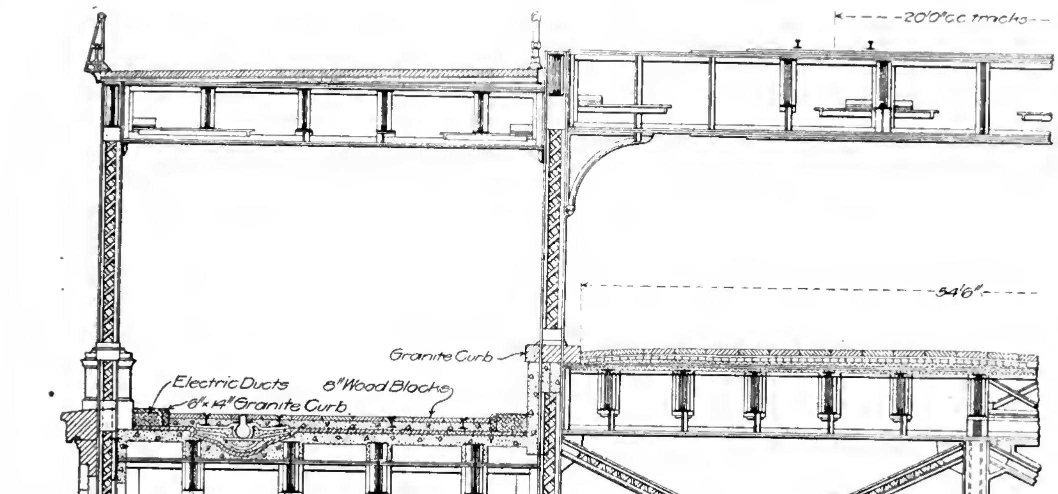
The Manhattan Approach of the Blackwell's Island Bridge.

The five main spans of the Blackwell's Island Bridge have a combined length of 3,724½ ft., a width over all of 86 ft., and a minimum height for a portion of each channel span of 135 ft. above mean high tide. They have, as described in various articles published from time to time in The Engineering Record, two lines of massive pin-connected trusses, 60 ft. apart, on centers which carry two decks, 15 ft. apart in the clear. The full-width upper deck provides for two elevated railroad tracks and two sidewalks, and is proportioned to eventually receive two more railroad tracks if necessary. The lower deck, 86 ft. wide, provides between the trusses for two Queens trolley tracks and a 36-ft. roadway. Outside of the trusses the symmetrical cantilever extensions are each proportioned to carry a single line of Metropolitan street car tracks.

The approaches are massive steel viaducts, connecting the shore ends of the anchor spans with the city streets at grade. They are built on tangents coinciding with the center line of the main span and provide for the same arrangements of decks and tracks, except as necessarily modified by the change of grade. They are, however,



Bent Adjacent to Anchor Pier.



Typical Transverse Half Sectional Elevation of Viaduct.

made considerably wider than the main spans, and although in the main conforming to standard high-grade bridge work, they are of somewhat unusual design and present features of interest, due to the efforts made to give them a monumental and artistic appearance, under difficult conditions and numerous imperative requirements that necessitated somewhat elaborate construction.

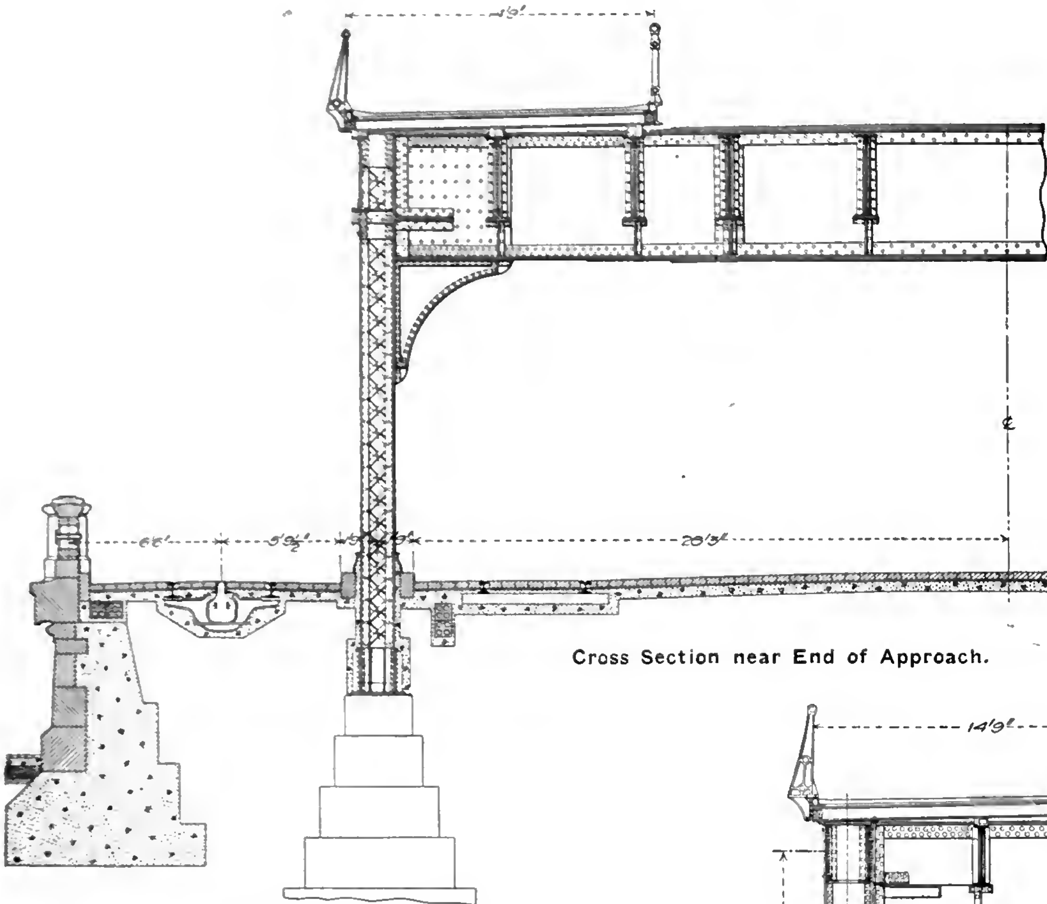
The Manhattan and Queens approaches are of very different character and construction, the former having a much more massive appearance and architectural treatment. It extends from a point between Avenue A and First avenue to Second avenue, two long city blocks, and occupies an area of about 1,070 x 230 ft. between curb lines. At Second avenue the main entrance occupies nearly the full width of this area, but the approach is soon reduced to a width of 120 ft., which is maintained up to the anchor pier, leaving spaces of about 90 ft. and 20 ft. on each side, which are paved up to the curb lines.

From the anchor pier, where the roadway is about 60 ft. above the level of the ground, the main deck is carried westward for 600 ft. on a steel plate girder viaduct, with 29-ft. spans, to a point where its height is only about 30 ft., and beyond which it is on a solid fill. Where it crosses First avenue a clear opening of 90 ft. is provided by a steel arch span, which carries the viaduct columns and is supported on massive masonry abutments. All of the steel work up to the lower deck is enclosed in granite and terra cotta, giving it the effect of stone masonry treated to represent slender arches between the bents of the steel work.

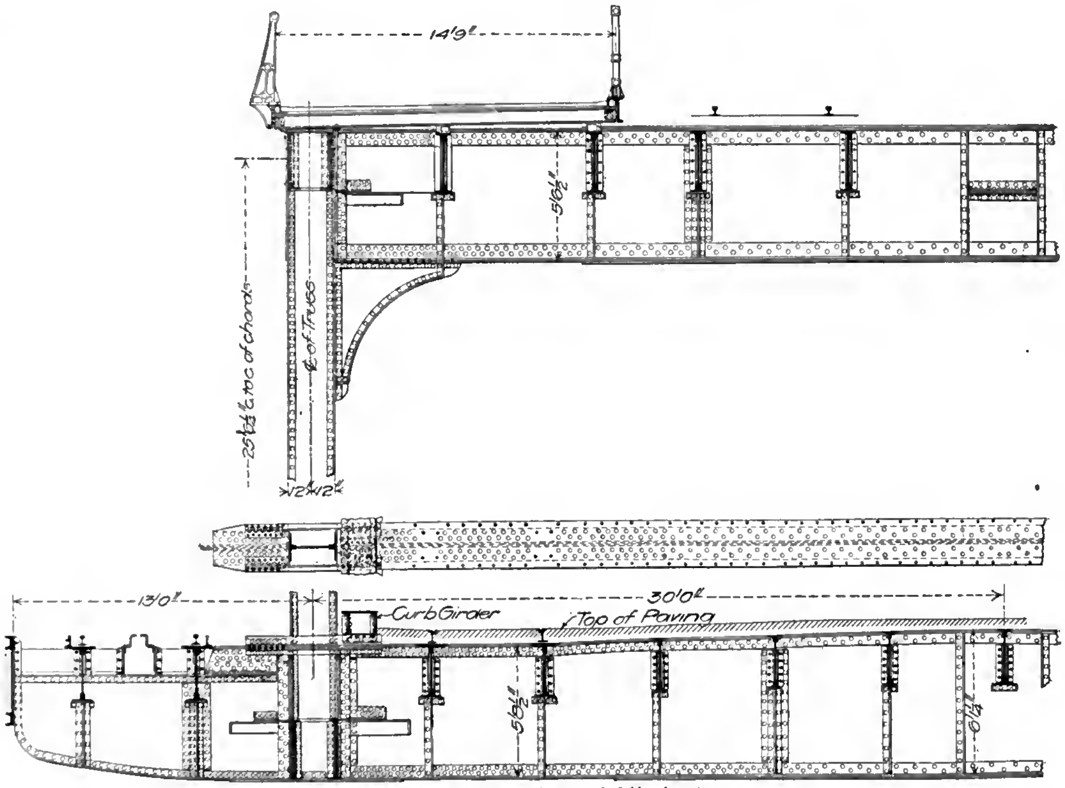
Each transverse bent has five vertical columns about 30 ft. apart, thus giving approximately equal spans for the longitudinal and transverse girders and dividing the horizontal plan into approximately square panels. Each of these panels is roofed about 25 ft. above the ground, with a waterproofed timbrel arch, which forms a false ceiling several feet below the solid roadway of the main deck, and provides underneath the viaduct an attractive sheltered space suitable for market and storage purposes.

The sidewalks are carried at the same grade as the roadway for a distance of about 100 ft. from the entrance, beyond which the grade increases, and they are carried by inclined longitudinal stringers, which gradually rise to the grade of the elevated structure at the anchor pier. The elevated railroad tracks from Second avenue are carried by inclined longitudinal stringers, which gradually rise to the grade of the elevated structure at the anchor pier.

The elevated railroad tracks from Second avenue are carried the full length of the approach on the second platform, which amounts to a plate girder viaduct, about 21 ft. high and 60 ft. wide, with 29-ft. spans. Each bent has two vertical columns 58.5 ft. apart on centers, which are seated directly on the tops of the intermediate



Cross Section near End of Approach.



Half Cross Section of Viaduct.

columns for the lower platform. The columns are continuous with those of the lower viaduct, but above the main floor are not enclosed in masonry, thus frankly revealing the steel construction and giving the effect of a light superstructure on a massive substructure.

The two outer tracks on the lower deck of the approach diverge from the center line of the bridge at a point about 300 ft. from the entrance and connect by reversed curves with the surface tracks in 59th street and 60th street, which are about 260 ft. apart. Adjacent to them on the lower decks are two more tracks for the Queens trolley cars, which toward the entrance descend below the roadway level to a subway station occupying a trapezoidal area 300 ft. long and 200 ft. in extreme width below the surface of the ground.

In the subway there are five loops, allowing for continuous car movements, with opportunity for safely and rapidly loading and unloading. In each of the spaces between loops double transverse stairways descend from the main platform to the subway station between tracks, thus giving access to all of the cars without the necessity of crossing the tracks. This station is designed to be eventually connected with the proposed subway line. The roof is supported on transverse I-beams and longitudinal plate girders, carried by riveted steel columns about 20 ft. apart and covered with vault lights and concrete slabs.

The transverse bents of the viaduct are sway-braced by solid-web knee-brace brackets under both ends of the elevated railroad girders, by detached knee-braces under both ends of the outer transverse girders in the lower deck, and by two panels of X-bracing between the three center columns below the roadway. Longitudinal bracing is provided by the main stringers and by wall girders connecting the outside columns and supporting the masonry between the tops of the arches and the parapet.

The wall girders consist of two pairs of angles from 3 to 13 ft. apart, and the space between them is divided into panels by vertical members and X-braced by single diagonal angles, besides which longitudinal knee-braces are run from the center of each panel to each column. The wall girders are made with pairs of 6 x 6-in. angles for the top and bottom flanges and for the web members, which are either zigzag or X-braces, according to the depth of the girder. Connection plates are riveted between the vertical legs of the flange angles to receive the members and project across the cover plates of the main columns, to which they are field riveted. The knee-braces have I-shaped cross sections, made with pairs of 4 x 3-in. angles, back to back, latticed.

The main columns have H-shaped cross sections, made with two built channels, latticed and connected by a center diaphragm. The center column extends to the lower deck only, and the four outer columns extend to the upper deck and are spliced just above the lower deck. Where they pierce the granite coping above the lower deck they are enclosed in a 4 x 2½-in. brass base, below which the interior of the column is filled with concrete. Except in three bents nearest the anchorage, all of the transverse girders are web-connected to the columns.

The longitudinal girders are spaced from 3 to 5 ft. apart under the sidewalks and roadway, besides one for each rail of each track. The roadway stringers support an 8-in. flat concrete slab, reinforced with transverse steel bars of 0.28 sq. in. cross sections, 6 in. apart, and longitudinal steel bars, 0.10 sq. in. cross section, 1 ft. apart, every alternate transverse bar being bent over the top flanges of the stringers. The upper surface of the concrete is covered with a ½-in. thickness of waterproofing, protected by a single course of red brick laid flat. On the bricks there is a 1-in. layer of cement mortar, in which the 4-in. creosoted wood paving blocks are laid.

The four transverse bents nearest the anchor pier are special and differ from the regular bents in the number and location of the columns and in the arrangement of the girders. Bent No. 1 is so near the anchorage that the sidewalk stringers can readily span from the anchorage to bent No. 2, and the regular transverse sidewalk girders are omitted, and the elevated railroad girders are made longer than the distance between their columns, so as to overhang them at each end. The center column supporting the lower deck is also omitted, and the two transverse girders in the outside panals are cantilevered 11 ft. beyond the interior columns, with notched seats on their ends to carry the extremities of a connecting center girder 26 ft. long.

Bent No. 2 differs from the typical bent chiefly in that it has an arrangement of cantilever transverse girders in the lower deck similar to that in bent No. 1, and that two auxiliary columns, making seven in all, are located under the extremities of the cantilever girders. Bent No. 3 resembles bent No. 2, except that the auxiliary columns are omitted. In bent 2 and 3 the intermediate upper columns supporting the upper deck are eccentric from the corresponding one supporting the lower deck.

In the regular bents the elevated railroad transverse girders, 58 ft. 6 in. long, have webs varying from 48 x ⅝ in. to 66 x ½ in., with 6 x 8 x ¾-in. flange angles, and three 18-in. cover plates of varying length and from 9-16 to ¾ in. thick. They are seated on solid-web knee-braces about 6 ft. deep, which give very rigid connections to the columns and provide for swaybracing without diagonals.

The side girders of the supper deck are 30 ft. long on centers of columns, have a 48 x ⅜-in. web plate, and in each flange two 6 x 6 x 9-16-in. angles and a 14 x ½-in. cover plate 22 ft. long. The ends are not knee-braced, but are seated on reinforced shelf angles and are thoroughly web-connected to the columns. The girders directly

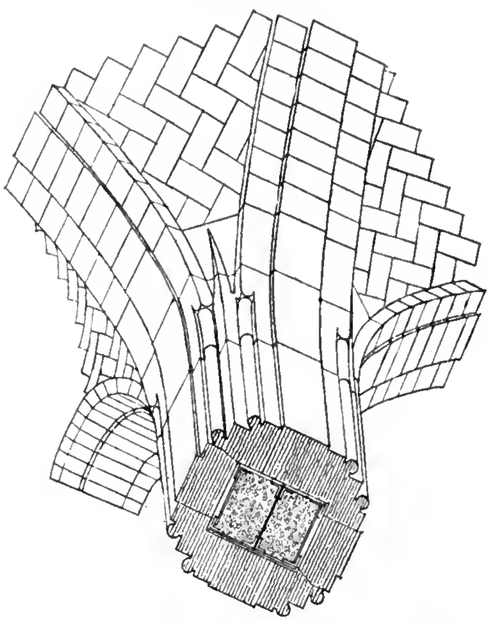
under these correspond to them, except in their dimensions, and that they have at each end a knee-brace made with a pair of 6 x 6-in. bent angles, riveted together back to back. They are 60 in. deep and have two cover plates.

The center transverse girder in the lower deck differs from the last described principally in having a single cover plate, and that it is made in two lengths, abutting in the axis of the bridge on top of the center column. There are also solid-web knee-brace brackets under both ends, which also serve as connections for the sway brace diagonals below the girder. The fixed ends of all longitudinal stringers are web-connected to the transverse girders.

The expansion ends of the roadway stringers are seated in pockets projecting from the face of the transverse girder webs and have their lower flanges supported by and are free to slide upon a horizontal bearing provided by the outstanding legs of reinforced shelf angles. Short angles are riveted to the under side of the top flange angles at the ends, with their outstanding vertical legs engaging the faces of the pocket angles, so as to provide sliding bearings and hold the girder firmly in transverse position.

The expansion connection of the elevated railroad stringers is the same as that already described, except that the seat in the lower part of the pocket is made with a curved stirrup plate riveted to the pocket angles and receiving a convex cast shoe, on which the bottom flange of the stringer rests.

The stringers in the outside panels of the lower deck are made with drop ends seated on the top flanges of the transverse girders, so that the stringer flanges are elevated sufficiently above the girders to give clearance for the yokes of the electric conduits between them. The expansion girders slide freely on the top flanges of the transverse girders and on horizontal bracket angles riveted to the web of the girder to engage lower flange connection plates.



Column Enclosed in Terracotta.

In transverse bents 10 and 15, which form part of the tower at the extremity of the First avenue arch, there is X-bracing below the lower deck. No other bents have transverse bracing to the ground. The feet of the columns are reinforced with vertical transverse diaphragms, making H-shaped cross sections, with wide vertical flanged cover plates stiffening the extended horizontal base plate, which is also reinforced by 12 short vertical angles riveted to the webs of the channels and to their cover plates, with their lower ends milled to bearing on it and thus distributing the column load over the full area of the top of its pedestal. The pedestals are webbed steel castings, 12 in. high and 48 x 52 in. on the base.

The arch at First avenue is made with five hingeless box plate girder ribs, with a rise of 13 ft. and a span of 100 ft. on centers. Each end of the rib is produced 5 ft. beyond the extremity of the 100-ft. span line to reach the skewback bearings concealed in the interior of the tower and thus increases the real rise and span to about 16 ft. and 108 ft., respectively. Each rib is made with a pair of built channels 48 in. deep, with latticed top and bottom flanges and webs 16 in. apart. Each channel is made with one 48 x 11-16 in. and one 36 x 11-16 in. web plates and two 8 x 6 x 11-16-in. flange angles.

The two ribs which carry the elevated railroad columns have much heavier loads and are made with correspondingly increased dimensions and materials. Their nominal rise for the 100-ft. chord is increased to 18 ft., and each channel is built with two 48 x 5/8-in. and one 36 x 3/4-in. web plates and two 8 x 6 x 3/4-in. flange angles. In all ribs the ends are heavily reinforced by double pairs of angles, with filler plates between them riveted together back to back on the outer faces of the web.

The ends of all arch ribs are faced normal to the curve and have an extended base plate, anchor bolted to a cut stone pedestal. Each rib is shipped in four sections, with radial butt joints at the crown and quarter points, which are thor-

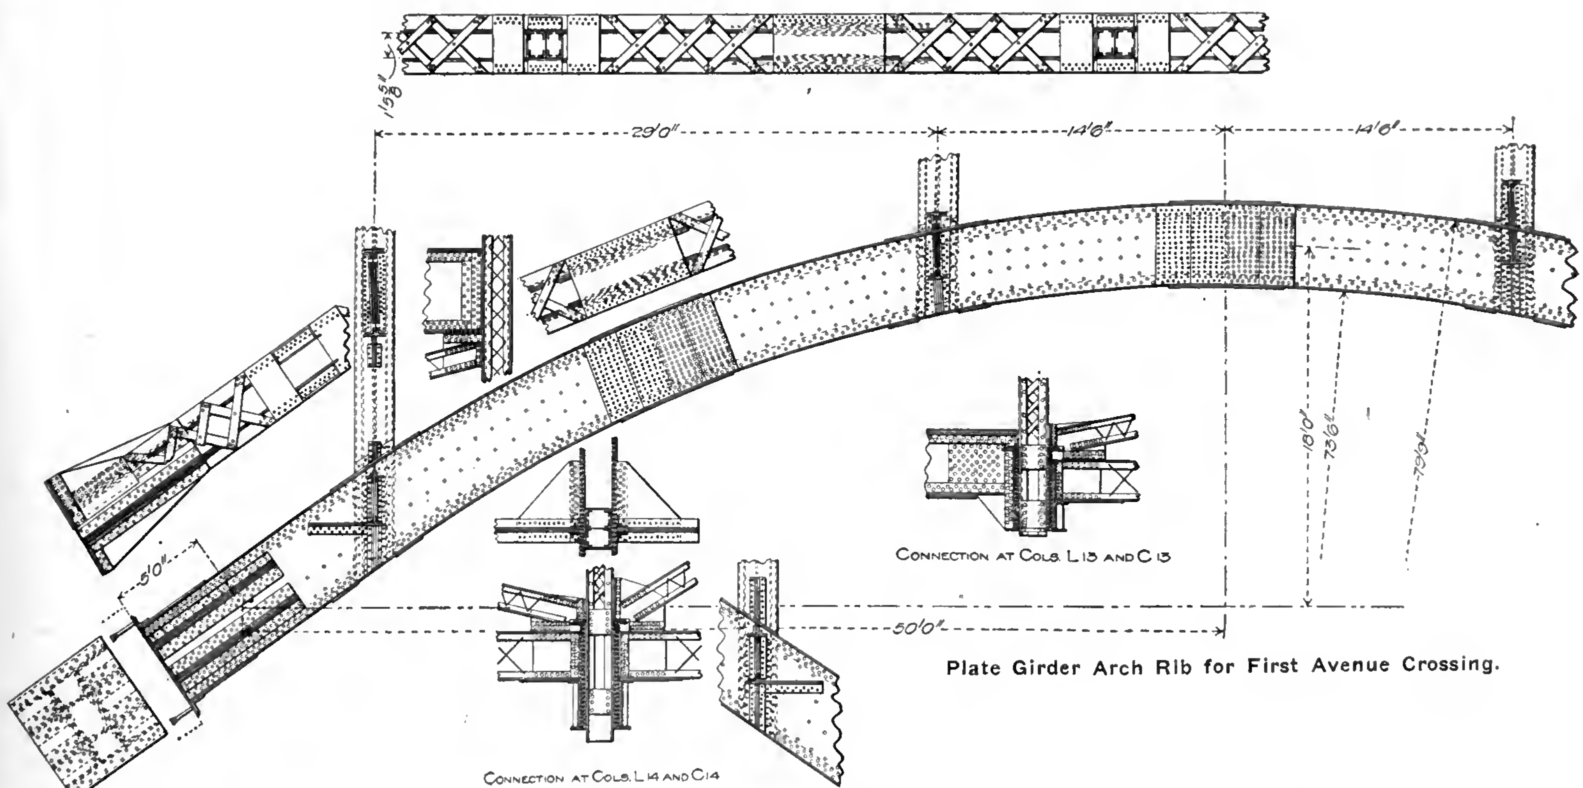


Plate Girder Arch Rib for First Avenue Crossing.

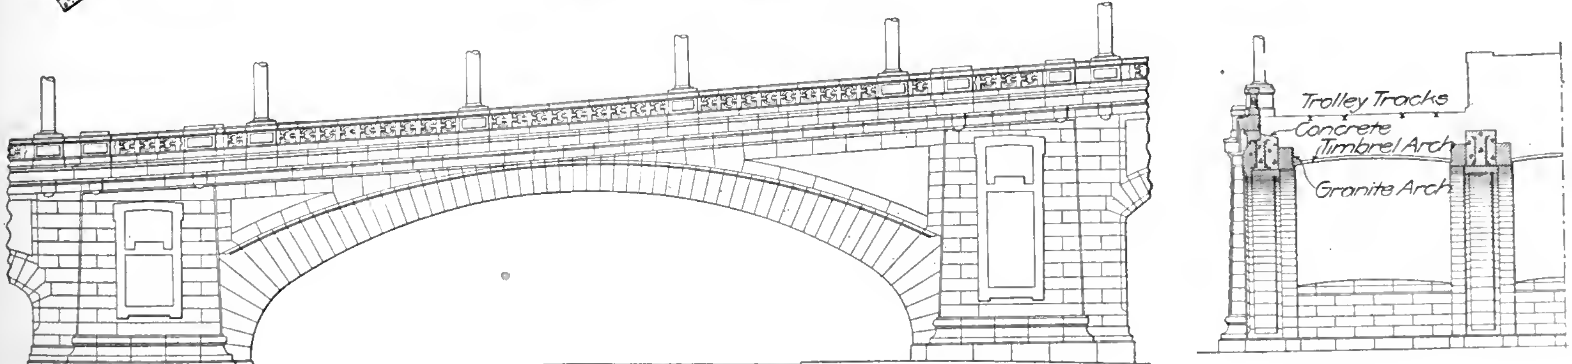

Plate Girder Arch over First Avenue.

oughly spliced with field riveted web and flange cover plates. Each rib carries four vertical columns, with its flanges field riveted between the webs of the rib. The quarter splices will be riveted before any floor weight is imposed on the span, but the crown splices will not be riveted until most of the dead load is carried by the rib.

The spandrel walls carried by the arch ribs will be built with ¼-in. vertical joints at the end bents, filled at first with asbestos felt and afterwards pointed with lime mortar. Each rib is to be enclosed in a solid rectangular mass of concrete and will be faced on the two vertical sides with granite voussoirs, anchored to it and provided with skew-back bearings, so that they really form independent, self-supporting arches. Thin flat soffit pieces of granite are also anchored to the rib to connect the two side faces and cover the intrados. Projections on the lower part of the side voussoirs receive and support the ends of the timbrel arches, which connect the main ribs and form panels of a ceiling between them.

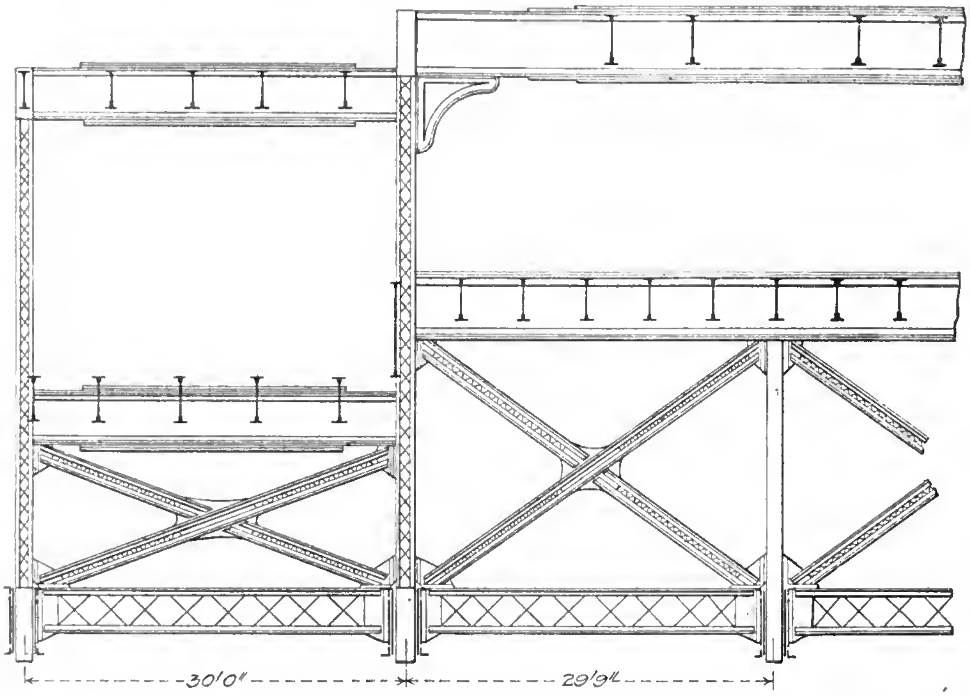
The lower portions of all columns are filled solid with concrete, and the columns are enclosed to the height of the timbrel arches with moulded terracotta blocks, which give them the appearance of cut-stone work, and are carried up to form skew-backs for the fascia arching and above them to divide the spandrel walls into panels, which between the arch and the parapet is filled in with ornamental tiles. The parapet is made with solid projecting courses, forming a cornice at floor level, and with ornanmental perforated courses, forming a massive balustrade.

The structure is proportioned for a maximum concentrated loading, and the specifications for material and workmanship of the different portions of the structure correspond in general to standard requirements. Concrete is made in three grades, namely, of 1:3:6 for the substructure, 1:2:4 for the upper part and 1:4:8 for cinder concrete as a filling under the floor. All concrete is machine mixed and thoroughly rammed and is made with Giant Portland cement, which in 40-ton or carload lots must show in the 28-day test average results 15 per cent. better than the 7-day tests for neat cement and 25 per cent. better than the 7-day test for 1:3 samples, besides developing the required minimum strength. All exposed granite work is finished with rock face, rough pointing, Pean hammering, or four cut. Rough pointed surfaces are uniform within ½ in.

All structural steel is made by the open-hearth process by either acid or basic methods, with the maximum percentages of phosphorous, sulphur, manganese and silicon limited to .06, —.04, —.06 and .10 per cent., respectively, for both, except for basic steel, which may not exceed .04 per cent. of phosphorous. All steel, except rivets, has an ultimate strength of 60,000 to 68,000 lb., elastic limit of 33,000 lb., elongation of 1,600,000, divided by the ultimate, and a minimum reduction of area at point of fracture of 44 per cent. Variations for weight are permitted, in accordance with the standard specifications of the American Society for Testing Materials. Rivet holes are drilled from the solid through materials more than ¾ in. thick and in other material are punched and reamed. All rivet holes are reamed with a special reamer making a 1-16-in. filet under each end of the rivet. All beam and stringer connections are reamed to cast-iron or steel templates ⅝ in. thick, with hardened bushings for all holes. Fluted reamers are not allowed. When hand rivets are unavoidable they must be driven entirely with 8-lb. hammers.

The concrete floor and roof slabs are waterproofed with hydrex felt or equal and coal tar pitch, which is also applied to the side walls of the subway stations. The concrete roadway and solid track floor are cast in position. The 1:2:4 reinforced concrete sidewalk slabs are cast in moulds in the contractor's yard and stored 30 days before using. They have a ½-in. wearing surface of 1:1½ Portland cement and sand, are laid on ½-in. mortar beds over the steel bearings and have ½-in. joints filled with 1:2 grout. Very complete specifications are given for the track construction conduits and electrical work. The principal quantities involved in the work include 35,000 cu. yd. of excavation, 6,000 cu. yd. of fill, 16,000 yd. of concrete, 110,000 cu. ft. of cut stone and 130,000 sq. ft. of terracotta. The estimated weight of the structural steel is about 12,000,000 lb.

The bridge was designed and its construction is being supervised by the Department of Bridges, of New York City, Mr. James W. Stevenson, Commissioner; Mr. C. M. Ingersoll, Jr., chief engineer. The contract was awarded May 21, 1907, to the Snare & Triest Co., Mr. Frank Miller, chief engineer, and Mr. J. C. Haine, resident engineer. The steel work is being fabricated at the Pennsylvania Steel Co.'s shop, and concrete is made with Giant Portland cement.



Half Transverse Section through Arch Span at Haunches, Blackwell's Island Bridge.

A Five-Span Bridge across the Rhine containing a center cantilever span of 678 ft., was completed during the present year. The bridge, which connects Homberg and Ruhrort, spans two canals, and a harbor basin, in addition to the river, and has a total length of 2085½ ft. The spans are 296¼ ft., 405¼ ft., 678 ft., 427½ ft. and 278¾ ft. The width is 54 ft., divided into two 8 ft. footwalks and a 38 ft. roadway carrying two electric railway tracks. The foundations, according to "The Engineer," London, proved a difficult task because of mines, which are still being worked, under the river, and their design was adapted so as to cause no danger to the workings. The cantilever arms are each 114 ft. long, and the suspended span, which is hung freely between them so as to expand and contract, is 450 ft. long. The total load coming on each of the two piers for the cantilever span is 9,194.6 tons, of which 1,782.8 tons is due to live load. The load on the foundations is about 11,800 lb., or 5.9 tons per square foot. The approach and anchor spans were built on wooden falsework. The cantilever span was built without obstructing the channel, except that a temporary timber pier was built in the center of the river to carry the suspended span during erection. The total cost of the structure, including piers, falsework and all expenses, was about $1,092,700.

Road Hardening and Dust Prevention about Boston.

At the regular quarterly meeting of the Massachusetts Highway Association on Nov. 12, road hardening and dust prevention were the topics considered. The first paper was read by Mr. John R. Rablin, engineer of the Metropolitan Park Commission, Boston. Mr. Rablin referred to the treatment with tarvia of 3½ miles of park roadway in Revere, Chelsea and Everett about a year ago, and stated that a test of this length of time, with attending severe winter conditions, enabled some judgment to be formed of the merits of the treatment. During the winter one portion of the roadway for a distance of about 2,000 ft. showed signs of scaling, the top surfacing of tar and screenings about ¼ in. in thickness breaking up and leaving the roadway in about the condition it was before treatment. This action he assumed was due primarily to the condition of the road on which the tarvia was placed, an excessive amount of binding material having been used in its construction, which prevented proper penetration. After the scaling the road remained in good condition, however, and seemed to derive some benefit from the treatment. One other section, 1,500 ft. long, appeared to have been lightly treated; that is, too little material was used, or it penetrated more rapidly or to a greater extent than ordinarily, as the larger stones of the road were not covered with the surfacing of tarvia and screenings. This road seemed thoroughly bonded and remained in good condition. Generally winter conditions had no bad effects, and the roadways have been clean and free from dust or mud.

In July, 1907, some other portions began to show the effects of wear, and during July and August about one-half of the 3½ miles treated in the fall of 1906, including the portion which scaled and the portion improperly treated, were re-treated with tarvia, and the balance of the 3½ miles patched where necessary. The average cost of the re-treatment was 6.4 cents per square yard. Considering the entire 3½ miles, the cost of maintenance of the tarvia surfacing, including re-treating and patching, was 3.5 cents per square yard.

During this year, about 90,000 sq. yd. of roadways have been treated with tarvia at an average cost of 7.3 cents, in addition to the maintenance of that laid in 1906. The cost of the different

jobs varied from 5.8 to 9.3 cents, the variation being due principally to the condition of the roadways treated, the cost of labor varying the greatest amount, and the cost of tarvia varying somewhat with the amount required for the different conditions of roadway. Some portions of this new work became uneven and rough on account of the bunching of the tarvia, attributed to a variation in the quality supplied. This condition did not lessen the effectiveness of the treatment, and in general the results of the use of tarvia have been satisfactory, the road surfaces being preserved practically dustless and mudless.

Various experiments were made during the year by the Metropolitan Park Commission in the use of oil on the roads, notably in the Charles River and Revere Beach reservations. These roads were treated with a petroleum product called "asphaltoilene," which is furnished and applied by the Good Roads Improvement Co., of Cincinnati. This material is a Kentucky oil with the naphtha and other volatile substances removed, leaving a heavy asphalt base, which is applied to the surface of the road in its natural state by the White oiler, a machine used in oil applications in California. This treatment requires a road in particularly good condition, either nearly new or newly resurfaced, and very little cleaning except the removal of loose dust is necessary. The cost of this work was 6 cents per square yard for the material and its application. The cost of cleaning was negligible.

The Charles River road is about 1 mile long and is constructed with a gravel surface. An excessive amount of oil was used here on account of the uneven condition of the road, necessitating a week's closing to allow proper penetration. A light sprinkling of gravel was required in some places to absorb the surplus oil. This road has been in excellent condition since the work was done in June, 1907, and has required no watering and no repairs. Although the appearance was not very agreeable at first it appears that the excess of oil will enable the treatment to last another year if the frost does not injure it to any great extent.

About 17,000 sq. yd. of the Revere Beach drive was treated with this material. This road is a macadam, had been constructed 1 year, and was in very good condition. Too little oil was used, especially at the sides, on account of a fear of marring the appearance of the concrete gutters and edgestones. Therefore the road was not thoroughly bonded, and early this fall began to pick up a little. Another light treatment was given it where necessary and it is now in very good condition. Mr. Rablin considered this treatment effective in preventing dust and in bonding the road surface, especially with a gravel surface. The oil gives no offensive odor. In the Middlesex Fells Reservation 140,000 sq. yd. were treated with a mixture of water-gas tar and Kentucky oil similar to that just described. At the beginning of this work an emulsion with 25 to 30 per cent. oil was used, but Supt. Price experimented with the mixture of oil and water-gas tar; considered it cheaper and fully as good, and used it for the greater part of the work. This mixture is made in proportions varying from two barrels of oil and six barrels tar, to four of oil and six of tar, depending on the road condition. This mixture was heated by a steam coil and applied by a special attachment to a watering cart designed by Mr. Price. This treatment thoroughly lays the dust, remaining effective eight to ten weeks, but after that time further treatment is necessary. The method has little, if any, bonding qualities and does not prevent the roads from being stripped of their surfacing, the materials working into the gutters. The average cost of one application is about 4 cents per square yard.

In the accompanying table cost data for *tarvia treatment* of roadways by the Metropolitan Park Commission are given in detail:

The cost to maintain the Revere Beach Parkway (8,880 sq. yd. new) was $2,377.25, 67,434 sq. yd. being treated. The cost per square yard was $0.0351.

Mr. Rablin stated that the net cost of oil per gallon was 7.5 cents, and tar 3.5 cents. One gallon of the oil mixture would take care of 3 sq. yd. of roadway, on the average. On the Revere Beach Parkway from 0.5 to 0.75 gallons of asphaltoilene per square yard were required.

Mr. F. C. Pillsbury, division engineer of the Massachusetts Highway Commission, pointed out that the effect of automobile travel has been so injurious on the through lines of main roads between Boston and interior points that if any one of these roads were to be macadamized new today and then subjected to the automobile traffic of the past season, it would be necessary to resurface it in about two years, even under ordinary repairs. The Highway Commission concludes for the present that tarviating is the best method for protecting the surface of macadam roads, consequently at Lynn, Weston, Wayland, and other points this process has been used.

At Lynn a road extends across the marshes, and is much exposed to sun, wind and high-speed automobile operation. The result was that one year from completion of about a mile of almost perfect road, the highway had to be resurfaced. A month later tarvia was applied. An unusual expense was incurred in the removal of a crust formed by the fine stone and dust swept to the sides by the automobiles, and used for binder in re-surfacing. It was rolled down with saltwater, and when the surface came to be cleaned about 0.5 in. of this crust was found, which had to be loosened with harrows and picks and taken up with shovels. The portion of the road on which the tar was coolest when used made the best surface. In order to allow use of the road it was tarviated half at a time, but the result was a patch at the overlap. Since July 4 the road has shown practically no signs of wear, though subjected to probably as much automobile travel as any road in Massachusetts. The only repairs necessary have been at a few small spots, the largest not over 2 ft. long, where all the crust of mud was not removed.

On the Wayland road it was necessary to first patch and re-surface the entire macadam and clean it, which ran up the cost. At Weston the surface was better. It was found at Wayland that by rolling clean sand into the No. 2 stone on the surface, only a little more tar was used than on an old hard road. This disproved the idea that one could not tarviate on a newly re-surfaced road. The tar was used on the clean, new stone without spreading stone dust and water. The result has been better on the newly re-surfaced places. A number of experiments with sand and stone screenings were made for a covering material, but the best results were obtained with pea stone. All fine dust and floury material should be excluded.

At Wayland, as an experiment, a mixture of pitch was tried in the proportion of one barrel of pitch to three of tar, and one to four also. There was no apparent difference in the applying nor as yet in the wear.

The U. S. Government, through the Good Roads branch of the Department of Agriculture, working with the Commission, conducted some experiments on the Wayland and Weston roads. Mr. Prevost Hubbard, a chemist, of Washington, was in charge. Tarvia, coal tar, water-gas tar, rosin, salt and terra-colio were tried singly and in mixtures. The terra-colio, an emulsion of a crude oil preparation, has done very well as a dust layer in two applications. There seems to be little choice between any of these; possibly the mixture of coal and water-gas tar with rosin and salt may have the best qualities for wearing surface and dust laying. The water-gas tar was also used alone. It was spread on the macadam from a tank car and then covered with fine gravel and rolled. At first the tar and sand mixture became loose in patches, but it gradually packed down and now presents a very good surface, giving practically no dust. Careful records of weather and temperature were kept in all this work. The following costs were obtained:

	Length.	Width.	Area.	Cost per Sq. Yd.	Tarvia per Sq. Yd.
Lynn	0.78 in.	31.4 ft.	14,480 sq. yd.	$0.087	0.44 gal.
Weston ...	3.15 in.	15.0 ft.	27,720 sq. yd.	0.12	0.55 gal.
Wayland ..	2.25 in.	13.0 ft.	18,286 sq. yd.	0.215	0.55 gal. resurf.

The tarvia work at Wayland cost about 8 cents per square yard. At Lynn the road was near the coal tar company's base of supplies. The Commission used two heating kettles, heating four or five barrels of tar at once. An average of 1,000 lin. ft. or 2,000 sq. yd. a day with one gang was about the best that could be done in fair, dry weather. Mr. Pillsbury advocated the use of larger kettles, regular machines for heating and spreading the tar, as in France; cleaner sweeping, perhaps with a vacuum cleaner; securing uniformity of tar by test and inspection, and not beginning work before May 1 or continuing it after Oct. 1. He stated that the Warren Brothers bitulithic pavement seems to stand the wear of automobiles best, but at too high a cost. He doubted the permanence of a coating of tar on state highways, and suggested increasing the depth of the tar surfacing, either by forcing it farther into the stone when the roads are first built, by using compressed air, or by increasing the thickness on the top. Gravel roads show the effect of automobile travel much less than those of broken stones. Macadam filled with sand of proper quality is much less damaged by automobiles than macadam consisting purely of the clean stone with the binding material used merely on the surface. Mr. Pillsbury stated that he had not noticed any tarviated roads in a slippery state yet. His construction outfit consisted of two kettles, one pair of horses, twelve to fourteen laborers and teams to haul sand and stone.

The next paper was on dust suppression in the Boston Park Department in 1907, by Mr. John A. Pettigrew, Superintendent of Parks, read by Mr. Shea. From 12 miles of roadway treated with oil in 1906, the treatment was extended this year over the whole system of roads, about 44 miles in all, with satisfactory results, the dust being laid perfectly. The cost of the oil treatment is cheaper than watering. The cost of watering was computed a few years ago at $489 per mile of 30 ft. roadway on 182 days in Franklin Park, and $883 per mile of 30 ft. roadway for the same service on 230 days on Common-

wealth Ave. An average of $686.00 per mile is a very fair estimate for the entire system. From April 15 to Nov. 1 the cost of oiling has been $352.67 per mile of roadway 30 ft. wide, or 2 cents per square yard. The total amount used between the above dates was 1.49 pints per square yard. The dusty season is not quite over. There is a difference of $333 per mile in favor of the oil treatment. The watering practice is to water whenever the dust flies, if the temperature is not below 24° Fahr.

The asphaltum in the oil has a binding effect on the road surface, and less surface repairs are necessary. Less washing results from rains, and less gutter scraping is necessary. The softer footing on an oil-treated road is a benefit to horses, reducing the cost of shoeing. The oil is applied in the form of an emulsion. The first application of the season contains about 16 per cent. of oil to form a basis; renewals contain from 5 to 8 per cent. of oil, and are made in from 10 to 20 days, according to location and use of roadways. The emulsions are made by steam pumps, which do all the work of the transference and agitation of materials. To emulsify 2 barrels of oil, 18 lb. of common soap, at 4¾ cents a pound, are sufficient, with one barrel of water. This stock is taken on the work and supplies the ordinary sprinkling wagons, which do the work of applying the emulsion to the roads, the mixing in the sprinkling wagons being accomplished at the street posts or hydrants.

The Department is still in favor of a thin rolling cushion of coarse sand or fine screenings saturated with oil. This is, however, hard to maintain on curved roads, the swing of the wheels throwing it to the outer side of the curve. It is thought that this cushion releases the air suction below the tire, so destructive to the road binder. Fine or dead sand of a yellow color makes a pleasing surface, but if too heavily treated with oil an asphaltum surface will result, with tendency to scale. In the brief discussion which followed, Mr. Shea stated that the oil used is a Texas variety with an asphalt base, and that about two applications of sand were made during the season. The cost of sanding was not figured.

Mr. Charles W. Ross, Street Commissioner of Newton, then described experiments made in that city with road preservatives, chiefly on Commonwealth Ave. This thoroughfare, which is a continuation of the avenue of the same name in Boston, extends 5 miles through this residential suburb, and is divided into a north side used for teams, a central boulevard section used by trolley lines, and a south roadway, 36 ft. wide, used exclusively for automobiles. A section of 3,500 sq. yds. had hot tarvia applied during 1906, and went through the past winter excellently. Mr. Ross stated that the road was in better condition this year than last, and he attributed a smoothing down action on the tarvia to the rubber tires traversing it. Another section was laid with tarvia over an area of 28,843 sq. yds., at a cost on the average of 11 cts. this year. The road has a coating like india rubber. At Washington St., Newton Lower Falls, tarvia was used covered with ¼ in. sand and fine screened gravel, which gave better results than the flour of screened stone, which is dusty.

Asphaltoline was also successfully used on Commonwealth Ave. at a cost of 6 cents per square yard. Mr. Ross stated that oil does not save the surface of the road, but it stops the blowing off of dust. No complaint has been received from residents of Newton streets on which oil or tarvia has been tried. The cost of spreading Texas oil with machinery was 2.5 cents per sq. yard. A light coating of sand shaken on afterwards has been found to stop spattering. On another street in Newton the roadway was rolled with ¾-in. stone, and hot screenings mixed with 20 gal. of oil per cubic yard of screenings were spread with shovels. The work was done in June and the whole cost was 12 cents per square yard. The street has not been watered since.

Another experiment was tried on a section of Commonwealth Ave., where the roadway was worn down 2 or 3 in. lower at the centre than at the sides. A thin mortar made of 1 part Portland cement and 4 parts sand was swept upon the road with a broom at a cost of 7¼ cents per square yard. This has been in service, with very good satisfaction, since last June. The experiment was also tried of sweeping tarvia upon the cement to smooth it, and on a short section of roadway this has lasted well since the past summer season. A penetration of ¾ in. had been obtained with the tarvia put down a year ago. Asphaltoline went fully 1 in. into the macadam.

Col. Wm. D. Sohier, of Beverly, referred to the success of the calcium chloride treatment as a dust layer in Beverly last summer, and also outlined work done with oil. In using oil he urged

Openings Cut in Stack at Bissell's Point Preparatory to Wrecking It.

putting enough material on top to permit the oil to come up through it. He emphasized the importance of not applying the oil in cold weather unless it is heated, pointed out the necessity of sloping the road first, and stated that the oil should not be allowed to go within 18 in. of the gutters. About half a gallon of oil per square yard is ordinarily adequate. Col. Sohier warned the members against leaving an oiled roadbed over night without gravelling the surface, on account of the washouts incidental to showers. Better results can be secured with calcium chloride and water than with water alone.

Mr. George Kimball, Superintendent of Streets, Manchester, stated that he used a tar and pitch composition, proportions not stated, on the top surface, mixed with egg and nut stone. This was applied in wheelbarrows with a rake, and no mud resulted. Dust was considerably reduced. Good results had also been obtained with calcium chloride. He had oiled 23 miles of road at a cost of 6.5 cents per yard, including spreading the top dressing of crushed stone, and had secured 2½ in. penetration below the surface.

Mr. A. B. Cowdery, of Boston, stated that the treatment of hollows in the roadway with tarvia and stone dust might cause the bunches previously referred to, unless the roadway were carefully surfaced first. Tarvia will not be smooth if the screenings are coarse when rolled into it. He emphasized the proper methods of handling such work from the standpoint of the tarvia representative.

Mr. Benjamin P. Richardson, president of the Calcide Process Company, discussed the classification of roads according to traffic, and stated that main arteries over which automobiles are allowed to run between towns at unlimited speeds are not advantageous subjects for calcium chloride treatment. This treatment is at its best in cities and towns where there is a large percentage of foot traffic. The treatment is odorless and spotless. Last summer a test was made under the supervision of the Department of Agriculture on a road in the government grounds at Washington. The road originally was built of trap rock, patched with limestone and then repaired a second time with trap rock. The upper and lower stones had ground the limestone to powder, and this dust had destroyed the binding properties of the surface. The first treatment with calcium chloride was in July, and since that time but two or three applications have been made. The road is now in very satisfactory condition. At Hingham, Mass., the calcium chloride treatment has been found cheaper than water, leaving no dust and mud, keeping new macadam moist and holding it in dry weather.

At Beverly Farms last summer 9.69 miles were treated, with an area of 108,013 sq. yd. This was treated for five months; the road was 19 ft. wide and over it passes heavy traffic at high speed. In one day 1,182 vehicles were counted passing in 10 hours, including 692 automobiles. The calcium chloride was applied by a new patented method, which loads a 600-gal. cart with a concentrated liquor and deposits 100 gal. each into six tins at the standpipes by the side of the road; when the cart is empty it turns around and syphons 500 gals. of water to 100 gals. calcium into its tank at each standpipe. The diluted liquid is spread on the road and the latter process repeated at each standpipe until the six tins are emptied. About four times as much work can be done in this way with one cart and a pair of horses as by the old method. It was found by a number of tests that a 600-gal. cart would cover an average of 3,800 sq. yd. per load and spread 28 loads of water per day at a cost of 2.4 cents per square yard, with three coats of water per day for seven months. Calcium chloride can be applied for a seven months' season at an average distribution of twelve 600-gal. loads per day, at a total cost, including the chemical, of 3.5 to 4 cents per square yard.

THE ORE-HANDLING ARRANGEMENTS at the works of the Bethlehem Steel Co. are rather unusual on account of the fact that the trains on which the ore is brought to the work come in on tracks considerably higher than the storage yard. As a result of this topographical condition the ore cars are run into a rolling car dump at the top of the retaining wall which bounds the high-level receiving track. This unloader is a long cylinder into which two cars are run at a time; these are then locked in place inside the cylinder which is rolled sidewise so that the ore is dumped over the edges of the cars, falling into hoppers at a lower level. These hoppers are located above a track on which cars can be run to receive the ore and take it directly to the furnaces. In case the ore is not to go directly to the furnaces, another type of car is run under the hoppers and transfers the coal a few feet sidewise to a long trough of concrete, which has a cross-section at the bottom approximately the same as that of a grab bucket. From this trough the ore is picked up by a bucket suspended from an ore bridge 550 ft. long over all, supported by two traveling towers 247 ft. apart on centers. This bridge covers the whole stock pile and enables the contents of the bucket to be dropped wherever desired.

Wrecking a Brick Smokestack.

By Edward E. Wall., M. Am. Soc. C. E.

On Sept. 28, 1907, the Water Department of St. Louis, Mo., threw down a brick smokestack at the abandoned low-service pumping plant at Bissell's Point. This plant has not been used for twelve years or more, but was kept in repair and the boilers under fire for emergency use, until 1903, when the fires were put out and the buildings closed up. A year later the engines and boilers were sold and removed. The buildings are substantial and in good condition, but this stack had been badly cracked along its entire length above the base, originally caused by being struck by lightning many years ago. It was strengthened by six steel hoops evenly spaced throughout its length. Lately the cast-iron cornice at the top opened up at the joints, and it was decided to throw it down before some portion of it fell upon the adjoining tracks of the Burlington railroad. There was danger that a portion of it might become dislodged by the jar of passing trains and fall upon a car and cause a wreck.

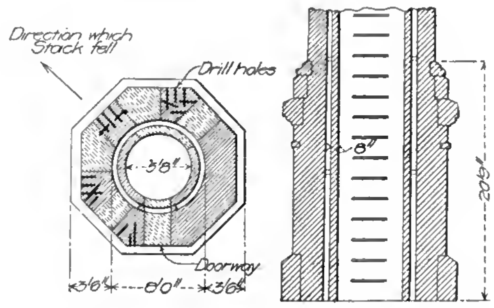
This stack was completed in 1871 and was built of hard hand-made brick laid in cement mortar. It stood at the southwest corner of the boiler house, about 10 ft. away, and not more than 15 ft. from the nearest railroad track on the west. There was about 45 deg. of available space to the southeast, where it could be thrown without causing any damage. This stack was octagonal in section, standing on a base of the same section 20 ft. 9 in. high, the walls of the base being 2 ft. 9 in. thick. The core wall was 8 in. thick, being separated from the stack wall by an annular space of 6 in.

The outside diameter of the base, exclusive of the stone trimmings, was 13½ ft., the stack above the base being 11 ft. in diameter and 8 ft. 8 in. just below the cornice. The total height above the ground was 127 ft. 4 in.

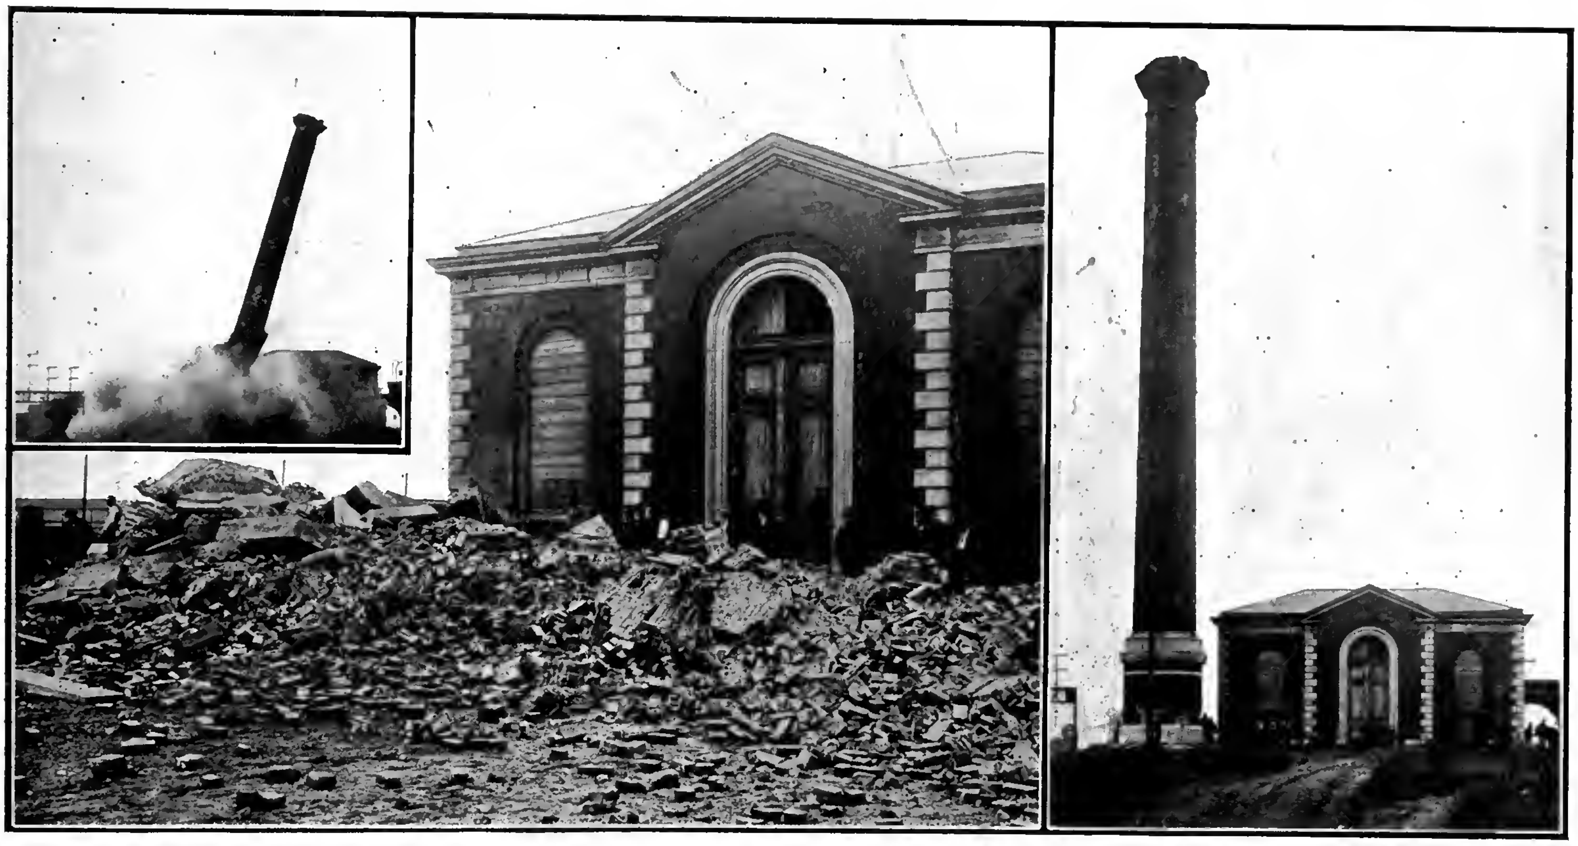
Four openings, approximately 36 in. wide by 24 in. high. were cut through the 2-ft. 9-in. brick walls of the base, as shown in the illustrations. There was doorway 2 ft. 3 in. wide and about 5 ft. high, built through the base on the north side of the stack, which left four piers supporting the stack between the openings. The core wall was cut entirely away for about one-fourth of its circumference on the south side. Nineteen 1½-in. holes were drilled in these piers, of depths ranging from 12 to 24 in., and loaded with two sticks of dynamite each, about 20 lb. altogether. Two of the holes in one of the central piers were drilled in the sides of that pier, sloping downward at an angle of 45 deg.

The brick masonry of the base was very hard, making the cost of cutting and drilling excessive. The total cost of labor and dynamite was $97. The salvage was only about 20,000 brick, owing to the fact that the masonry was so well bonded together that the bricks did not readily separate at the mortar joints. The space covered on the ground by the wreck was 146 ft. by an average width of 20 ft., and the farthest brick was found 185 ft. away. The cost of clearing away the debris was about $175.

No damage was done to the adjoining boiler house, and nothing whatever fell on the railroad tracks. The stack fell with its center line not more than 2 ft. from the location previously marked out for it.



Position of Holes Cut in Stack.



Views of the Brick Stack of the Bissell's Point Station, St. Louis Water-Works.

The Mont Cenis Route, the oldest of the Alpine through lines, is to follow the lead of the St. Gothard and Simplon routes and employ electric traction on its mountain division. Under the stress of the competition of the more recent lines, the French government has also double-tracked the approach to the tunnel on its side of the mountains and the Italian government will carry this double-tracking to Turin.

Instructions for Foremen.

A manual of rules for construction, prepared and copyrighted by John W. Ferguson Co., Paterson, N. J., and New York.

General Foreman.—A General Foreman will be placed in charge of each job, he will be responsible for the care of tools, material and the property of this company, and the maintaining of harmonious relations with the Owners, Architects and Sub-Contractors (in other words, he will be the representative of the Company on the particular work where he is employed and be responsible for the results obtained).

Other Responsibilities:

1, That all records are properly kept by Timekeeper.

2, To examine all plans (original or corrected).

3, That old plans are cancelled.

4, That only latest information is used in executing work.

5, To examine all letters, instructions and other information coming to job—initial same and give to Timekeeper.

6. That danger signs are placed at all Elevators and all persons prohibited from riding on them.

7, That "No Smoking" signs are put up and the rule enforced as soon as any carpenter work is started or where the Rules of the Owners prohibit smoking on their property.

8, That all street obstructions are properly guarded by red lanterns at night, and all city or other ordinances are observed.

9, That the watchman properly attends to his duties.

10, To enforce Book of Instruction and any special instructions.

Sub-Foremen.—Sub-Foremen will be responsible for the work under their immediate charge and the final result obtained and shall be subject to supervision and instruction from General Foremen.

Timekeeper and Material Clerk.—The Timekeeper will be subject to instructions from the General Foreman.

Responsibilities:

He shall keep all records neatly and accurate-

ly in books and on forms furnished by Main Office. He shall do other clerical work as required by Book of Instructions, or special instructions.

Regular Records:

1, All men employed, time worked by each and the distribution of labor.

2, Number of men employed by Sub-Contractors.

3, All materials received (including checking, as unloaded, or delivered).

4, All charges for extra work against Owner, or Sub-Contractors.

5, He shall file all instructions, letters, schedules, etc., in such manner as to be easy of access. He shall see that the General Foreman has initialed all such papers and shall himself initial them also, before filing.

6, All records, files, drawings, etc., shall be preserved and delivered to Main Office when job is completed.

7, Duplicates (carbon sheets) of all orders, letters, instructions, etc., must be sent to the Main Office.

Drawings:

1, All drawings shall be properly cared for and preserved.

2, They should remain flat (not rolled) and be easy of access.

3, Drawings made void by new drawings must be plainly marked in red pencil, "Void."

4, Void drawings must be kept in a place separate from all other drawings and must not be destroyed except by some one in authority from Main Office.

Contract Number, Headings and Job Numbers:

1, All time and material shall be recorded and reported according to the Headings supplied by, or approved by, Main Office. This is absolutely necessary and applies to everything.

2, Each General Contract will be given an individual number, which shall be used in connection with all orders, reports, etc.

3, The word "Heading" is used to designate the divisions of work under the General Contract; also each individual piece of extra work done in connection with each General Contract under the classification of Day's Work, Unit Price Work or Extra Contract Work. In addition to the Heading each item of Extra Work will be given a serial number called Job Number, to aid the Main Office when rendering bills for Extra Work. The same Heading with Job Number must always be used for the same division or piece of work.

4, It should be borne in mind always by General and Sub-Foremen and by Timekeepers that the men in Main Office who are keeping the books are not familiar with the construction work and accordingly must depend upon the written information from the job, to make necessary charges and credits.

5, Any work in Original Contract and about which Timekeeper has any doubt as to the proper Heading shall be reported to Main Office, with request for information.

6, If there is occasion to start Extra Work, before Main Office has stated what Heading to use, the Timekeeper shall use a distinctive Heading approved by General Foremen, and promptly notify Main Office. Such a Heading shall be written the same always, or until changed by, or any change approved by, Main Office.

Labor.—Time must be taken at least four times a day, at the morning and noon starting times, and the noon and evening quitting times.

Distribution:

1, A statement showing the distribution of all labor according to the Headings and Job Numbers must be returned to Main Office each week, ending on the day for closing the pay.

2, The statement must show the number of hours at each rate of pay which were spent on each Heading, whether on Original Contract or Extra Work, or to be charged to Sub-Contractors.

Material.—The General Foreman will be furnished by Main Office with the following:

Copy of each order for material.

List of materials as ordered with dates for delivery.

Foreman's bill showing where material is to be used.

If above or other information is not received promptly, it must be asked for at once.

1, The General Foreman must note particularly the time stated for the delivery of each lot or item of material and promptly notify the Main Office if he thinks the date is too early or too late.

2, The General Foreman will be held responsible for keeping himself supplied with material. He must not take for granted that it is going to be delivered at the time mentioned in the order, but shall make inquiries as to its shipment from time to time and look far enough ahead to insure its being on the job when required.

3, To be properly supplied with material, will insure rapid and economical work.

Care of Material:

1, Any material which can be damaged by being exposed should be properly protected.

2, Cement and lime should be stored in sheds and raised off the ground to prevent its being affected by moisture.

3, Kiln-dried lumber should be properly stored under cover, preferably in a shed, if not, it should be well protected by canvas or boards.

4, Light lumber, such as beams, plank, boards, etc., should be properly piled when received and when not used immediately should be "stuck" so that it may dry out and not become water soaked.

5, Brick should be put under a shed or well covered with canvas during the Winter months.

6, All hardware and small supplies should be kept under lock and key and only given out as required for immediate use.

Receipt of Material:

1, The General Foreman must give all material a General Inspection before it is unloaded, particularly from cars or boats. If he finds that it is not up to the quality contracted for, he must not permit it to be unloaded, but at once notify the party from whom it was purchased (and at the same time the Main Office) that the quality is not what it should be, so that an inspection can be made by the seller before the material is unloaded or used.

2, Material delivered by team should be accompanied by invoice or delivery slip in duplicate, one to be signed and delivered to driver, and the other signed and returned to Main Office. If invoices or delivery slips do not accompany material, receipts in duplicate shall be made out on the proper forms, and treated in same manner.

3, Brick, sand, stone or other material delivered in large bulk can be receipted for by the use of tickets for each load, with a receipt at the end of each day for the full amount delivered.

4, Invoices or slips for material must be marked with the proper Heading (if for original contract so state), showing where material is to be used.

5, Material delivered on cars or boats must be tallied or measured as unloaded.

6, A separate report shall be made for each car or boat showing date received, car number and initial or name of boat, so that Main Office may identify each lot.

7, When lumber has been passed by an Official Inspector, a reporting showing merely the number of pieces received is sufficient.

Record of Material:

A complete record must be kept in a book for that purpose of all material received with the dates and other information for identification. This is in addition to the invoices and reports made to Main Office. A separate page in the Record Book must be allowed to each firm supplying material.

Transfer of Material:

1, All material transferred from one job to another, or from the Original Contract to any item of Extra Work, must be accurately tallied, and a report made to Main Office of such transfer the same day.

2, The report must show the Heading from which the material was taken, and the Heading to which it has been transferred.

Shortage and Damage of Material:

1, The General Foreman should compare the total amount of material delivered with the amount ordered, so that any shortage may be noted at once and not found out when too late to avoid delay in the work.

2, Invoices or slips shall be marked before returning to Main Office, indicating any shortage, defects or criticisms.

3, All shortages or damage of materials must be reported without delay to the parties furnishing it, either by General Foreman direct or through Main Office.

4, If material is damaged in transit, claim must be filed promptly with the Agent of the Railroad Company, and he shall be requested to inspect the material before it is unloaded. The Main Office shall be notified at once by letter of such action.

Tools.—Each job will be furnished with an equipment of tools necessary for the execution of the work. The General Foreman must make a list of his requirements before starting the job, and be responsible for having all the tools required on hand before they are actually needed. The General Foreman will be responsible for their proper care and return when the job is finished, also that any necessary loss or damage does not occur. Any shortage or breakage must be accounted for.

In an Emergency, the General Foreman is authorized to purchase special equipment required, but he should endeavor to look far enough ahead so that what he requires may be supplied from the Yard or purchased by Main Office. Report must be made immediately upon the purchase of special equipment, noting the urgency which demanded it.

When the job is large enough a Storekeeper should be placed in charge of all tools, equipment and small supplies, who shall be held responsible for their general care and for any losses which may occur. In case it is advisable to employ a Storekeeper, the General Foreman should designate some one to look after the tools and equipment, to insure their being properly cared for and not lost, stolen or destroyed, or left lying around when not in use.

The General Foreman must see that the equipment of tools and scaffolding or material is not wastefully used, cut up or destroyed, and he cannot be too strongly impressed with the necessity of enforcing this rule, when a tendency to violate it is shown by any one in his employ. This should be done at the start and not after it has become a habit with some workmen.

Any part of the equipment which becomes damaged or unfit for use should be set one side separate from the other tools and returned to the Yard for repairs at the earliest possible moment. All the equipment should be kept in condition for use, by temporary repairs, if possible on the job.

Inspection of Tools:

1, If any tools are transferred to another job, report should be made promptly to Main Office so that the General Foreman can be credited for the tools. An original and duplicate slip should

be made out, the original being sent to Main Office, and the duplicate given to driver of team, who must have it signed by the person receiving his load. It should then be mailed to Main Office. (When shipments are made by Railroad, the duplicate slip must be mailed).

2, A correct account of all tools received and sent away from the job must be entered on Form headed "Tool Account," so that at any time during the progress of the work, just what tools are in use can be seen.

3, This record must be sent to Main Office promptly, when the job is finished.

4, Sub-Contractors must not be allowed to use this Company's tools, scaffolding or equipment, except where special arrangements have been made for such use. The General Foreman must see that the equipment, so loaned, is returned in good condition, and that any which may be lost or damaged are charged to Sub-Contractor.

5, General repairs of Engines, Boilers and heavy equipment not to be made on the job without special instructions.

6, The General Foreman should see that the equipment furnished him is in proper shape and if not, immediately report its condition to the Main Office.

7, General Foremen must examine and see that all material used for scaffolding, derrick blocks, etc., is in perfect condition. All scaffolding must be built of material selected for that purpose and it should be constantly examined to see that it is properly constructed and in proper condition.

8, All derricks must be carefully examined before being put in service and frequently examined to see that they are safe and in perfect working order. Derrick booms should be lowered and properly lashed and fastened when not in use.

9, All rope, blocks, chains and other appliances for handling material must be examined and none used which show the slightest indication of defect.

10, All ladders must be carefully inspected to insure their being in perfect condition, and sufficiently heavy for the use to which they are placed.

Paying Off.—General Foremen and Timekeepers must observe the following regulations in distributing the money on pay day and at other times:

Pay Day:

1, The General Foreman must be present when the men are paid, to identify them, and personally check each name on the pay-roll as the money is delivered to the man. After paying off, the pay-roll should be signed by both General Foreman and the man distributing the money, certifying that the names checked have been paid.

2, On pay day, the General Foreman must Compare Discharge Tickets with Unchecked Names on pay-roll and Envelopes left over and mark the letter "D" next names of discharged on payroll.

Envelopes Left Over:

1, A list should be made out immediately after paying off of the names and amounts of all the envelopes left over, on form headed "Report of Employees Unpaid," and the original of this list returned to Main Office with pay-roll sheet.

2, Each envelope retained by General Foreman shall be marked at once with the date of pay day, and Contract Number, and held by him until called for (not to exceed one week). If not called for in one week, the envelope with the money therein shall then be returned to Main Office.

Paying After Pay Day:

1, If a man calls for his pay within one week after pay day, he must sign a receipt for his pay on the special Pay Receipt Form provided for that purpose. This receipt must be sent to the Main Office promptly.

2. No money shall be paid to any one but the party to whom it is due, except upon a written order from said party, and the party receiving the money on such order must be properly identified.

3, The order must be sent to Main Office with the receipt of the party to whom payment is made.

4, If a man calls for his pay more than one week after pay day, his name and address should be taken and sent promptly to Main Office, stating the amount of his back pay. Upon receipt of such request Main Office will send a Special Pay Roll Check to the man at his address for the amount.

Pay Receipts:

The General Foreman will be supplied with books of Pay Receipts and should carry one in his pocket. He will fill out one of these and have it signed by each man discharged; also by men paid on job for previous week. The receipt must be sent at once to Main Office, and stub filled out and retained by Foreman.

Daily Reports.—The Daily Report must be made every day on a blank furnished for that purpose, showing the following:

Number of men employed in each class of work and where they are working.

Number of men working for Sub-Contractors.

Commencement of any particular part of work.

Receipt of Material for Sub-Contractors.

Time Sub-Contractors start and finish their work.

Receipt of important and special material.

Report of any accident or damage to work.

Condition of weather when work is prevented.

A special letter must accompany daily reports, covering important matters that cannot be embodied in the regular report.

Sub-Contractors.—General Foreman must inspect, and be responsible for, the quality of work done by Sub-Contractors. He shall see that proper progress is made, and that Sub-Contractor is given sufficient notice ahead of time as to when he is required on the job.

Sufficient notice does not mean one day's notice, but time enough for Sub-Contractor to secure his men and material.

Labor or material must not be furnished a Sub-Contractor except upon a written order, and daily charge slips signed for the same and sent to Main Office.

Accident Reports.—In the event of any accident, however slight, happening to any one on the work, whether in the employ of the company or not, it is absolutely necessary that a detailed report of such accident be made promptly in writing on the blank furnished for that purpose.

These reports, and all data connected therewith, must be written with Indelible Pencil.

If any accident, the report must cover all the facts in detail. In case the accident is of a serious nature, a complete statement must be obtained from the injured person and all witnesses, in writing, and their signatures to such statement, witnessed by a second party.

In case of accidents which are liable to prove fatal these statements must be sworn to before a Notary Public, and Main Office notified without delay. Photographs should be taken in such cases, if possible, before anything has been disturbed.

In case of accident of serious nature an investigation will probably be made by an Examiner, who should be given only the actual facts in the case. Any information beyond this must be procured by him from Main Office.

The General Foreman must see that tools, materials or equipment that caused the accident are removed if possible to his office, properly marked and preserved.

In case of doubt or any misunderstanding on the part of the General Foreman, Main Office should be consulted as to what information is considered necessary as a record of the accident.

Where the injured person remains at work, this must be stated on the Accident Report, and in cases where they are taken to the hospital, frequent inquiries must be made as to their progress and a report made immediately to Main Office. Main Office must be advised of the Return to Work of any person injured.

Car Demurrage.—All cars should be unloaded immediately, unless there is a good reason for not doing so as in case of damage or shortage, as a demurrage charge is made by the Railroads, for cars held more than forty-eight hours after they are placed on the siding.

A monthly time book may be used for recording the number and initial of each car (noting what it was loaded with), the date of its arrival, and the date it was unloaded. In case of a small job or only a few cars, this record can be kept in some other book, but a record must be kept in all cases.

Cartage.—Cartage for each class of material must be kept separate and a report made of the total cost of cartage of material when the hauling is completed. This report, together with a complete record of the distribution of all cartage is to be returned to Main Office once a month, and upon the completion of the job.

Diary.—A diary must be kept on each job showing a daily report of what transpires, such as:

Condition of weather.

Temperature (with thermometer readings at 8 a. m., 12 m. and 5 p. m., during the winter months).

Notation of visitors (Owner, Architect or any one from Main Office).

Starting of all divisions of the work.

Starting of work of Sub-Contractors.

Arrival of material, and of Outside Contractors not under our control.

Records of accidents.

Taking possession of the building by the owners.

Diary records should be briefly noted on Daily Reports.

Telephones.—Where the job is supplied with a special telephone it must be used only for business purposes. All calls made by sub-contractors or individuals must be noted and charges made against them. Post conspicuously, adjacent to the telephone, telephone numbers for Ambulances, Hospitals, Fire Department and Police Department.

Cement Bags.—Care must be taken to have all empty bags collected and kept dry with as little damage as possible so that they may be returned to the parties from whom the cement was purchased and due credit may be obtained by this Company. The General Foreman will be expected to account for any excessive loss from this source.

Main Office will furnish shipping tags and full instructions for the return of empty bags, but care must be used in every case that none but the bags marked with the respective company's trade or brand of cement mark are sent to them.

On making shipments Bills of Lading must be made out in duplicate, and both copies together with a material slip showing number of bundles and total number of bags shipped forwarded at once to Main Office.

Extra Work.—Any work not included in Original Contract, shall be known as Extra Work, unless Main Office should instruct otherwise, and will be done under the following classifications:

Extra Contract Work: Where a fixed amount covers all labor and material for the work under one Heading.

Unit Price Work: Where a fixed amount per unit of work covers labor and material, such as price per yard, per thousand, etc.

Days Work: Where the actual labor and ma-

materials are charged for at cost plus a percentage.

Authority for Performing Extra Work:

1, We should like to make it an invariable rule that Extra Work should not be started except upon properly written authority from Main Office in regular form, with Headings and Job Numbers designated. We recognize, however, that it is sometimes necessary to start Extra Work before receiving written authority from Main Office. In such cases General Foreman should call for written authority from Owner before starting the Extra Work, and should send to Main Office this written authority the day that he receives it.

2, If it should be necessary, in the judgment of General Foreman to start Extra Work upon being requested to do so by Owner, or his proper representative and without any written authority whatever, General Foreman should immediately notify Main Office, stating all the circumstances.

Reports of Extra Work:

1, When so requested a Daily Charge Slip for each item of Extra Day's Work shall be furnished to Owner, (unless so requested Daily Slips need not be made at all).

2, If Daily Slips are made a (carbon sheet) duplicate shall be made also, and held on the job until end of week, at which time they shall be attached to Weekly Charge Reports, and sent therewith to Main Office.

3, Weekly Charge Reports for labor, shall be made for each item of Extra Day's work. These shall show the class of labor (whether mason, carpenter, etc.), the number of hours worked of each class, at each rate of pay. They shall be sent to Main Office at end of each (pay) week.

4, If so requested (carbon sheet) duplicates shall be furnished to Owner.

5, Charge slips for material shall be made each month, or immediately when each item of extra work is completed, and shall show the quantities, kind of material and from where it came. These slips shall be sent to Main Office promptly.

6, A bill, on Extra Work Bill form, including labor and material for all Unit Price and Day's Work under its respective Heading and Job Number must be sent to Main Office as soon as any item of the work is completed.

7, In case such work extends over a period longer than one month, a bill must be returned to the Office at the end of Each Month, showing the amount of labor and material furnished for each individual item, such bill to be clearly marked "Unfinished."

8, Prices of material, when known, to be inserted in pencil in column designated "Prices"; only one item to be entered on a line.

9, Remember that the men in Main Office depend on these Extra Work Bills to charge the work against the party to whom it is furnished.

Sub-Contractors on Extra Work:

1, No Extra Work shall be done by a Sub-Contractor except upon an order in writing from Main Office. In case of Emergency, the General Foreman may order Extra Work, but must notify Main Office so that it can be confirmed immediately by a regular order.

2, No Extra Work shall be done by a Sub-Contractor except upon an agreed price either at a lump sum, or unit price for the labor and material. In the latter case the time and material must be checked daily and reported to Main Office.

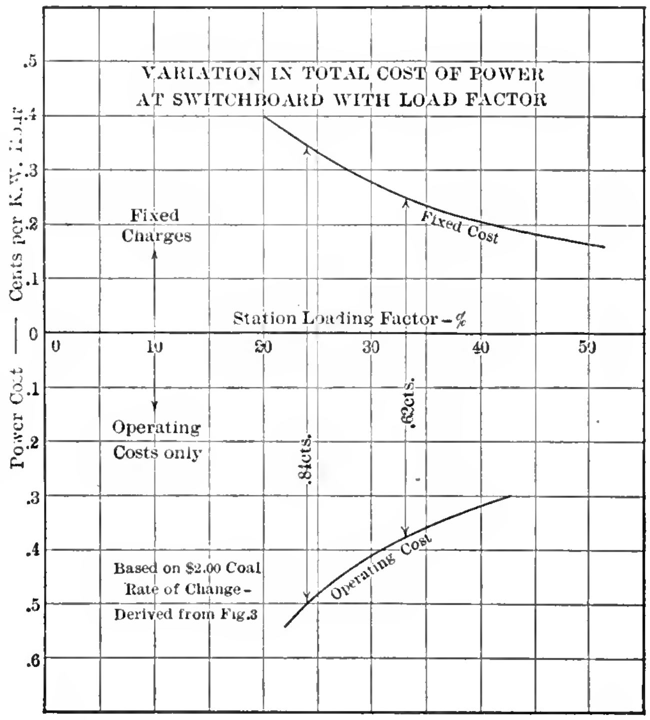
Orders by General Foreman.—In cases of necessity the General Foreman may order material and give an order for work to be done by Sub-Contracts, on Order Forms furnished for that purpose, sending a duplicate (carbon sheet) at once to the Main Office. On the carbon sheet write a full explanation of why and for what purpose the material was ordered, and the necessity for any item of work ordered of a Sub-Contractor.

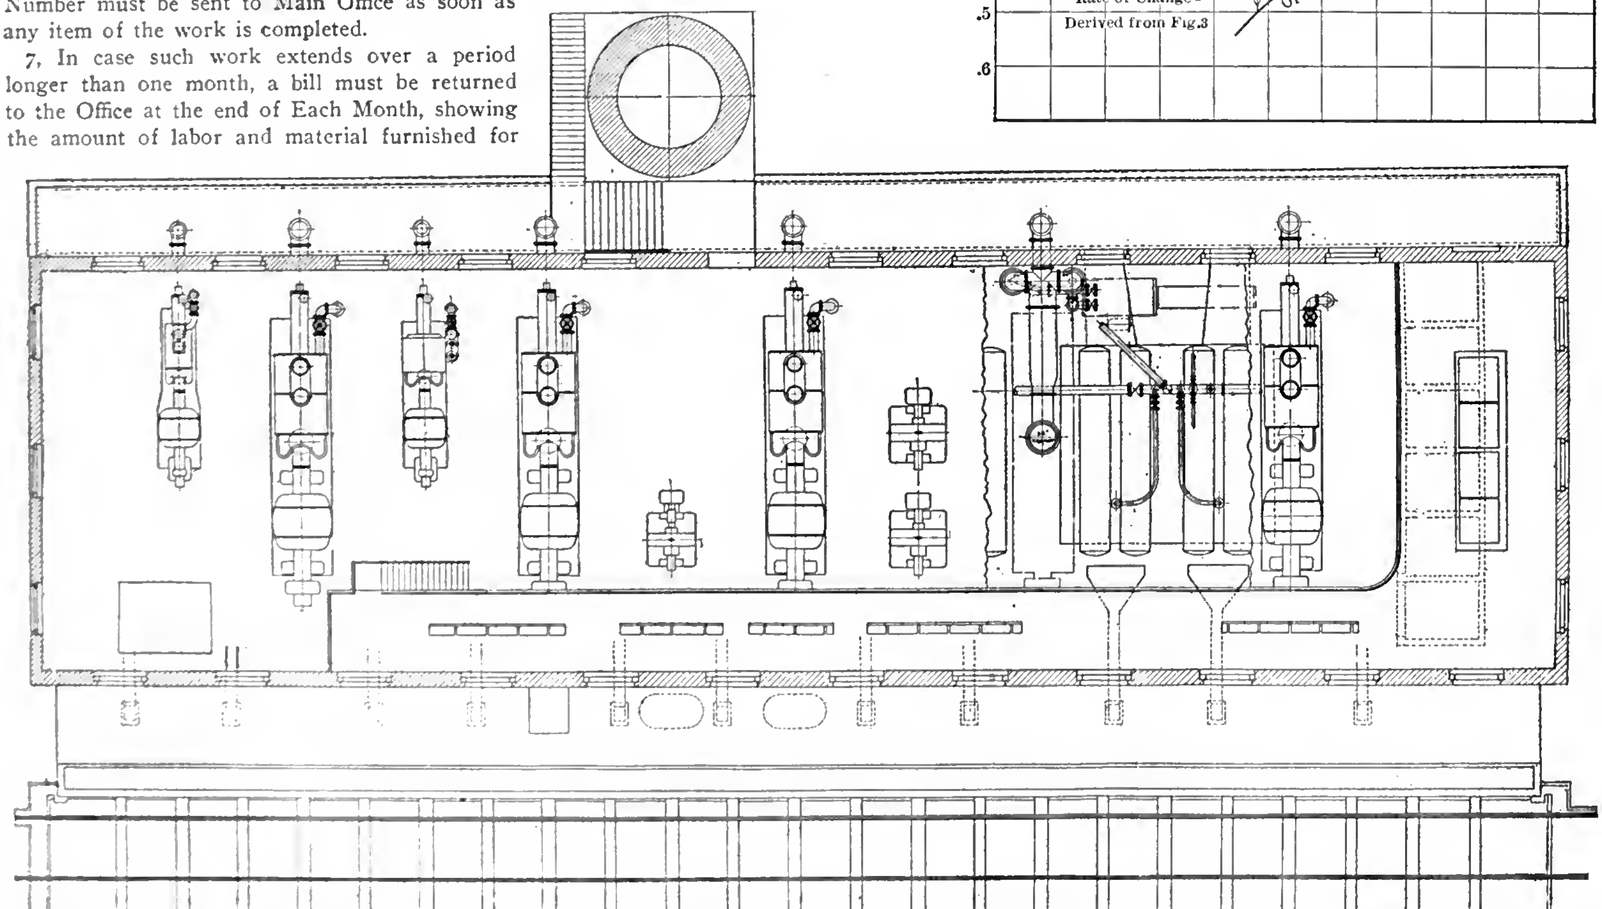
RELOCATION OF LINE on the Columbia & Port Deposit branch of the Pennsylvania R. R. has been recently completed along some thirteen miles of the Susquehanna River, which will be raised by the McCall Ferry power development. The new double track line had to be built on steep rocky bluffs, making the work so dangerous to trains on the old track at a lower elevation that regular service was entirely abandoned.

The Spy Run Station of the Fort Wayne & Wabash Valley Traction Co.

The Spy Run station of the Fort Wayne & Wabash Valley Traction Co. has been arranged along decidedly novel lines and presents an interesting example of the engineering possibilities of turbine plant construction. At the recent convention of the American Street & Interurban Railway Engineering Association, the station was described at considerable length by Mr. J. R. Bibbins, from whose paper the following account has been abridged.

Like many other similarly situated railway concerns, the company has adopted the policy of developing light and power business in connection with its traction system, serving both traction and lighting systems from a central power station, as previously outlined. In the city of Ft. Wayne, this business has assumed such proportions that nearly one-half of the new power station is devoted to 60-cycle lighting equipment, the remainder to 25-cycle equipment for traction pur-

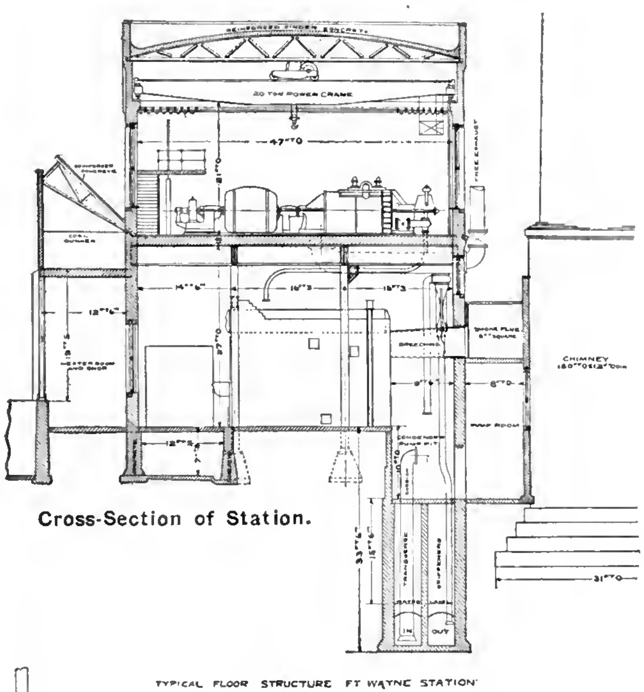




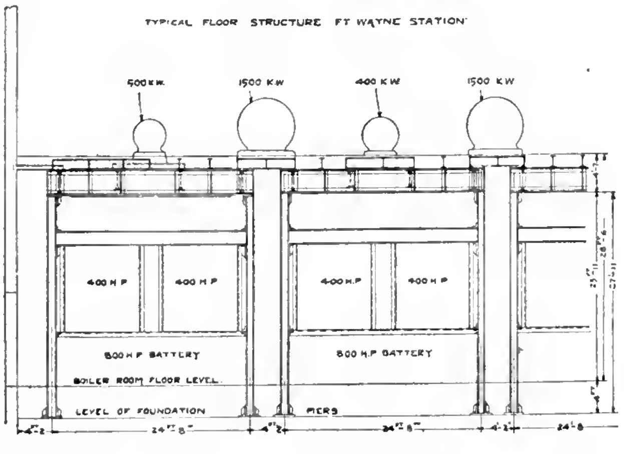
General Plan of the Spy Run Power Station of the Ft. Wayne & Wabash Valley Traction Co,

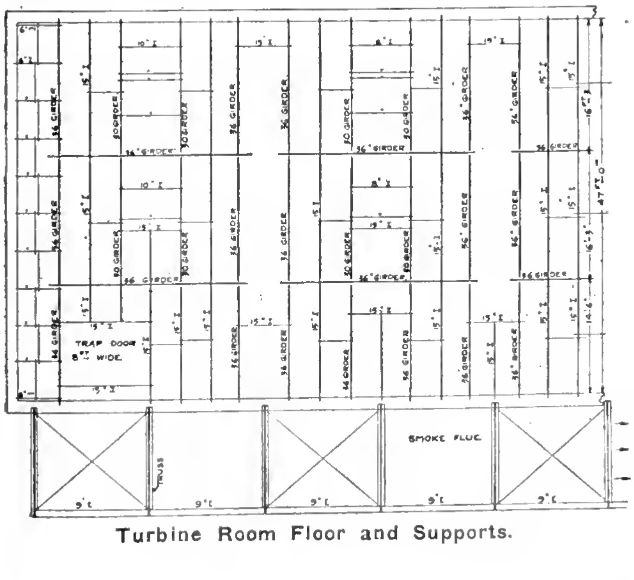
poses. High tension transmission lines parallel the railway from Fort Wayne to Lafayette, a total transmission distance of 112 miles from the source of supply. En route, the lines touch Wabash, Logansport, Huntingdon, Peru, and numerous smaller towns, in most of which considerable lighting business is available. Along this route are eleven rotary converter substations ranging in capacity from 200 to 500 kw., totalling 3,600 kw., or somewhat in excess of the present station generating capacity. But as the maximum demands from these substations do not superpose, owing to the distribution of cars, there results at the station an unusually uniform load for traction work.

The site chosen parallels a small stream—St. Joseph's river—from which the water supply is drawn for both feed and condenser purposes. Owing to the contour of the country, 25 ft. difference in level between river bed and station floor was unavoidable. A lower location would not only have introduced difficulties in coal trackage, but also would have endangered the station at periods of excessive flood, to which the stream is liable.



Cross-Section of Station.





Turbine Room Floor and Supports.

The principal features of the station may be summarized as follows: (1) A two-story, rectangular brick structure with side wings for the accommodation of auxiliary apparatus, coal bunker, machine shop and stores. (2) Generating machinery on second floor over boilers. (3) Structural foundation with concrete arch floor construction. (4) Independent barometric jet condenser—moderate vacuum. (5) Gravity conduit system for cooling water. (6) Independent, direct-driven exciters—common bus for each system. (7) Steam piping—simple, short and direct, with continuous upward slope from boiler nozzle to turbine throttle. (8) Sufficient superheater surface to maintain dryness, or moderate superheat at beginning of expansion in the turbines—100 deg. to 125 deg. at the boiler. (9) Mechanical stoking with gravity fuel feed. (11) 6,000-ton (two months') coal storage, served by gantry crane. (12) Steam-driven auxiliaries for feed heating. (13) System of forced ventilation for turbo-generators. (14) Fireproof transformer compartments, with transformers mounted on rolling trucks to facilitate removal. (15) Remote control oil circuit-breakers with time limit overload relays.

Essentially the station represents an attempt to produce a power property that will show to best advantage in the balance sheet with a medium price coal—one in which the absence of engineering "frills" for securing the highest efficiency, is compensated for by lower capital cost. This should be borne in mind in the discussion of the operating results later noted.

The building construction in turbine power plants is largely influenced by arrangement of boiler equipment. In this case it was apparent that a somewhat lower boiler capacity than usual would be required for the combined service. For moderate-sized units, a well-equipped boiler room requires from 2 to 2.5 sq. ft. per boiler horse-power, in some extremely compact arrangements, requiring as low as 1.5 sq. ft. per boiler horse-power. The Fort Wayne arrangement works out 1.75 sq. ft. per boiler horse-power. Assuming a capacity ratio of 0.6 boiler horse-power per kilowatt, the floor area then works out slightly over 1 sq. ft. per kilowatt for boiler room alone.

Now, for a fairly compact generating room in a station of this size, from 0.75 to 1.15 sq. ft. per kilowatt are required. But for the Ft. Wayne plant, some provision had to be made for the accommodation of direct-current sub-station apparatus. Assuming 1 sq. ft. per kilowatt as a reasonable area, we find that this practically coincides with the above boiler room area. The designer thus had two alternatives: First, a double decked power station, or, second, a building of twice the area with two equal-size operating rooms in parallel and under one roof, which arrangement would be preferable. From an investment standpoint, it is hardly open to question. As it stands, the building cost about $12.50 per kilowatt, including additions, which is by no means excessive.

Inseparable from this building arrangement is the question of structural foundations, which are entirely justifiable in the cases of steam turbines owing to the absence of cyclical movement arising from unbalanced parts requiring in the case of low-speed reciprocating engine the most rigid foundations. Moreover, there was ample precedent for this type of foundation structure, notably the two turbine stations of the Philadelphia Rapid Transit Co.

The floor structure of the Ft. Wayne station is shown in detail in an accompanying illustration. It consists of individual pairs of transverse plate girders extending across the building under each turbine bed plate. Short cross girders serve to tie the longitudinal girders together at column intersections, the whole forming bents or cradles between the several generating units. Box columns divide the building width into practically three equal spans, these columns rising between the several boiler batteries. Thus the weight of th generating machinery is distributed between two building walls and two rows of columns. Only in the case of the smaller machines and rotaries does any of the weight fall upon the areas intervening between columns. In order to insure even settling, the precaution was taken of carrying footings for both columns down to practically the same level so as to encounter homogeneous strata.

TABLE OF DATA OF POWER HOUSE.

Dimensions of building, ground floor plan (47 ft. by 177 ft. 2 in.)	8,340 sq. ft.
Dimensions of building, condenser room (9 ft. 6 in. by 177 ft. 2 in.)	....
Dimensions of building, pump room (8 ft. by 177 ft. 2 in.)	1,419 sq. ft.
Dimensions of building, heater and pump room (12 ft. 6 in. by 173 ft.)	2,160 sq. ft.
Total area of power house	11,919 sq. ft.
Total area of power house, single deck basis.	20,273 sq. ft.
Height boiler room, 28 ft. 6 in.; turbine room to crane rail, 21 ft. 7 in.	
Present capacity, 60-cycle, 3,500 kw.; 25-cycle, 3,500 kw.	7,000 kw.
Utimate capacity	8,500 kw.
Ultimate capacity, entire plant max. rated overload	12,750 kw.
Present substation capacity, 1,300 kw. ultimate	2,600 kw.
Present boiler capacity, 10—400-h.p.	4,000 bo. h.p.
Ultimate boiler capacity, 12—400-h.p.	4,800 bo. h.p.
Relative area—	
Station, ground floor plan	1.39 sq. ft. per kw. ult.
Station, single floor plan	2.39 sq. ft. per kw. ult.
Operating room (floor plan)	0.98 sq. ft. per kw. ult.
Operating room (exc. high-tension and sub-station equipment)	0.722 sq. ft. per kw. ult.
Boiler room (net floor plan)	1.74 sq. ft. per bo. h.p.
Total boiler room and bunker	2.19 sq. ft. per bo. h.p.
Boiler settings (24 ft. 8 in. by 23 ft. 5 in.)	0.725 sq. ft. per bo. h.p.
Relative boiler capacity, ultimate.	0.56 bo. h.p. per kw.

It is apparent from the illustration that the location of the large turbines was chosen so as to accommodate under each floor bent a single battery of boilers. With the small boiler units chosen, this, of course, provides a larger turbine room above than is necessary; but, by utilizing the excess floor space for substation apparatus, this disadvantage is largely overcome. The floor plan of the equipment arrangements shows to what advantage the space has been utilized.

It is noteworthy here that with larger boiler units, a far more compact arrangement would be possible with little increase in floor span between batteries.

This relative disposition of boilers and turbines evidently permits of the simplest form of piping. Strictly on the unit principle, this would involve but two bends, as shown in the cross-sectional drawing. The addition of an equalizing header running the length of the building then complicates the piping only to the extent of extra valves, fittings and hangers, resulting in: (1) Most direct path of steam from boiler to turbine; (2) Equalizing connection to compensate for varia-

tions in the rate of steaming of boilers in service; (3) Provision for most convenient distribution of boiler capacity to carry any load; (4) A cost of $2.50 per kilowatt for steam piping, complete.

In the normal operation of the plant, effort is made to keep those boilers in service nearest to the turbines in operation, thus giving the minimum distance of steam flow. When occasion arises, the plant may be operated on the unit system, valves in the header between the various risers being supplied for this purpose.

Superheaters were installed principally for the purpose of insuring thoroughly dry steam at the beginning of expansion in the turbine. Although the presence of moisture in the steam system is not encountered in normal operation, the precaution was taken of delivering steam from the boilers underneath and discharging it above the header, so that a continuous draining is provided from turbine throttle back to boiler. This is likely to be an advantage in starting a section of the plant that has stood idle for a time.

In the arrangement of the breeching, the main smoke flue might have been run inside the boiler-room walls, thus avoiding the breech connection shown in the cross-section. This, however, would have necessitated locating the condensers outside of the building. With the present arrangement, a 10-ft. space back of the boilers is ample for all condensing apparatus, and the space under the external smoke flue is utilized as additional boiler-room area for small auxiliaries, oil filters, and the like.

Superheated steam is provided direct from the main to all principal auxiliaries in the plant. This avoids an auxiliary steam main. According to customary practice, the auxiliary main draws its supply from opposite extremities of the steam system so as to avoid to the greatest degree possible a shut-down of auxiliaries. At Fort Wayne nearly the same security is provided by connecting auxiliaries directly into the steam main at different points. Thus boiler feed pumps are connected in duplicate to opposite sections of the steam main, each of which is supplied by at least four boilers. Similarly, condenser pumps are connected to the same section of the main as the turbines which they serve. If a turbine unit is disabled, the pumps will not, of course, be needed.

The absence of economizers will be noted. These were not considered necessary with coal at $2 to $2.50 per ton. For feed heating auxiliary exhaust steam is entirely relied upon, all boiler, service and condenser pumps, also fan and stoker engines contributing heat through the medium of open heaters. Exciters are direct-driven. Nevertheless, a feed temperature of 160 deg. to 180 deg. is obtainable during the day, and 200 deg. at night. This feed is drawn from the hot condenser discharge tunnel and delivered to elevated tank, which provides a static head on the heaters and are of sufficient capacity to supply the plant for three hours at full load. Similarly the heaters are elevated a few feet to insure a positive lift of feed pump valves. With this feed system, boiler cleaning is not necessary oftener than at monthly intervals.

Mechanical stoking was adopted not only to minimize labor cost, but also to provide ample forcing capacity for peak loads or emergencies. With Hocking Valley screenings, three men can handle without difficulty ten boilers, or 1,330 boiler horse-power each. Hand firing for the same capacity would require ten firemen and two water-tenders, or 400 boiler horse-power per fireman, a reduction of 60 per cent. Present boiler-room labor, averaging $11.75 per 12-hour shift, would be increased to about $28 per shift, providing 12-hour shifts could be maintained.

The character of river water had, of course, an important bearing on the design of the condenser system. Although carrying considerable sediment at times, the water is extremely soft and develops no hard scale even after many weeks of continuous running. This annulled the principal advantage of the surface condenser., viz.: return of pure exhaust steam for feed water. The 25-ft. difference in level between ground floor and low water made one of two condenser systems imperative: (a) Surface condenser with continuous pipe loop (balanced water column), with power-driven circulating pumps to overcome fluid friction. (b) Barometric jet condensers mounted near the level of turbine exhausts with tail pipes extending downward to the normal river level, with power-driven circulating pump to overcome excess barometric head.

With the former, dry vacuum pumps would be imperative in order to prevent the condensers from becoming air-bound, or losing their vacuum altogether through air leaks in the water system, thus adding another auxiliary. Moreover, the surface type of plant is extremely bulky and would have seriously interfered with the "double-decked" layout.

On the other hand, the barometric type fits particularly well into the scheme. The condenser head may be suspended beneath the turbine, where its most bulky part is out of the way. The tail pipes may then be carried down at any angle or turn sufficient to clear necessary obstructions. Thus the 9.5-ft. area way which would ordinarily be provided in the rear of the boilers is conveniently utilized as operating space.

With the arrangement employed, a difference of about 47 ft. exists between the condenser head and low water level. This, however, does not interfere with the operation of the condensers, as a partial void simply results in the upper part of the barometric column.

The use of twin condenser units permits the use of less bulky apparatus, and also makes it possible, in the event of the disablement of one side, to continue operation on the other with reduced vacuum. Long stroke reciprocating pumps were chosen for this purpose instead of high-speed centrifugal pumps, as being best suited to the high lift, 16 ft. With this type of pump, a small air chamber will suffice to carry over the moment of reversal without any dip in vacuum, which would otherwise accompany the non-uniform flow of injection water. This equipment without dry vacuum pumps yields a vacuum during warm weather of about 26.5 to 27 in. at full load, referred to 30-in. barometer. Its simplicity and ease of upkeep is apparent, especially in view of the low cost, about $2.50 per kilowatt, including pumps and piping, but no tunnel work.

Water is conducted to and from a screen house on the river bank entirely by gravity through a double-duct concrete conduit. At the river a double screen prevents debris from entering the intake, which is at right angles to the current, while the discharge is down-stream. This conduit system, of course, necessitated considerable excavation in the rear of the boilers. The two retaining walls were then reinforced at intervals by transverse stiffener arches sprung across the pit.

The Ft. Wayne plant uses normally about 100 tons of coal per day. In the provision for coal storage, an elevated bunker of relatively small capacity (400 tons) fulfils all requirements for gravity feed. Even this would tide the plant over a period of at least three days in case of failure of coal-handling apparatus. The main storage yard will contain about 6,000 tons—sufficient for two months' supply, but only about 4,000 tons is ordinarily held in stock, except in case of impending fuel shortage. The gantry crane serving this storage yard combines the function of unloader, crusher, elevator and distributor. Its efficiency is attested by the fact that while its normal capacity is considered to be one 50-ton car per hour, the operators have unloaded a 40-ton car in 16 minutes, and a maximum of eleven cars (500 tons) in a short working day. The crane is electrically operated from a controller tower by one man.

The two sections of the generating plant, 25-cycle and 60-cycle, are, of course, separated electrically, and each therefore controlled by a separate switchboard. Two additional boards control the rotary converter output for both 25-cycle and 60-cycle systems, the latter consisting of a direct-current power circuit for elevators and other intermittent power. A fifth board controls the exciters. With perhaps the exception of the exciters, the generating plant is quite standard throughout. In place of the usual steam-driven exciter unit, with motor-driven duplicate, each generating unit is provided with its own direct-connected exciter, all generating at the same voltage—125 volts. Each exciter has sufficient capacity to carry two generators. All may be connected to a common bus, as an emergency condition. Normally the 25 and 60-cycle exciters are separated to permit the use of independent voltage regulators.

Assuming the case of instantaneous fluctuating loads, the voltage regulation of a direct-connected engine-generator-exciter unit is not, of course, comparable with that of steam-driven exciters, due to cumulative drop in speed and voltage. Of the three systems (a) independent steam-driven exciter, (b) independent motor-driven exciter, (c) exciter-driven by prime mover, the first undoubtedly gives the best results. But with the use of the automatic voltage regulator, the three are brought practically to an equality.

This subdivision of exciter capacity assures uninterrupted service to a degree quite impossible with the usual arrangement of independent exciters, and almost to the same degree as the standby storage battery quite frequently employed as an insurance against current interruptions. With half the exciters in the station inoperative, there would still be ample capacity remaining.

These direct-connected exciters add 2.6 per cent. to the expense of the main generating unit. A detailed comparison of the total cost of the exciting plant, as compared to the cost of an inequivalent independent exciting plant, including reserve unit, shows some 20 per cent. in favor of direct drive.

All the generators draw their supply of ventilating air from a sheet steel duct running the length of the plant above and in front of the boilers. This has served its purpose, but a positive pressure fan has been installed as an auxiliary to accelerate the air flow during certain prevailing winds when the required draft is more difficult to maintain through the long supply duct. This system of positive generator ventilation has the advantage of maintaining low generator temperatures the year around, while by means of the fan auxiliary a large excess of air can be supplied to any of the units that may be for any reason abnormally overloaded. In other words, the fan blast may be regarded as a generator auxiliary. It makes possible greater generator overloads.

In some large turbine plants of recent design where considerable distance must necessarily intervene between switchboard operator and turbine throttle, it has been found desirable to control the running speed entirely from the switchboard by a small motor-driven mechanism connected to the governor. This system has undoubtedly advantages from an electrical standpoint in synchronizing and distributing load. Yet in compact stations such as Ft. Wayne, it seems a better plan to commission the engineer in charge with entire authority over the mechanical equipment, as is the case. All speed adjustments are taken care of at the individual governors by the engineer or from the switchboard.

Designers of large plants also tend to concen-

trate in a continuous return cooling and filtering system, the usual independent oil system used on these turbines. At Ft. Wayne, however, the independent system has been used, largely with the intention of isolating trouble in so important a function as the lubrication. Each turbine has its own oil pump, cooler and strainer reservoir, all of which apparatus is readily accessible from the engine-room floor. When desired, however, the oil may be entirely drained out of any of the machines into the filter below, where it is screened, washed and returned by a small steam pump.

In the final analyses of the ultimate cost of power, fixed or capital costs, of course, have an important bearing, and it is in this regard that the type of station described exerts its strongest influence. In the preceding discussion, it has been the object to show wherein the double-decked station has made the greatest advance along engineering lines. Owing to the absence of many refinements, it is evident that the maximum possible efficiency could hardly be obtained. In compensation, we should look for a considerable reduction in the capital charges in order to bring the total cost of the power generated to as low a point as would result from the use of a more efficient plant. This proves to be the case with the Ft. Wayne station.

Analyses of the total power costs from modern steam plants of 5,000 to 10,000 kilowatt capacity shows that the capital costs, including interest and depreciation, amount to about 50 per cent. of the total. For such high-grade stations, with thoroughly modern equipment, we should expect an investment cost of from $150 per kilowatt in the smaller, down to $100 per kilowatt in the larger sizes. In a few very large stations the investment cost has been less than $100 per kilowatt, but for stations under 10,000 kilowatt it very rarely occurs that the cost is below the above figure. The Ft. Wayne station is thus unique in having set a new standard for power-station cost which may well be emulated in cases where turbine machinery is applicable. The table shows the cost of the complete station, exclusive of substation apparatus, but including main line transformers—a total of $66.25 per kilowatt generating capacity.

In this summary, the building cost is naturally high, owing to the large amount of structural material necessary. On the other hand, boiler and condenser costs are extremely low, for reasons previously set forth.

Using as a basis the above costs, and the rate of variation with loading factor, the ultimate total cost of power at different loading factors may be predicted; in other words, the total financial result of station operation. The diagram has been prepared along these lines. Fixed charges are dealt with entirely above the horizontal line, and operating costs below. The total power cost, at a given loading factor, is then represented by the total vertical distance between the two outer curves. These fixed costs are based upon the following assumptions: (a) Bond interest and taxes, 7 per cent.; (b) sinking fund, equivalent to 6.43 per cent. depreciation, 4.2 per cent; (c) total fixed charges on capital cost, 11.2 per cent. Depreciation determined by summing the depreciation on the several parts of the plant, as follows: Building, 3 per cent.; boiler plant and coal-handling apparatus, 10 per cent.; condensing plant, 6 per cent.; generating plant, 7.5 per cent.; general average, 6.43 per cent.

Cost of Completed Power Station, 8,500 kw. No Substation Apparatus.

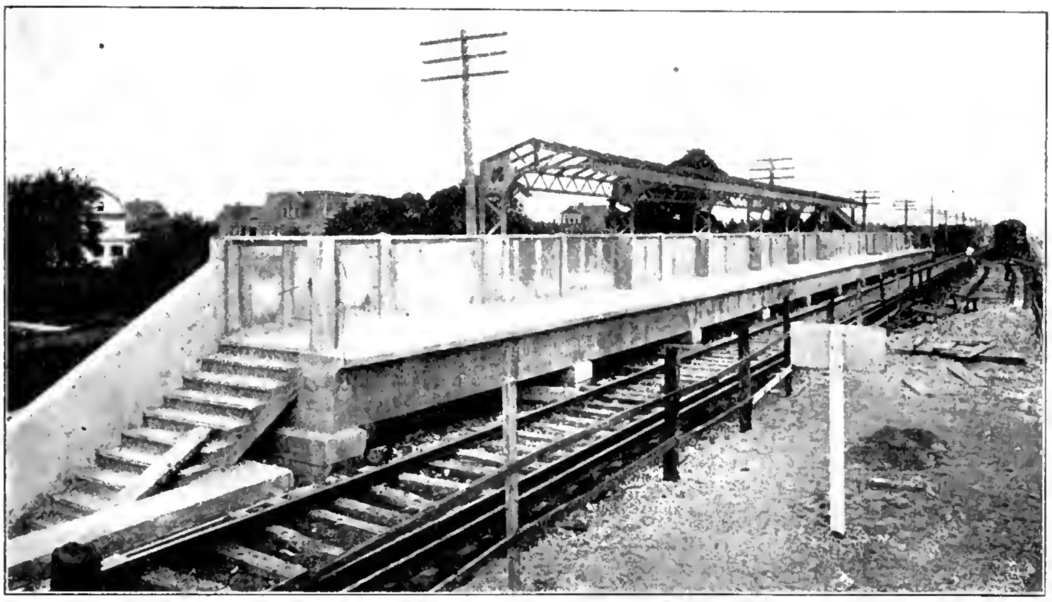
	Total.	Per Kw.
Building, including general concrete and steel work, galleries, coal bunker, smoke flue, condenser pit, coal storage pit, etc.	$93,217	$10.97
Generating plant, including turbines, generators, exciters, cables, switchboards, transformers and ventilating ducts	259,711	30.55
Boiler plant, including boilers, superheaters, stokers, piping, pumps, heaters, settings, breechings and tank	118,313	13.92
Condenser plant, including condensers, pumps, piping, free exhausts, water tunnels and intake screen	33,790	3.98
Coal-handling plant, including gantry crane, crusher, motors and track	7,990	0.94
Erection superintendence, engineering and miscellaneous	50,500	5.94
Total, excluding property and siding	$563,520	$66.25

From these curves the total cost of power at the present station loading factor, 24 per cent., is 0.79 cent per kilowatt-hour. At 33 per cent. loading factor the total cost would be 0.57 cent per kilowatt-hour, and at a possible loading factor of 50 per cent., 0.41 cent per kilowatt-hour. This, Mr. Bibbins ventures, is a result which it will be difficult to duplicate in any station of expensive construction burning the medium grade of bituminous coal at a cost in the neighborhood of $2.25 per ton. It is the ultimate result that proves the correctness of the engineering principles involved in the design of the station.

The Removal of a Rock Barrier in the river Clyde has just been completed. The "Elderslie Rock," as it was called, was a ridge 900 ft. long and 300 ft. wide extending obliquely across the river, and 8 ft. below low water. In 1880 the first steps were taken for its removal, the channel being given a depth of 20 ft. over it at low water. Subsequent work deepened the channel to 23 ft., and in 1903 it was decided to secure a depth of 28 ft. This work has now been completed, and in addition the channel, which was to have been 200 ft. wide, has been made 230 ft.

Concrete Fences on Station Platforms of the Brighton Beach Line, Brooklyn, N. Y.

Solid monolithic fences consisting of cement plaster covering Truss Metal lath have been built on the platforms of six of the new stations on the Brighton Beach Line, which is operated by the Brooklyn Rapid Transit Co., Brooklyn, N. Y. The improvements which necessitated the new stations and some general data regarding them were given in The Engineering Record of May 18, 1907. The platforms are of reinforced concrete slabs carried by beams and girders of the same material, and are covered with a granolithic finish. The fences referred to are the guard railings on the outside and ends of the platforms, the stations where they are used being on the embankment section of the road.



Completed Concrete Platform Fence on Brighton Beach Line, Brooklyn, N. Y.

The fences running the length of the platforms, which are 240 ft. long, are 4 ft. 6 in. high, and 2 in. thick, and are surmounted by a railing 4⅝ in. high and 5 in. wide. The reinforcement consists of Truss Metal lath of No. 28 gauge. It has a cross section of 0.18 sq. in. per foot of width and weighs 67 lb. per 100 square feet. The lath is 1 in. high, so that the minimum plaster thickness covering the metal on each side is ½ in., though of course the plaster entirely fills the convolutions of the lath.

The lath is carried in continuous sheets through the whole length of the fence, and is not broken at the posts. The latter which are on 10 ft. centers are reinforced with four ½-in. rods set deep into the concrete platform. The post is formed by two short pieces of lath bent in the shape of channels and placed around the reinforcing rods, one channel on each side of the continuous sheet which forms the reinforcing of the panels. The plaster has been similarly carried around the lower parts of the steel canopy supports by short pieces of lath bent in channel shape. The posts measure 9 in. long and 8½ in. wide at the base, tapering somewhat toward the top in the width. The railing is reinforced by two ⅜-in. rods running longitudinally and by a strip of lath laid horizontally.

The intermediate panels between the posts are formed by putting on an extra ½-in. thickness of plaster for the raised part of the panels.

The platforms were completely cast before the fences were started and blocking was inserted to form a trough in which the fences were to be set. After they had been built the joint between them and the platform was covered by carrying the 1-in. granolithic finish up a quarter round curve onto the bottom of the fence. The rods for the posts were set when the platforms were built.

In constructing the fences the lath was held in place by studding of 1-in. angles supported by braces. The plaster was then put on from the side opposite the studding, and after it had set the studding and braces were removed and the other side was finished. The plaster was made of one part of Atlas Portland cement, and two parts of sand.

The fences were erected by the Truss Metal Lath Co., New York, under the direction of the engineering department of the Brooklyn Rapid Transit Co.

Snow Loads on Roofs may considerably exceed the values usually allowed for them in designs, according to investigations made last winter by S. de Perrot, of Neuenburg, Switzerland. It was observed that after a heavy fall of snow, a succession of thawing and freezing periods followed by more snow produced masses of snow and ice 24 to 30 in. thick and weighing 70 to 100 lb. per square foot of roof, which is three to four times the value usually assumed. Several such accumulations of snow and ice were found to weigh 36 to 38 lb. per cubic foot.

The British Road Tarring Trials.

Brief mention has been made in this journal of the competitions carried out during the last year at Staines, England, by the Roads Improvement Association to ascertain the best substance to spray on roads as a dust preventive and the best machine for doing this work. The tests of the machines were made on roads of broken granite, flint and gravel, but the preparations were applied only on the granite road. The judges were men of the highest standing among British road engineers, technical chemists and automobile enthusiasts, who have just made their report, which the "Journal of Gas Lighting" has reviewed as follows:

After setting forth the circumstances which led to their appointment, the judges explain that unfavorable weather militated against the carrying out of the trials as originally arranged. It is generally accepted that an application of two coats of tar is necessary for preserving the surface of a road, and the judges were desirous of carrying out the trials under this condition; but this, for the reason mentioned, could not be done. It could not be expected, therefore, that the surfaces treated with one coat only would be durable; and the judges explain that the trials in respect of durability do not reflect on the machines competing. The final judgments and awards in the machine competition were based upon the machines only. However, in spite of the generally unfavorable nature of the weather, they say the results, on the whole, may be considered satisfactory, and much useful information has been obtained in connection with the comparative merits of the various materials used and of the methods of spreading them. They consider that enough has already been done to show that "machinery can be successfully applied for this purpose, and that by the use of such machinery tar spreading can be carried on with great rapidity after preliminary preparations have been made." The judges say the cost of spreading tar by machinery has worked out at a far lower figure than the cost of applying the same quantity of the material by hand.

Tar-Spreading Machines: Aitken's Patent Pneumatic Tar-Sprayer. The judges consider this to be a well constructed machine, possessing many important advantages. It is self-contained and can be moved rapidly from one part of the road to the other. It can also cover a considerable superficial area of road in a day's work. Its construction is solid and well thought out, and the cost of working and maintenance may be expected to be low. The judges believe that by the use of this machine, under the most favorable conditions, the actual cost of laying on one coat of tar in a sufficient quantity may be cut down to almost 1-50th of a penny per superficial yard, or with a road 6 yards wide to approximately £1 per mile. This includes everything that ought to be charged to the cost of the operation, interest and sinking fund on the plant employed, a fair sum for upkeep and ample allowances for fuel and labor, but is exclusive of the cost of tar. Though in point of rapidity of working and excellent mechanical construction the judges put this machine at the top of the list, in some respects the results of the spreading were not so satisfactory as in other cases. This arises from the fact that the distributor was not properly adjusted. The judges have decided to award the first prize of 100 guineas and the Association's gold medal to this competitor.

Emulsifix, Limited. This machine is of the nature of a special form of water-cart, having means for mechanically mixing tar and tar oil with a certain proportion of water, and spraying the road before the mixture has time to separate. Although the judges are informed that this competitor put an additional application on to the road shortly after the actual trials, yet little or no trace of the application was to be seen shortly afterward. It should be mentioned that this competitor intimated that it was impossible for his machine to use the standard tar as supplied by the Association to the other tar-spreading machine competitors; and, under the circumstances, the judges allowed him to bring his own material.

Johnston Lassailly Patent Tar Road-Binder. This machine consists of a separate portable boiler for heating the tar up to 200° C. or over, from which the heated tar is transferred to distributing carts fitted with trailing brushes for evenly spreading it. The work done by this apparatus was good. A heavier coat of tar was put on than in the other cases, and, chiefly owing to this, the durability of the coating has been greater than in the case of any of the other competitors. Against this must be set the consideration that the machinery is cumbersome to handle, the working consequently slow, and therefore more costly than that of other competitors.

Tarmaciser, Limited. Owing to an accident on the road en route to the scene of the trials, this machine was unable to compete. With a view of ascertaining its comparative merits, a special test was arranged and subsequently took place on the road between Swanley Junction and Farningham, in Kent. This trial was, of course, quite independent of the tests for the competition awards. The machine did not come up to its proof. It required a considerable amount of adjustment prior to starting, and then partially broke down while at work. Though there are probably possibilities for this machine, the judges are of opinion that it cannot at the moment be considered an entirely practical apparatus.

Tarspra, Limited. This company entered three machines. The first was a 700-gal. Thornycroft motor van, and resembled in some respects the Aitken machine. This competitor entered a 1,000-gal. van, which was drawn by a small tractor. The third machine entered was a 200-gal. cart drawn by horse power. In all cases the principle of spreading the tar was the same. All three machines worked well and spread the tar evenly. The 700-gal. Thornycroft motor van is well designed. The workmanship is not quite equal to the Aitken machine, and probably the cost of upkeep will be greater. It should be mentioned, however, that different sets of nozzles can be used with these machines, and the number of square yards covered per gallon of tar can be adjusted to suit the road surface or the wishes of the person treating the road. The judges have decided to award the 700-gal. Thornycroft Tarspra machine the second prize of 50 guineas and the Association's silver medal.

Thwaite Anti-Road-Dust System. This consists of a portable tar-boiler, which holds 300 gals. of tar, and this competitor's principle is to raise the tar to a high temperature, and consequently it does not require so much pressure to lay it on the road. The judges were impressed by the good working of this machine, which seems to be simple and effective. The first cost of the apparatus is very moderate, but operating costs are not so low as the Aitken or Tarspra.

Reeson's Patent Machine. This apparatus is for putting on a preparation of tar, but it was not entered for the tar-spreading machine competition. It consisted of a tank fitted with gravitation sprinkler and two rotary brushes. At a special test of this machine on the road between Swanley Junction and Farningham, Kent—at the same time as the special tests of the Tarmaciser were made—it worked satisfactorily, and was very favorably commented upon. The heating arrangement consisted of a Wells light burner, paraffin being the heating agent. The air pressure for this heater was obtained by means of a hand pump.

Preparations of Tar. The preparations of tar tested were of two classes—(1) those containing very little tar, and (2) those in which tar formed the main ingredient.

In the first class were the compounds "Crempoid R," "Crempoid D," "Ermenite," "Hahnite," and "Pulvicide." The results of treating the roads with all these compounds may be dismissed in a brief paragraph. Within a very short time after their application—*i. e.*, a week in the case of "Ermenite," a fortnight in the case of the "Crempoids" and "Pulvicide," and a month in the case of "Hahnite"—they had practically disappeared. The compounds have not the durability of tar, and the judges do not consider their use as economical. Moreover, complaints have been received to the effect that the dust raised from the sections of the roads treated with some of these materials is injurious to the eyes of those using the roads and to the frontagers living along their routes.

The preparations containing a large proportion of tar were, on the whole, very satisfactory. We deal with them in their order of merit.

Clare's Patent Tar Compo. This was applied to a quarter-mile section of road extending from the steam laundry at Staines to a point a quarter-of-a-mile eastward from the same laundry by one of the smallest of the "Tarspra" machines, similar in type to the 200-gal. one entered in the tar-spreading machine competition. This section of road, as regards dryness of surface, was approximately in the same condition as the other lengths. The macadam was in good condition. The quantity of the material appears to be 1 imp. gal. to 7 sq. yd., applied in two coats. At the price quoted by the competitor—3½d. per gallon delivered in London—and after making allowance for getting the material into position on the road, it works out, excluding the cost of spreading, for a coating of 7 sq. yd. to the gallon, at 0.57d. per square yard of road surface, or approximately £25 per mile of road 6 yd. wide. From the time of laying until recently it has been uniformly good, and is now in better order than any other portion of the road. The surface is wearing rapidly, especially in the center. The judges have decided that the Ballymenagh 100-guinea trophy and the gold medal of the Association for the best preparation of tar for road purposes be awarded to Messrs. Clare & Co., of Liverpool. The smell of the material is relatively evanescent and unobjectionable.

In the judges' opinion the success of the Clare Company's compo is greatly due to the fluidity obtained. When applied cold (as recommended by the manufacturers), as was the case on the Staines Road, the penetration was very considerable. In spite of this, the tar has body enough to hold together in a highly satisfactory manner the small dust-forming particles. Moreover, it has been ascertained that the cost of treating or adding to tar by this method is not considerable, and is far more than compensated by the extra penetration, as described above. The preparation flashes at ordinary temperatures, and special care must be exercised to avoid risk of firing during treatment.

Oil-gas tar was entered by the Gaslight & Coke Co. This material was applied to a length of road adjoining that of the Clare Co. by a special form of machine devised by the Gaslight & Coke Co.'s engineer, Mr. Reeson, which is commented upon under the heading of "Tar-Spreading Machines." This length of road is in a fairly good condition. Oil-gas tar probably penetrates deeper than anything else, but it does not form so durable a wearing surface, and consequently is not so great a protection to the face of the macadam as a good tar preparation. It is not a new substance and has in the past been used in various places, but the actual material entered by this competitor is understood to have been a specially treated

oil-gas tar, from which the more readily volatile and low-flash constituents of ordinary oil-gas tar have been removed. The smell of the preparation was penetrating and of the same character as that of ordinary oil-gas tar, but less strong and persistent. It would probably be very useful for the purpose of giving a first coat to a road, to be followed by one of coal-gas tar or similar substance.

T. G. Marriott's "Marbit." The third in order of merit of the competing preparations is "Marbit," entered by this competitor, but the condition of the section of the road treated is not quite so good as that of the first two named.

Tar Supplied by the Association. In addition to the competing preparations, it is necessary to make some mention of the various kinds of tar supplied by the Association for comparative purposes.

1.—This was a new crude coal tar, which had merely undergone the ordinary mechanical separation process, supplied by the South Metropolitan Gas Co. for the use of the tar-spreading machines on the Staines and Hounslow granite road and the Twickenham and Kempton Park flint road. The judges consider that, though this was a fair average specimen of tar, it did not yield satisfactory results unless applied in quantity in excess of that found necessary in the case of the Clare patent tar compo. One gallon of the Clare material has given an exceedingly good surface to 7 sq. yd. during the summer months, whereas in this case quite 1½ times the quantity is required to give equal results, which greatly affects the total cost of the completed operation.

2.—This also was crude coal tar which had undergone the ordinary mechanical separation process, supplied by the Reading Gas Co. for use in the tar-spreading machines at Ascot. It was far inferior for road purposes to that supplied by the South Metropolittan Gas Co. It was apparently unsuitable for spraying in the machines, probably owing to the foreign matter which it contained when it arrived in the tanks at Ascot.

3.—This was a "refined" or "freed" tar from the South Metropolitan Gas Co., and was kindly supplied by the company for experimental purposes free of cost to the Association. This was also laid upon the road by a 200-gal. Tarspra cart. This is a coal tar from which the water and naphtha have been distilled, and has a specific gravity of about 1.24. The distillation serves to remove the ammonia, which is an objectionable constituent of tar for road treatment, and the light oils. The cost of this tar is about ¼d. per gallon above the same company's market price for crude coal tar. The preparation answered well in the trial.

4.—This was an ordinary refined coal tar from the tar distillery, as supplied by Messrs. Burt, Boulton & Heywood, of Silvertown. This material was applied by a 200-gal. Tarspra cart, similar to the one entered in the tar-spreading machine competiton, on a section of the Staines and Hounslow granite road. The specific gravity is about 1.21. The net cost at the wharf is about 3d. per gallon. For some reason this tar did not answer quite so well as the somewhat similar preparation from the South Metropolitan Gas Co., but it was fairly satisfactory.

5.—This was a blast-furnace tar, supplied by Messrs. R. & A. Reid, of Glasgow. It was applied to a section of the granite road between Hounslow and Staines by a 200-gal. Tarspra cart. The tar is derived from blast furnaces using splint coal in the neighborhood of Glasgow, and therefore offers a supply entirely independent of gas works. Its specific gravity is 1.1, but it is highly vicious and needs considerable heating to make it sufficiently fluid for laying on the road. Its smell is rather objectionable and persistent. The cost in London is 2¼d. per gallon, but appreciably less in the North. In order of merit it comes after the refined gas tars.

Judges' Observations. Speaking generally, the whole of the machines tested showed considerable originality and forethought in design, and considering the short time the demand for this machinery has been before inventors, the results obtained are exceedingly promising. No doubt most of the machines exhibited can be improved, and when using the proper material in correct quantities they are all likely to give satisfactory results. Suitable tar compositions are practically insoluble, yield no matter liable to be washed away into the watercourses to pollute and to cause damage, nor should there be any considerable quantity of tar-dust ground off the road surfaces after treatment. The judges believe that the complaints made under this head previous to these trials have been due to the use of improper materials—that is, tar from which the more unsuitable compounds have not been extracted previous to it being used on the road. Now that this is understood, it is probable that most of these difficulties will disappear.

It will be noticed that little has been said in this report as to the Ascot experiments. The judges consider that this portion of the work was not satisfactory, for several well understood reasons. In the first place, the tar supplied from the Reading gas works was apparently unsuitable for spraying by machinery. Through some unexplained cause, a great deal of foreign matter found its way into the tar, which blocked the nozzles of the machines and caused very irregular working. Moreover, as regards the dampness of the road material, the road surface at Ascot compared very unfavorably with those at Staines nad Twickenham. Some heavy rain had fallen in the night previous to the experiments, and the road being greatly sheltered by trees the moisture did not dry out. It was therefore not to be expected that the tar would adhere to the surface of the road, and in consequence it could be seen that in many cases the tar, instead of penetrating, was lifted off by traffic in the form of a detached film, leaving the road unprotected.

Book Notes.

All engineers who keep in touch with technical writings in German and French will regret to learn that the Society of German Engineers has resolved to discontinue work on the "Technolexicon," the great technical dictionary in German, French and English, which it has been engaged in preparing for several years. The director of the society reports that the work has turned out to be far more expensive than anyone anticipated and the cost of carrying it through to completion within the allotted time far exceeds pecuniary resources available for the purpose. It has always seemed to this journal that the enterprise was one of such magnitude that it was hardly practicable on the scope proposed by the society, although the latter is the largest engineering body in the world. Few people who have not actually taken part in the preparation of a high-grade lexicon have any appreciation of the enormous amount of skilled work required to carry through such an undertaking, entirely apart from the labor of the technical experts who take part in the authorship. The society has not announced in what condition the matter is at the present time, and it is to be hoped that the work has progressed to such a state that some of the enterprising German publishers may be willing to take hold of the data already collected and publish a technical dictionary, not so comprehensive as that proposed by the society, but still more modern and accurate than those now available.

A book that will be found particularly valuable by all interested in public health has just been published under the title of "Sanitation of Public Buildings," the author being Mr. Wm. Paul Gerhard. This work is, in a sense, a continuation of the same author's well-known book, "Sanitary Engineering of Buildings," which is devoted largely to the sanitary work in dwelling houses, apartments and tenements. In the new book the author discusses the drainage, water supply, lighting and ventilation of hospitals, theatres, churches, schools, markets and abattoirs. While the book is a thoroughly practical one, it is also based on the most advanced theories accepted generally by sanitary specialists of Europe and this country. There is probably no other book in the English language which so thoroughly covers the subject of sanitation in public buildings as this. (New York, John Wiley & Sons, $1.50.)

Dr. W. K. Shepard, of the Sheffield Scientific School of Yale University, has prepared a volume of "Problems in Strength of Materials" which will doubtless be of material assistance to teachers of the subject. Nobody can hope to master a subject of this nature who is unwilling to spend time in solving well-selected problems, any more than a person can hope to become a lawn-tennis expert by reading a book concerning that sport. This is so well recognized in most schools that recitations are carried on very largely today by means of the solution of problems. This volume should be of material help to the instructor in helping him to obtain a wide range of such examples. In addition to the classroom use of the book, it should prove of value to those engineers who are accustomed to spend a little time every day in solving one or more exercises in branches of engineering work with which they are not directly connected at the time. (Boston, Ginn & Co., $1.30.)

About a year ago a review was printed in these pages of the excellent treatise on "Producer Gas," by Messrs. J. E. Dodson and A. T. Larter. Naturally enough this volume has been very warmly received by engineers and it has been accordingly necessary to bring out a second edition. The revisions which have been made have been mainly in the chapters relating to suction gas plants, although some new illustrations have been added in other portions and additions made in the text in many places. The book is unquestionably the most comprehensive work on the subject that we now have, and any engineer who contemplates putting in a producer plant for heating or engine work will find in the volume a large amount of useful information. (New York, Longmans, Green & Co., $3.00.)

Letters to the Editor.

Temperatures Destructive to Concrete.

Sir: We are rather interested in knowing the highest temperature that concrete construction has been able to withstand without cracking or crumbling. Can you secure this for us? Yours truly, Blaw Collapsible Steel Centering Co.

Pittsburg, Oct. 28.

[This inquiry was submitted to Prof. Ira H. Woolson, of Columbia University, who has kindly furnished the following information:

"Replying to the inquiry relative to the ability of concrete to withstand heat without crumbling or cracking, I would say that I have conducted a considerable number of tests in an investigation of this proposition in connection with the work of the joint-committee of the American Society for Testing Materials. The results of those tests were presented to the Society in three papers, the first in 1905, the second in 1906, and the third this past summer. The paper of this year was devoted largely to an investigation of the thermal conductivity of trap, gravel, and cinder concrete, as the work of the previous years had demonstrated that the non-conducting properties of concrete was the reason of its ability to withstand high temperatures.

"Although there were a few instances where trap rock concrete cubes were heated to a temperature of 1500° without showing serious deterioration in strength, my own judgment is that the result of all the work shows that if concrete is heated throughout to a temperature of 1000° to 1500° F., it has lost the major portion of its strength and is very likely to crack and crumble if allowed to stand undisturbed. This is particularly true of quartz gravel concrete. In many cases a thorough heating to a temperature of 750° will reduce the strength of the concrete to a large degree. On the other hand, it is a well known fact that concrete will withstand a temperature of 1500° or over for an hour or two when heated on one or two sides only, and will still be in excellent condition. The reason for this is plainly shown in the paper on thermal conductivity above referred to, in which it was demonstrated that a concrete could be heated on one face at a temperature of 1500° F. for an hour and the temperature of the interior two inches in from the heated face with a rise of only 200° or 300°.

"In that paper I drew the following conclusions from my investigations: First, that all concrete mixtures when heated throughout to a temperature of 1000° to 1500° F. will lose a large proportion of their strength and elasticity, and this fact must be well remembered in designing. Second, that all concrete has a very low thermal conductivity and therein lies their well known heat resisting properties. Third, that as a result of this low thermal conductivity, 2 to 2½ in. of concrete covering will protect reinforcing metal from injurious heat for the period of any ordinary conflagration (provided, of course, that the concrete stays in place during the fire). Fourth, that reinforcing metal exposed to the fire will not convey by conductivity an injurious amount of heat to the embedded portion. Fifth, that quartz gravel concrete is not a reliable or safe fire resisting aggregate."

There is so much interest shown just now regarding the effect of successive increases in temperature on the compressive strength of concrete that a series of tests with different grades of concrete subjected to different temperature up to 1000° will be likely to yield information of general value.—Editor.]

THE STATUS OF MANUAL TRAINING.

SIR: The letter from "C. E.," of Boston, on the relations of the public school to industrial education in your issue of Nov. 16 leaves the present status of manual training somewhat uncertain. In fact, in many minds there is not a clear differentiation between vocational and manual training. Through ignorance the former has been here and there regarded as superior to and the possible successor of the latter. In point of fact, however, the manual training school is accepted among leading educators as only one of the essential elements in a complete educational system, the vocational or trade school being recognized as entirely independent in purpose, organization, and curriculum.

Following close upon the report of the Superintendent of the Boston schools, referred to in the above-mentioned letter, there has just been made public a document which proclaims the status of the manual training school in general, and of the Mechanic Arts High School of Boston in particular. It is in the form of a report made at the request of an investigating committee known as the Finance Commission. That it must be accepted as authoritative, and is certain to attract wide attention, is evidenced by the names signed thereto. They are Charles W. Eliot, President of Harvard College; Henry S. Pritchett, late President of the Massachusetts Institute of Technology, and Rev. Fr. Thomas I. Gasson, who is President of Boston College.

The question propounded to them was as follows: "The City of Boston has, for the current year, a million dollars to spend in land for the Phillips district and various buildings. Taking into account the needs of both the elementary and the high school education, is it wise to spend approximately $500,000 out of this million in rearranging the present Mechanic Arts schoolhouse and erecting a large addition to it?"

In their reply the special committee assume as admitted the following fundamental principles regarding the conduct of public education in a municipality: (1) That it is the plain duty of a municipality, such as Boston, to support, and support generously, high school education as well as elementary education. (2) Under modern conditions, it seems equally clear that a municipality must support several kinds of high school education, adapted to the various needs and desires of its population. The city of Boston to-day supports Latin High Schools, English High Schools, the Mechanic Arts High School and the Commercial High School. All these give a general education, but guide their pupils in different directions.

In seeking to answer the given question, the Committee made an exhaustive examination of statistical information regarding cost of building, equipment, instruction, etc., as well as of records of graduates. But they recognized that their decision was to be based not alone on statistical data, but also on certain fundamental considerations concerning the character of the education provided by the Mechanic Arts High School. Its work is thus described:

"The Mechanic Arts High School is an institution in which the elements of the mechanical arts are taught in connection with a thorough academic course, rich in mathematical and scientific subjects. Its fundamental object is to promote general culture, but the specific training which it gives is excellent preparation for many mechanical pursuits. It teaches the principles and processes which underlie many trades; but it is in no sense a trade school. The time which is devoted to any branch of mechanical work is entirely inadequate to give the knowledge and skill required by a journeyman. Moreover, the educational value of a shop exercise is determined by the thought which the pupil must bestow upon it; consequently no operation is repeated mainly for the purpose of increasing skill; but a new problem is presented as soon as the difficulty of a given process is fairly mastered. The most important function of the school is to reveal to boys, through its many-sided activities, their dominant aptitudes and help them to lay a firm foundation for the work for which they are best fitted. It aims to discover how executive and creative ability can be most effectively stimulated, diversified and directed. This ability is one of the most important factors in our complex civilization. Some men show it by excellent work at the bench, others at the drawing board, and others as foremen, overseers, superintendents, engineers, or organizers of industries. The school which opens the door of opportunity in a wide range of industrial activities is vocational in the largest and best sense of the term. In this age, characterized by a marvellous development of industries based upon scientific and mechanical principles, such a school meets a highly important and pressing need of the community."

It is made evident that it is not a trade school, nor does it send out young men who are likely to become journeymen in the various trades. Its purpose is to give a general education, with such training in the mechanical arts as will suggest to its pupils industrial pursuits.

This purpose is manifestly entirely different from that of an industrial school or a trade school. For example, the new Franklin Union, and the Wentworth School to be established in Boston are to be schools in which the theoretical foundation of many trades is to be taught at night to such men, already in the trades, as desire such instruction. The committee assert that the existence of these schools, which are for entirely different objects from those of the Mechanic Arts High School, have no bearing on the question.

The records show that during its fourteen years of existence the graduates of the school have gone mainly into pursuits suggested by the mechanical instruction which they have received. Some of them have entered high-grade engineering schools and become engineers. A larger number have filled the position of draughtsman. Others have become foremen. In general a strong tendency has been developed to engage in those occupations which look toward the producing side of business life. A reasonably large number have come into executive places by proving their administrative ability in mechanical positions. Speaking broadly, the records of the graduates show that the school is accomplishing its purposes.

A considerable number of graduates of the school enter the Massachusetts Institute of Technology, although this number constitutes but a small percentage of all the students who enter the school. The records made by these students at the Institute have not in the past equalled those made by students from the best suburban high schools. It appears, however, that very few of the youths who enter the Mechanic Arts High School do so with the thought of going to a school of technology later. The choice of an engineering career is the result in most cases of the student's experience in the school, which inspires the ambition to enter an engineering profession.

The school is now attended by nearly eight hundred pupils, although only about three-fourths of that number are satisfactorily seated. In light of this fact, and of their general attitude toward the entire subject of manual training, the committee unanimously conclude:

1. That the Mechanic Arts High School fills a useful purpose by opening to the youth of Boston new ways toward good livelihoods.

2. That additional facilities must be furnished, if those boys who wish to avail themselves of this form of education are to have the opportunity to do so.

3. That this need is now more urgent than that of any other specific addition to the school system of Boston.

4. That it is, therefore, expedient for the city to proceed with the enlargement of the Mechanic Arts High School without delay.

This report, local though it is in its primary application, but rendered by educators of such recognized standing, must be accepted as fully establishing the present status of the manual training school as a vital element in our educational system. It distinctly differentiates between manual and vocational training, and recognizes the independent field for the introduction of educational courses looking to the development of the journeyman in the various trades.

WALTER B. SNOW.

Boston, Nov. 7, 1907.

THE AMERICAN COKE INDUSTRY during the last three years has been marked by a steady decrease in the consumption of coal per unit of coke, due for the most part to the development of by-product manufacture, in which the yield of coke from the coal is considerably greater than in the beehive oven. The figures for the calendar year 1906, compiled for the U. S. Geological Survey by Mr. E. W. Parker, show that the total value of coke produced was $91,600,000, the average value per ton being $2.52.

THE ENGINEERING RECORD
PUBLISHED WEEKLY BY THE
McGraw Publishing Company
James H. McGraw, Pres.; Curtis E. Whittlesey, Sec. and Treas.
MAIN OFFICES:
239 WEST 39TH STREET, NEW YORK.
BRANCH OFFICES:
CHICAGO: Old Colony Building.
PHILADELPHIA: Real Estate Trust Building.
CLEVELAND: Schofield Building.
SAN FRANCISCO: Atlas Building.
LONDON OFFICE: Hastings House, Norfolk St., Strand.

SUBSCRIPTION RATES.
United States, Cuba and Mexico..........$3.00 a year
Canada ....$4.50 a year
Foreign subscription....................$6.00 a year
25 shillings. 25 marks. 31 francs.
Foreign subscriptions may be sent to our London office.

NOTICE TO ADVERTISERS.
Changes in advertisements intended for a particular issue should reach the office of THE ENGINEERING RECORD on Friday of the previous week. New advertisements can be received up to noon of Wednesday of the week of issue.

NOTICE TO SUBSCRIBERS.
REMITTANCES.—Remittances should be made by check, New York draft, or money order, in favor of THE ENGINEERING RECORD.
CHANGE OF ADDRESS.—The old address should be given as well as the new, and notice should be received a week in advance of the desired change.
BACK COPIES.—No copies of issues prior to July, 1906, are kept on sale, except in bound volumes.
DATE ON WRAPPER indicates the month at the end of which subscription expires. The sending of remittances for renewal prior to that date will be much appreciated by the publishers.
CLUB RATE.—In acknowledgment of assistance rendered by subscribers in the securing of new orders, a club rate of $2.50 per annum is quoted. This rate applies to subscriptions in clubs of two or more, at least half of the names in the club to be those of new subscribers.

Entered at the New York Post-Office as Second Class mail matter.

Of this issue of THE ENGINEERING RECORD 15,000 copies are printed. Total circulation for 1907 to date 702,000 copies, an average of 14,625 copies per week.

TABLE OF LEADING ARTICLES.

The So-Called Panic.

It is unfortunate that a number of young men engaged on our daily papers have not learned to be a little more careful in their use of the English language. A somewhat careful observation of the news sheets of the country during the last fortnight shows that, in an attempt to be sufficiently sensational to make papers sell, conditions in the manufacturing and commercial world have been called by pretty hard names they by no means deserved. If the American people did not have an exceptional amount of common sense and were not thoroughly convinced that because a thing was stated in the newspaper it was not necessarily correct, we might have had a real panic on our hands. Nothing of the sort has happened because about all the people who have been hurt are those who, for one reason or another, have had their affairs so extended as to be unwieldly. A shipmaster who carries all sail too long has a good deal of trouble when the wind freshens with unexpected rapidity. A business man who was doing more than his capital warranted in flush times is likely to have trouble when such an exceptional period subsides to the normal. We have been having flush times for a number of years. They have been continuing for so long, indeed, that we have become accustomed to them, and have forgotten just exactly what is necessary when real normal conditions prevail. When mills are filled with orders so far ahead that new business is not wanted, as was the condition a year ago, affairs may truly be called booming. It is wholly unreasonable to expect them to continue to boom. We must expect to work harder than we have the last two or three years in order to accomplish as much, but it is difficult to see what reason there is for anticipating a panic. Certainly there is very little in view at the present time to warrant any such apprehension, and a misapprehension of some recent events, magnified in the newspapers, is the only thing that needs explanation just now.

In the first place there have been reports concerning the shutting down of some industrial plants. It is well to look at these things in a rational manner. A good many establishments have been running under the highest pressure for some years. Their machinery has been used by day and night forces until it is in great need of repair. More than a year ago The Engineering Record was informed by the managers of certain works that it would be necessary to shut down for repairs or their plants would drop to pieces, yet these same plants have been kept running all through the summer. Some of them are among the mills which have closed recently. They have not stopped solely because of business conditions, but because it is high time for repairs and renewals. Probably many more establishments would report the same condition of affairs. This is the beginning of the season when such work is done. Because production has been conducted under such extreme pressure during the last two years that these annual periods of recuperation have not been possible is no precedent for their continual omission. It is noticeable, moreover, that in a good many cases where these shut-downs have occurred that the American workmen are kept busy, at least in a considerable measure, and the men who have been turned off are the Italians and other Europeans who are taking advantage of this closing of the works to visit their native land. That is not a mere conjecture can be ascertained by inquiry at any shipping office.

There are a few manufacturers who are apprehensive and talking of closing down their plants entirely. It might be well for them to consider that any unnecessary retrenchment is likely, in view of the recent prevalence of unwarranted rumors of a panic, to be a cause of further hardening of conditions, rather than a remedy. "Every business enterprise which is making any unnecessary retrenchment," according to a recent address by Mr. Henry L. Doherty, "is adding just that much to the situation which is bringing about a threatened industrial depression." Mr. Doherty's connections are so important and so widely spread throughout the country that his further assertion that we are suffering merely from a lack of confidence deserves careful consideration. "United efforts on the part of the men of influence of this country could quickly restore the confidence which is lacking," in his opinion, "but unfortunately they have as yet no means of taking united action, no attempt has heretofore been made to do so, and of the numerous half-baked suggestions which have been offered as a cure, few, if any, would stand the analysis of proper logic."

It may be confidently asserted that the thing for business men, particularly manufacturers, to do at the present time is to form local associations for steadying the weak-kneed people in their vicinity. One good, strong local association of manufacturers in any city can accomplish a great deal of good. If the trouble which is now passing away had no other effect than to form these local organizations it would have accomplished a great deal. Manufacturers must stand together just as laboring men stand together. During the last two weeks there has been a pitiful exhibition of cold feet on the part of the bankers in some cities, particularly west of the Allegheny Mountains. Manufacturers should unite to prevent any such fright affecting them. It is entirely practicable for them to do so by simple means. A great deal of cash can be brought to light, when bankers are too scared to advance money on good security, by making a trust fund of these securities and issuing notes of small amounts against it, or something of this sort. There are plenty of men having small sums to invest who will come forward at such times, provided they are assured that responsible people are connected with this method of raising money. If an association of local manufacturers undertakes to raise funds for some of its members in this way, it is safe to say that a good deal of hidden money will be brought to light and the currency conditions will be so much improved.

It is the currency conditions that are mainly responsible for the present trouble. Some of these conditions can be changed only by Congress, and fortunately Congress seems to be willing to talk about the matter. Moreover, it will act just as soon as the influential men of the country call loudly enough for a reform. Congress has never failed to do this in the past and there is no reason to expect it will refuse to do so now. But all of the trouble has not been due to our rigid currency laws. Some of it has been caused by the hasty action of people who felt that a panic was coming and withdrew their money from the banks, hiding it away where it was of no use to them or to anybody else. This not only deprived them of interest and jeopardized the safety of their funds, but it also had a tendency to create a condition that might have become very serious. These people, most of them of small means, may be pardoned for their timidity. This cannot be said, however, of those banks which have shown the white feather before firing began. There is nothing so pitiful as a coward who does not even wait to see if the fight is going against him. The cowardice of some bankers during the last month is hardly to be believed. Instead of doing all they could to allay the sudden wave of unwarranted apprehension which swept the country, they did all they could to increase the uneasy feeling. They have hoarded away enormous sums of currency which should have been paid out to their customers in the usual banking ways, without regard to the fact that bank reserves are kept for the purpose of relieving sudden unexpected calls for large sums and not as ornaments for the annual balance sheets. Every bank owes an obligation to the community in which it is situated. Any bank holding more currency than its legal reserve is doing great harm to every business interest and merits no consideration whatever at the hands of merchants, manufacturers or labor. It is high time for manufacturing and mercantile interests to do no business with these lily-livered institutions which are no help to the community. Business men will do well to remove their accounts from such banks, to think twice before making any unnecessary reductions in their force of employees, and to form local associations to check still further the senseless scare.

Costs of Engineering Work.

The Commissioners of Accounts of the city of New York have been conducting during the past ten days an investigation of the conditions under which Contract No. 3 of the Board of Water Supply, covering the construction of the main dam, dykes and other works of the great Ashokan Reservoir was awarded some months ago. As was set forth in this journal there were five bids for this work. The law under which the Board of Water Supply is acting does not require the tender of the lowest responsible bidder to be accepted, but lays upon the Board the most serious responsibility of so awarding the contract as will, in its judgment, best serve the interests of the city. After carefully canvassing all the bids the contract was awarded to MacArthur Brothers Co. and Winston & Co., who were next above the John Peirce Company, the lowest bidder, the contract price being above the bid of the latter.

This investigation, like most other investigations of technical matters by city commissioners whose members know little or nothing about the things to be investigated, has already developed into a voluminous irrelevant examination, of the members of the Board and its engineering organization, but it has occasionally touched on things more germain to the real substance of the inquiry. After the usual efforts of lawyers under such conditions to discredit the the evidence of eminent engineers of twenty to forty years of active professional work, it has seemed to be one of the principal objects of the Commissioners of Accounts and their technical advisors to show that the unit costs of such earth and rock excavation and rolled embankments of selected material, are as susceptible of accurate estimation by the aid of information disclosed by wash and core borings and other preliminary examinations as the unit prices of standard grades of structural steel work. The physical environment of the structural shop is with rare exceptions steady and unchanging. The labor conditions are as constant as it is possible to make them, and the various classes of structural work produced may be fairly well determined under the specifications and contract plans. Such circumstances enable the cost of work to be predetermined, not with mathematical exactness but with reasonable accuracy for business purposes; hence, it may be argued by the layman, the estimated cost of any engineering work should be determined with equal accuracy under similar specification and contract plans, especially if the location of the work may be examined by prospective bidders and if the requisite borings have been made and other practicable means have been taken to secure the requisite information as to physical or other conditions affecting the work to be done.

All this appears plausible enough but any engineer of extended experience knows well how fundamentally misleading such plausibility may be, and usually is. It has been fully and forcefully brought out by the chief engineer and by the consulting engineers of the Board of Water Supply that reasoning from practically fixed conditions, such as those of the structural shop, to the erratic and indeterminable conditions of most of such great field constructions as those of the Board of Water Supply is both misleading and dangerous. If, for instance, the earth and rock excavation required for the Ashokan dam and the dykes, gate houses and other appurtenances of the reservoir in question, amounting to perhaps 2,000,000 cu. yd., were to be made under conditions practically equivalent to those which governed similar parts of the new Croton dam contract, it is reasonable to suppose that a fairly close estimate of cost for the former could be made, allowing for difference in the labor conditions at the two sites. A little familiarity only with the two pieces of work, however, is enough to show that there is no parity between them. Remarkably full examinations have been made at the site of the Ashokan work and enough has been disclosed there to show that the materials to be taken out are radically different from those at the Croton dam nor is there reason to suppose that the general physical conditions have any material similarity. The treatment of the rock foundation bed will have to be very different, the depths to which trenches for core walls will have to be carried is not certainly known, although probabilities have to be estimated, and the amount of water to be encountered and taken care of is exceedingly uncertain. In fact the general character of the conditions found at Ashokan, as at every other great work of the same class, is really unknown until the actual progress of the work discloses it. It is only the tyro in engineering, or the bookman, who would attempt to predict with accuracy the elements of cost of any of the great classes of field construction.

Both the engineer and the contractor must make estimates of cost under such circumstances as best they can. It is usually these great uncertainties of cost which make the corresponding divergencies in such estimates so often found among even experienced engineers and contractors, and exhibited frequently in the wide range of prices in competitive bidding. It is in this particular field of engineering that the well developed judgment plays the crucial part. The estimated unit costs in such cases are more largely matters of judgment than of carefully systematized analyses of other work of the same class. Most careful consideration must of necessity be given to prior contracts of the same kind, but comparisons must be made by the aid of and frequently radically tempered by judgment developed by experience; any direct reference without the qualification of such judgment is practically certain to be grossly misleading, and it has been frequently seriously misleading to contractors as was shown in the Jerome Avenue reservoir contract in New York. No attractive printed tabulations of preceding costs of other contracts can safely form the basis of sensible conclusions of the costs of these great field constructions; such sources of data are deceptive and dangerous unless cautiously handled. The law has wisely made the duty of awarding the Ashokan and other contracts of the Board of Water Supply, a matter of the best judgment of the Board guided by its experienced engineering organization, acting for the best interests of the city, and it is not good public policy to permit captious criticism of politics or the unscrupulous members of the daily press to frustrate the intent of the statute when it is efficiently followed in spirit and letter.

The Steel Rail Controversy.

The unsatisfactory results in service of the heavy-section steel rails rolled during recent years have brought forth from both the manufacturer and the consumer numerous suggestions of the causes of these results and of methods to prevent them. The representatives of the steel mills are united in the opinion that the number of actual rail failures has been greatly exaggerated. They consider such failures as have occurred to be due primarily to the fact that the standard sections adopted some years ago are not suited to the heavy rails required to carry the greatly increased train loadings, the tremendous volume of traffic and the higher speeds which have developed since then. They are of the further belief that improvements in the construction of track and equipment have not kept pace with the requirements presented by these changed conditions. The railway interests have generally conceded likewise that the present standard rail sections should be modified, and in numerous meetings of the various technical societies made up of, or including, railway engineers and operative officers as members, improved methods of track and equipment construction have been much discussed. These interests, however, attribute the unsatisfactory rails that have been produced to several more causes considered equally vital. Chief among them are, first, the failure to discard a sufficient amount of steel from the top of the ingot from which the rails are rolled; second, improper chemical composition of the steel; and, third, the physical weakness of the rails due to existing methods of manufacture.

The steel makers and the railway interests are not only agreed that the present standard section should be revised, but they are also in accord regarding the general plan to be followed in making the changes. For the heavy rails now regularly used on the main-line tracks of most railroads, the flange and web are held to be too light in proportion to the head. A proposed change, known as the Harriman sections, as well as another series, known as the Pennsylvania sections, both of which add considerable weight to the flanges and webs in proportion to the heads, and also have a narrower flange than the present standards, have been recommended by the rail committee of the American Railway Association. Since the rail manufacturers have made no protest against these findings of this committee, it is reasonable to assume they are satisfied with the action that has been taken, and, in fact, the decision of the committee followed consultation with the manufacturers.

The proposed changes have been suggested chiefly to overcome the difficulties of manufacture presented in rolling rails to the present standard sections. The latter have so much metal in the head in proportion to the web and flange that the head cools much more slowly than the balance of the rail, resulting in internal structural strains. The large proportion of metal in the head also requires the work of rolling to be executed while the steel is too hot to yield the most satisfactory results in structure. The improper balance of proportions in the parts of the rail affect particularly the high-carbon steel used in a large percentage of the rails now produced. The lighter head and the narrower, thicker flange of the proposed sections are expected to alleviate greatly this paramount difficulty of manufacture, and thus result in rails which will be mechanically stronger and better. Grounds for objections to a section with a narrower flange than that of the present standard might appear to be justified, due to a reduction of bearing area on the cross ties, if it were not for the fact that tie plates are now almost universally used by railroads having heavy rails, particularly where soft wood ties are employed.

While the manufacturers and consumers are more or less generally agreed concerning the changes which should be made in the standard sections for rails, they are widely at variance in regard to the percentage of steel that must be sheared from the top of the ingot to eliminate defects from piping. A committee of the American Railway Engineering and Maintenance of Way Association and one from the American Society of Civil Engineers have both recommended that a minimum of 25 per cent. should be discarded from the top of each ingot. The committee of the American Railway Association has discussed the rejection of a minimum of 20 per cent. of the ingot. The rail makers regard any such discard as an injustice, and as unnecessary. They also state that a rejection of 25 per cent. of each ingot will reduce the output of the mills by that amount, and will increase the cost of manufacture accordingly. As a matter of fact, a very carefully compiled record made

recently shows that in about a dozen of the largest rail mills in this country an average of from about 5 per cent. to about 14 per cent. of the ingot is discarded under the present methods. Freedom from piping danger may not be in exact proportion to the proposed amount of metal to be discarded, but it is evident that the proposed increase will not alter conditions so greatly as might first appear.

The chief controversy between the steel makers and the railway interests over the chemical composition of the steel now used is principally in regard to the phosphorous content. The consumers desire to limit the phosphorous to 0.085 per cent. The manufacturers contend that with the available ores this is an impracticable limit, and suggest 0.1 per cent. This contention may be well taken, but one steel mill on this continent is producing in the neighborhood of 150,000 tons of steel rails per year, which contain as a maximum 0.085 per cent. of phosphorous. These rails are made from ore purchased in the open market in this country, and have given and are giving satisfactory results in service.

The details of the existing methods of manufacture which produce physical weakness in rails are not easily defined. The reduction in the number of passes or times an ingot is put through the rolls to produce a rail doubtless has some bearing on the unsatisfactory results. The structural strains incident to the more rapid forcing of the steel into the rail section may account also for some of the numerous mysterious breaks which have occurred in apparently sound rails. On the other hand, the proportions of the present sections are probably somewhat responsible for the poor physical character. It is apparent, moreover, that sections with smaller heads would have the structure of the latter of more nearly the same character as the balance of the rail, due to the additional work which the heads would receive. The methods of paying the mill operatives according to the total output and other similar conditions also have a tendency to produce hasty work, which naturally may not be done with sufficient thoroughness. In other words, in the effort to increase production there is danger that the quality of the product has not been kept sufficiently prominent.

Whatever the merits of the contentions presented by the two interests chiefly concerned may be, it is certain that heavy rails which will give uniformly satisfactory service must be produced. If such rails cannot be manufactured at the existing prices, the steel mills should present the case clearly to the railway interests with the provision that they can and will meet the proper requirements at an increased cost, to be demonstrated. Action of this kind made in a reasonable manner would relieve the makers of responsibility. It would also forestall any grounds for government investigations and perhaps interference, which appear to be probable, and would likewise remove a strong argument for the reduction or removal of the tariff on steel rails, as has been widely advocated of late from various responsible quarters.

Repair Shop Expansion.

A modern industrial plant designed for the economical manufacture of standard products is almost always built with the idea of providing for future growth without undue expense. Remodeling of factory buildings is becoming less frequent, as comprehensive plans for expansion are originally laid down, and few owners begrudge the time taken by their architects and engineers to round out a logical scheme of development on paper before the earth is turned at the site of the new establishment. The power plant is located in or near the center of future distribution, and space is usually provided for a large increase in generating capacity without the erection of a new building; side tracks, passageways, spurs into buildings and the main structures themselves are put down in such a way that liberal growth can take place without hampering the usefulness of existing facilities. Even the foundations are often built for future tool locations, and the heating and ventilating problem in the larger plant is ordinarily met by an extension of the methods of solution found satisfactory in the first installation.

The conditions in a shop devoted to repair practice or other non-routine work are decidedly different. To foresee the line of development probable in such an establishment is far more difficult than to plan for the growth of a standard-product factory. In a repair shop attached to a particular industry alone the conditions are easier, although the development in every line of mechanical endeavor is so progressive in these days that expansion plans must be made on a broad basis if later conditions are not to find cramped and inefficient facilities at hand. Thus, in the electric railway field a new repair shop can be built to handle the present type of rolling stock with efficiency and space allowed for growth along present lines; but a wise design will consider not alone the probability of being obliged to maintain here an increased number of cars like the present units, but also the fair certainty of having to deal in a very few years with motors of perhaps 50 per cent. more power and cars of from 25 to 50 per cent. more weight than those of to-day, on any line or system where the competition to secure faster service or greater comfort is beginning to be felt. The probable growth of the industrial unit cannot be overlooked in the planning of expansion.

In the general shop for machines and metal repairs and for the development of varied iron and steel structures on special orders, the exact trend of future business can seldom be definitely postulated. Several points can be provided for, however, in the endeavor to meet the changed conditions anticipated. Ample power supply, absence of obstructive movements of stock against the normal course of internal handling, provision for plenty of natural light and continuous expansion of the heating and ventilating systems are essential to the avoidance of congestion. By planning the concentration of the heaviest class of machine tool work at one section of the building, as in the standard centre aisle swept by overhead crane facilities, the most indefinite future repair jobs on a large scale need cause few anxieties. Extension of the centre aisle for heavy work and expansion of the side bays for the lighter jobs will meet any probable conditions. When the design will not permit of symmetrical expansion, as in city shops, located on odd-shaped lots, the problem can sometimes be solved by reconstructing a portion of the bays devoted to the lighter work and turning these sections over to the heavy tools, which naturally are grouped together on the ground floor. It is a simple matter to relocate benches and speed lathes, small shapers, grinders and the less massive equipment of the ordinary machine shop, and sometimes a special mezzanine floor section can be built for this transfer. Interference of one job with another must be avoided like a pestilence, if economy of shop operation is to be retained in the growth of the works.

It is in changes of this character that the usefulness of the electric drive specially appears, for the independence of line shaft locations common to every electric system enables tools to be placed almost anywhere that the shop structure can support them. Even the group driving of machines by motors offers only less latitude in the re-location of equipment. Modern methods of electric lighting are equal to almost any demand from the shop foreman in the way of making the desert places to blossom with productivity, and the flexibility and economy of electric power never can do otherwise than facilitate expansion.

Notes and Comment.

Grade Crossing Elimination is work of such growing importance near most of our large cities that the article on an undertaking of this sort on the Boston & Albany Railroad, printed on another page, deserves special notice. There was nothing particularly novel about this work, nor was it so difficult as the grade crossing elimination carried out by the Lackawanna engineers in Newark. It is for this reason that prominence has been given to the description, for it will doubtless be helpful to a good many engineers in the future, who have to carry out similar improvements. The problems in any such case are two-fold, to handle the traffic and to transport materials. Where the right of way is limited in width, the successive steps in the construction must generally be planned so as to avoid interference with traffic so far as practicable, and this may make it necessary to put down retaining walls in very narrow trenches. Cableways are employed to advantage in such work, but it would seem as though they might be supplemented with good results by the narrow-gauge railways that are coming into more general use by our contractors and have been extensively employed on all kinds of foundation work by European contractors for many years. Where the speedy completion of the change in grade is desirable, which is generally the case, these light railways present features that deserve careful consideration.

Greater Pittsburg, a city of 38 square miles in area and a population of 550,000 is assured by the decision of the United States Supreme Court that the consolidation of Pittsburg and Allegheny was not contrary to the Constitution or to any federal laws. The decision defines in explicit terms the rights of a state over a city, as shown in the following extract: "The state at its pleasure may modify or withdraw all such powers, may take without compensation such property, hold it itself, or vest it in other agencies, expand or contract the territorial area, unite the whole or a part of it with another municipality, repeal the charter and destroy the corporation. All this may be done, conditionally or unconditionally, with or without the consent of the citizens, or even against their protest. In all these respects the state is supreme, and its legislative body, conforming its action to the state constitution, may do as it will, unrestrained by any provision of the Constitution of the United States. Although the inhabitants and property owners may by such changes suffer inconvenience, and their property may be lessened in value by the burden of increased taxation, or for any other reason, they have no right, by contract or otherwise, in the unaltered or continued existence of the corporation or its powers, and there is nothing in the federal Constitution which protects them from these injurious consequences. The power is in the state, and those who legislate for the state are alone responsible for any unjust or oppressive exercise of it." Particular attention is called to this opinion of the court of final jurisdiction of the nation, because of its significance in connection with many important engineering affairs. For example, the water, sewerage and park work about Boston, the water-works at New York and the drainage works at Chicago are not strictly municipal undertakings in some respects, although directly for the benefit of the cities concerned. There is a manifest tendency toward state commissions for larger public works.

GRADE CROSSING ABOLITION AT NEWTON HIGHLANDS AND NEWTON CENTRE, MASS.

By Walter C. Whitney, Assistant Engineer, Boston & Albany R. R.

The Boston & Albany Railroad Co., is just finishing the work of the abolition of grade crossings on that part of its line known as the Newton Highlands branch. This is a double-track line which leaves the main line at Brookline Junction about 1½ miles from the South Terminal Station and running out through Brookline, and Newton joins the main line again at Riverside, about 10 miles further out. The work to be described lies in that part of the city of Newton known as Newton Highlands and Newton Centre. New grades of the railroad and streets were specified in the decision of the commissioners which passed upon the general project, and were ordered by the Superior Court. The work being on a branch line on which the traffic is wholly suburban passenger, with only one freight train a day, heavier grades were permissible for the tracks than would otherwise have been the case. Owing to the location of Crystal Lake close to the tracks it was deemed advisable to depress the tracks very little at that place. This fact made it possible to divide the work into two sections. The retaining walls and abutments of the Newton Highlands or westerly section were built in 1905. In 1906 the steel work of the bridges was erected at Newton Highlands and the retaining walls and abutments were built at Newton Centre. This year the steel work is being erected at Newton Centre.

The general layout and scheme of the work was as follows: Starting at Sta. 189 of the location of the railroad, the tracks were elevated at the rate of 0.316 per cent. or 16.68 ft. per mile to the first street at Sta. 201, where the tracks were elevated a total of 6.30 ft. and the street depressed 9.70 ft. The new rail grade from Sta. 201 descended at the rate of 1.06 per cent. or 56.0 ft. per mile until the fill ran out at the old rail grade at Sta. 208. The depression of the tracks began at Sta. 208 and the rate of 56 ft. per mile was continued to Langley Road at Sta. 215, where the street was raised 8.23 ft. and the track depressed 9.60 ft. From Langley Road the tracks run level to Institution Ave. at Sta. 222, where the railroad cut was 9.00 ft. Institution Ave. crossed the railroad by means of a wooden bridge and the elevation of the floor of the new bringle is about 1 ft. lower than the old. From Sta. 222 to Sta. 236, the new grade ascends at the rate of 0.336 per cent. or 17.74 ft. per mile. At Sta. 226 Cypress St. originally crossed the tracks by a wooden bridge, but was so elevated that in the change the new elevation of the street where it crosses the tracks is over 6 feet lower than the old. The railroad was depressed 7.30 ft. Glen Ave. and Institution Ave. are both 40-ft. streets, Langley Road 60 ft. and Cypress St. 50 ft. At Sta. 236 Centre St. crosses the tracks on a skew of 20 deg. 6 min. The street was originally 50 ft. wide but was widened 6 ft. in connection with the work. Centre St. was raised 13.47 ft. and the tracks depressed 5.33 ft. These five streets comprise the Newton Centre section. The work of making the fill at Glen Ave. and the construction of the abutments at that place were done in 1905, the remainder of the work in 1906 and 1907.

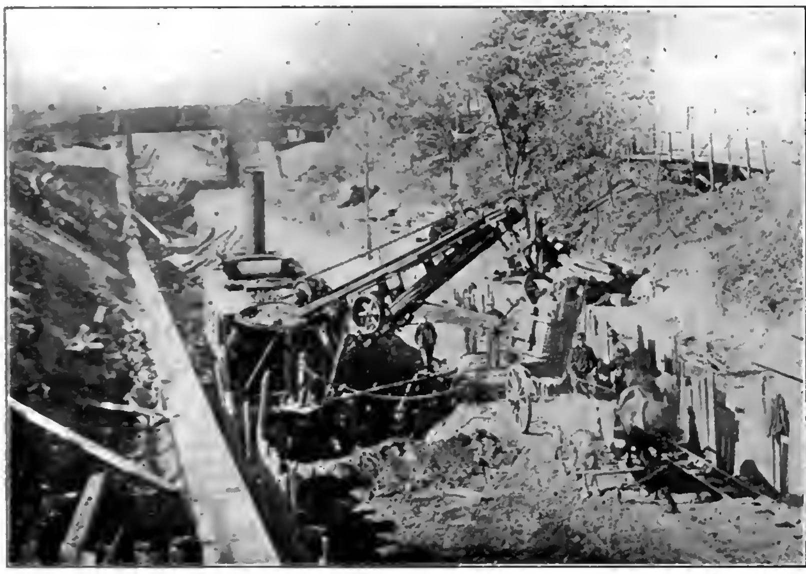
From Sta. 236 to Sta. 250 the tracks ascend at the rate of 0.41 per cent or 21.86 ft. per mile. At this latter station the depression of the tracks was only 5 in. and this point was made the dividing point in the steam shovel work between the two years' work. Rogers St. originally crossing the railroad at Sta. 247 was discontinued, and a new location given it at Sta. 251, where both abutments of the bridge are built on the face of a ledge. Rogers St. as relocated is 40 ft. wide. From Sta. 250 the tracks again descend, this time at a rate of 0.809 per cent. or 42.71 ft. per mile to Boylston St. at Sta. 277, passing under Hyde St. 40 ft. wide at Sta. 258 and Walnut St. 70 ft. wide at Sta. 266. Walnut St. is the main street of Newton Highlands, and the principal square is only about 100 ft. away from the railroad. At Hyde St. the tracks were depressed 6.25 ft. and the street raised 11.58 ft. At Walnut St. the depression was 11.80 ft., a part of Newton's boulevard system, is 90 ft. wide. The recently built Boston & Worcester Electric R. R. runs its cars over this bridge. At the time the line was built they were refused a crossing at grade with the railroad and passed over it by means of a wooden trestle. Piles were driven for the four bents nearest to the railroad, two on each side of the tracks, and these bents were so spaced that the concrete abutments could be built and the excavation for the railroad made without disturbing the electric car tracks, save for a small amount of rebracing that had to be done. From Sta. 277 the new grade ascends at the rate of 0.876 per cent. or 46.25 ft. per mile to Sta. 290, where it runs out at the old grade of the tracks.

The tracks in front of the Newton Highlands station were lowered 10.5 ft. and those in front of the Newton Centre station 9.5 ft. These changes of grade necessitated a remodeling of the depots to meet the new conditions. Both stations are of Milford granite and are about 30x75 ft. In both cases the change was made by building new foundations under the front and sides of the building, carrying them deep enough to be below the new subgrade of the tracks. Access to the station from the platform at Newton Highlands is obtained by two flights of granolithic steps, which start on the front at the two ends of the depot and come to a common landing in the centre of the station at elevation of the floor of the station. At Newton Centre, the station being nearer the tracks, there was not room on the front for these steps and a flight of granolithic steps was built at each end of the station and new doors built in the ends instead of on the front as formerly. Paths with a maximum grade of 12 per cent. lead from the streets at each station to the platform.

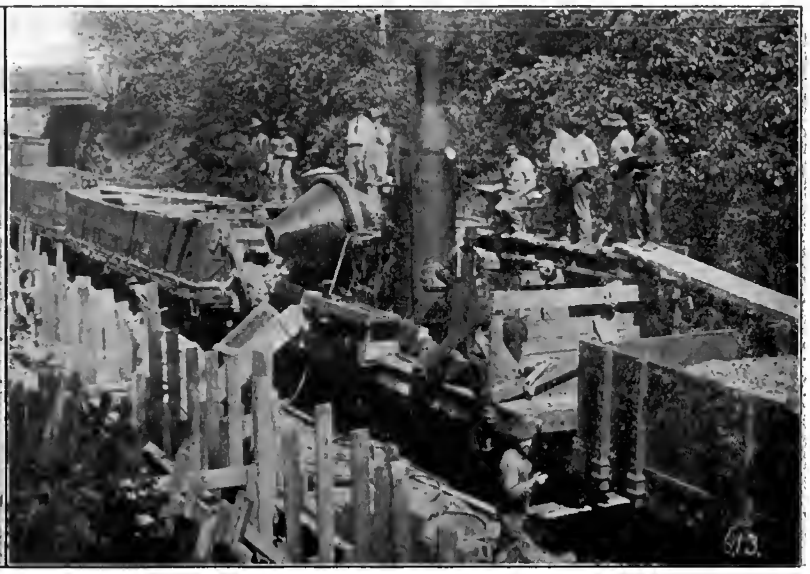
The platforms, in conformity with the standard of the Boston & Albany R. R., are of granolithic construction. The main platform slabs are 4 in. thick; the lower 3 in. is composed of 1:2½:5 concrete; the granolithic finish, 1 in. thick, consisting of 1:1½ mortar colored with 1 lb. of lampblack to each barrel of cement. The front curbing next the track is 24 in. deep and 7 in. thick and is tied to the main platform by two pieces of galvanized iron chain 12 in. long in each slab. The slabs are made to be as near 5 ft. square as is practicable. Where practicable the platform is given a pitch of ⅜ in. to 1 ft. Beneath and in the middle of both platforms a 24-in. drain of Akron pipe was laid to carry the water in the railroad ditch by the station.

At Newton Highlands the baggage is taken from the track level to the street by means of an elevator worked by hand. Outward baggage is also handled the same way. At Newton Highlands the baggage room is in the basement of the station, while at Newton Centre it is handled in a small building, also built of Milford granite and situated about 90 ft. from the station. Baggage coming from the trains is raised from the track to street level by means of a hand elevator. That which is to go on the train is transferred from the street to the platform by means of a granolithic chute.

The concrete work on both sides of the track is continuous from Sta. 209 to Sta. 239, and from Sta. 250 to Sta. 280. Where it was not necessary to build a retaining wall to hold the slope a low wall, called a ditch wall, was built to protect the foot of the slope from the anticipated large amount of ditch water to be taken by the depressed roadway. This wall is 2 ft. 6 in. high and is built so that the top of the wall is



Shovel Loading Teams for Street Fills.



Concrete Plant Discharging into Wall Forms.

The Newton Highlands Station before and after Lowering the Tracks.

level with the top of the rail. The ditch is 2 ft. 6 in. below the top of rail and the outside of the ditch at the face of the wall is about 8 ft. 2 in. from the rail. The ditches are all made 2 ft. 6 in. wide. The ditch walls have a foundation 3 ft. deep and are 2 ft. 6 in. thick, made of the same 1:3:7½ mixture of concrete throughout.

Spruce lumber was used throughout for sheathing and bracing, and for forms for concrete. Planks 2 in. thick were used for sheathing. Rangers and braces were usually 6x8 in., although in some cases 4x6 in. were used. For forms in 1905, 2 in. stock was used, planed on one side for face form, unplaned stock being used wherever the work would not be exposed to sight when completed. In 1906, 1 in. stock was used for forms but did not prove as satisfactory as the 2 in., it being much harder to keep it true to alignment and the finished surface, in general, being more uneven.

The planks and boards for face forms were fastened together into panels from 12 to 16 ft. long and 2 ft. 6 in. wide. This made it easier for the carpenters in putting up and taking down the forms. They were held in place by 2x4-in. uprights, spaced from 2½ to 4 ft. on centers. Before concrete was laid, the forms were gone over with a plane to remove any uneveness and open joints were stopped up with hard soap.

Lowering the ditches of the railroad a maximum of 14½ ft. at Newton Highlands, and 12 ft. at Newton Centre necessitated the lowering of all drains in the streets which crossed the tracks and some changes in tributary streets. Means also had to be taken to care for the surface water which would fall on the railroad slopes, and from there find its way into the ditches. Fortunately at Newton Highlands Boylston St. and Walnut St. were the only ones which had drains in them. At Walnut St. a new 40-in. circular concrete drain 1,500 ft. long was laid, which emptied into an open concrete drain which was laid 3,000 ft. further to South Meadow Brook. Entrance was made into this drain in both the railroad ditches by means of a special catch basin, in which was incorporated the invert of the 40-in. drain. Under the tracks two lengths of 40-in. cast-iron pipe was laid. This pipe was laid at night at different times so that there might be no interference with trains. At Boylston St. a 20-in. concrete drain was laid, the ditch water being taken care of by catch basins similar to those at Walnut St.

The new grade of the railroad at Crystal Lake being only about 18 in. above the level of the water in the lake, it was necessary to provide some safeguard so that in times of high water the tracks should not be endangered. This was done by building a concrete overflow at the east end of the lake next the tracks, so that should the water ever rise higher than the grade of the overflow the water may be carried off through a drain which passes under the tracks at Centre St. and thence through private lands 2,500 ft. to the lowlands. This drain is of concrete 48 in. in diameter, laid under and built in connection with a ditch wall on the north side of the tracks and carried under them by means of four lengths of 48-in. cast-iron pipe. As soon as the drain passes under the south abutment at Centre St., it is enlarged to 60 in., and is then built of concrete.

Langley Road was the only other street at Newton Centre in which there was a drain, and the work was done in a similar way there, the water from the ditches being taken care of by catch basins. All work on the drains outside of the railroad location was done by the City of Newton by day labor. Newton having the so-called separate system of sewers, the sewers in Walnut St. and Langley Road had to be lowered independent of the drains, temporary means being provided to maintain their flow.

The work at Newton Highlands was started in the spring of 1905, as soon as the frost was out of the ground. There being land enough south of the main tracks to permit it, a temporary line was built the whole length of the work, about a mile and a quarter. Single track was laid on this and the two main tracks abandoned or given up for construction purposes. A flagman was stationed at each end of the temporary track and a third man near the middle had charge of the train movements. The flagmen's cabins were connected by telephones and trains were allowed to enter the single track from either end only by order of the man in charge. There were fifty-two regular trains every day in both directions and to get a train in and out of the single track section necessitated two movements or orders by the man in charge. Often there would be three or four work trains in the section and orders would have to be given putting them into clear so that it was no unusual thing for from five to six hundred movements to be

The Newton Centre Station before and after Lowering the Tracks.

made in one day. All this was done for two years without a single accident and without any delays to traffic longer than a few minutes. Here delays were all caused by trains arriving at both ends of the single track at practically the same time.

At two places in this temporary track, trestles were built, one 368 ft. long, and the other 512 ft. long. These were built where there was not room enough to make the steam shovel cut to grade without undermining the temporary track. Piles were driven varying in length from 6 to 12 ft. They were capped by 12x12-in. caps on which were laid the 10x16-in. stringers. When the temporary track was completed, the traffic was transferred to it and excavation was started with the steam shovel, enough width being obtained on the bottom of the cut at the elevation of the new sub-grade to lay a track which would have clearance from the face of the walls and abutments on the north side. As soon as the steam shovels had a section of the cut completed, the contractor for the masonry work started work on the walls and abutments on the north side. When these had all been completed a track was laid at the new depressed grade, and, traffic being turned on to that, the temporary track was torn up and the steam shovel excavation was made under the site of the other or southerly track, after which the south walls and abutments were built.

The material excavated was disposed of in three ways. Wherever possible it was loaded on teams provided by the City of Newton and used in making the street fills. When this was not feasible, it was loaded on dump cars and used for raising the railroad grade at the fill at Glen Ave. The surplus material was wasted on the company's land at the west end of the work. At Newton Highlands one street, Walnut St., was kept open to teams all the time the work was being done. A temporary wooden bridge was maintained supported by wooden bents, and on the bridge abutments at different stages of the work.

At Newton Centre the right-of-way owned by the road was so narrow there was no room for a temporary track outside the others, as at the Highlands. All abutments and retaining walls on the north side were first built in a trench, the northerly track being given over to the use of the contractor and for construction purposes by the railroad company. All passenger trains were run on the southerly track, making single track in the same way as the year before at Newton Highlands. As soon as the walls and abutments on the north side were completed the same routine was gone through on the south side, the northerly track being used for single track. When the abutments and walls were all completed, which was late in the summer, single-track was again made on the southerly track and the steam shovels, one at each end, excavated about half way down to final sub-grade under the northerly track, this being as deep as they could go and have width enough on the bottom of the cut to lay a track and at the same time not undermine the southerly track. Traffic was now diverted to a temporary track laid in the cut as close to the walls on the north side as was possible, and the steam shovels then excavated under the southerly track to sub-grade. After this was completed traffic was again transferred to the southerly track and the excavation completed under the northerly one.

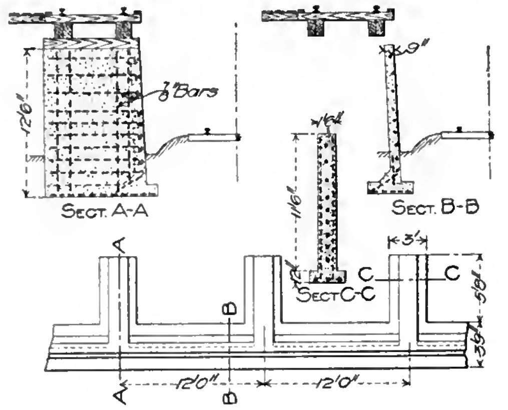
At Newton Centre two streets were kept open to the public all the time until the steel work was put on. Both crossed the railroad on overhead wooden bridges, and the change of grade of course necessitated new abutments and new bridges. One was originally supported on wooden bents and carried an electric car track. The foundation stones of the old bents were taken out and new timber supports put in reaching down to the new elevation of the sub-grade. The grade of the street at this place was lowered about 6 ft. so that it was possible to build the new abutments to their full height without interfering with the old bridge. The bridge was a wooden bridge resting on stone abutments. A temporary timber bent was put in front of the old masonry and carried down to the new sub-grade. The old abutments were then torn out by the railroad forces and the new abutments built by the contractor.

The various mixtures of concrete used on the work were as follows:

All foundation concrete, and that used in ditch walls, was one part of cement, packed in the original package, three parts of sand measured loosely, and seven and one-half parts of broken stone.

Main wall concrete and coping for retaining walls was one part cement, packed in the original package, two and one-half parts sand measured loosely, and six parts broken stone.

Wing-wall coping and bridge-seat concrete was



Coal Pocket Walls.

one part cement packed in original package, two parts sand measured loosely, and four parts broken stone.

Wall facing mortar consisted of one part cement and two parts sand specially screened.

Coping and bridge seat finish mortar consisted of one part cement and one and one-half parts specially screened sand.

The specifications required that the sand should be free from organic matter and should contain not more than 7 per cent. of clay or similar material. The sizes desired were preferably a mixture of coarse and fine, but no batch should consist of wholly fine sand, that is so fine that after having the coarse parts screened out by a No. 12 sieve, more than 50 per cent. would pass through a No. 50 sieve. No dead sand was allowed in the work. The larger part of the sand used both years came from the railroad company's pit at Riverside, about 4 miles from the work. It was provided in the contract for the work that the contractor should be allowed to obtain it there free of charge and it was transported from the pit to the work without cost to contractor. At Newton Highlands excellent sand was found in several places and was used in the work.

At Newton Highlands both broken stone and gravel concrete were used, the gravel being obtained directly from the excavation on the work. Its maximum size was specified as 3 in. At Newton Centre the nature of the excavated material was different, being either filling, peat, silt or hard pan. All the concrete laid at Newton Centre was broken stone. It was required to be free from dirt or dust other than that caused by crushing the stone itself. The size of the broken stone was specified as the entire product of the crusher, including dust, up to and including that which had passed through the crusher screen having a diameter of about 2 in. The amount of sand in the coarse mixture was made smaller than usual on account of the fact that the dust from the crusher, with the accompanying void-filling fine stone, was introduced with the crusher stone.

Hand-mixed concrete was laid in some of the smaller walls, but the bulk of concrete was machine-mixed. Two Smith mixers were used. They were mounted on a flat car hired from the railroad and could be easily transported from place to place as needed. The mixing train as made up consisted of a car of cement and one or more gondola cars each of sand and broken stone. A movable plank runway was laid on top of the gondolas and the sand and stone wheeled in wheelbarrows to the mixer. One of the illustrations shows this very well.

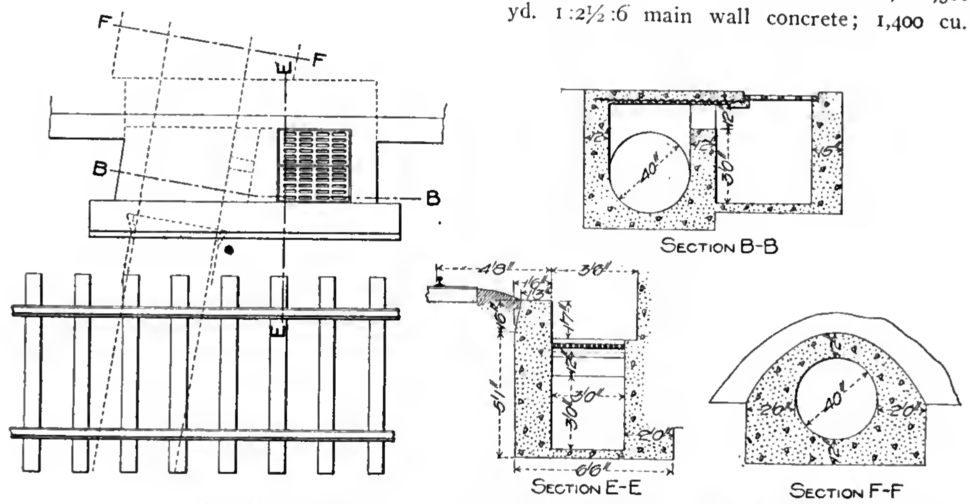
As a general rule the foundation concrete was deposited against the banks without the use of any forms where the nature of the material was such that sheathing was not necessary. Where sheathing was required the foundation concrete was deposited against the sheathing. A piece of plank was placed on the front of the foundation level with the top so that the concrete would be true to grade at the 6 or 12-in. step at the top of the foundation. This was necessary, as this step marked the bottom of the railroad ditch. After the foundation was laid the mixer was moved to another part of the work and the forms for the main wall were built. The moving of the mixer from place to place and the supplying of the two mixers with sand, stone and cement was all done by the railroad free of charge to the contractor and required practically continuous service of one engine and train crew. In depositing the main wall and coping concrete, it was either dumped direct from the mixer into the trench by means of a chute or was dumped onto a platform and then shoveled into place. The 1 in. of facing mortar was deposited at the same time as the body concrete. A metal plate about 8 in. wide and about 5 ft. long was used in placing the facing mortar. On one side of the plate were riveted four 1-in. angles about 7 in. long. A slight flare was given the upper edge of the plate and two handles provided for raising it. This, when placed next the form, insured that there was 1 in. of facing mortar and not several inches as is the case when no guide is used, or none at all in places as is the case when a ⅞-in. board is used. When the top of the plate was reached it was raised up by the handles, and being thin left practically no void to be filled.

In both years there was considerable ledge found in excavation for the walls and the roadbed. This was taken out by the contractor at a yardage price and he was allowed to use it in the walls and foundations as rubble in the concrete. Between different day's work these rubble stone were placed one-half in one section and the upper half left out of the concrete, so that it would help make a bond when the new concrete was laid on the old. When it was not possible to complete a wall at one day's work, horizontal level strips were nailed on the face forms and the concrete brought to the level of these and then stopped. This did away with the irregular streaks which are found on the face when the top of the concrete is left in a rough shape on the face at night. All of the concrete except that laid on an incline, as in wing walls and inclined copings, was what would be called a wet mixture. In some cases it was possible to lay the coping at the same time as the main wall, in which case the dowels were dispensed with. As a general thing, however, this was not possible and the top of the wall under the copings was given a downward, backward slope so that water would not remain on the outside near the face.

After the forms were removed the face was rubbed down and any irregularities chiseled off.

At Newton Highlands the finishing of the face was done as soon as possible after the forms were removed, but at Newtown Centre nothing could be done until after the steam shovel excavation was complete, which in some places was nearly six months later. The face was then thoroughly wet down with a hose and a thin mortar of one part cement and one part sand was applied and thoroughly rubbed in. The face was then smoothed with horizontal strokes of a whitewash brush to give a uniform appearance, free from streaks. This work was made continuous between expansion joints as far as possible, in order to avoid a streaky appearance.

On the south side of the Newton Centre freight yard there was a coal track 12 ft. from the inbound track and leading from it by a trailing point switch. The ground immediately south



Drainage Catchbasin, Boston & Albany Improvements.

of this track was from 5 to 6 ft. lower than the track, which was supported by a wooden cribwork laid on the slope. The coal was unloaded by shoveling over the sides of the cars and letting it fall down this cribwork slope. This was a costly and unsatisfactory way. The railroad was lowered about 6 ft. at this place, which brought the new elevation of the rail about level with the ground in the coal yard. It was decided by the railroad company and the owner of the coal yard that a reinforced concrete wall built to give the same effect as the ordinary wooden coal trestle was what was needed at this place.

The design as worked out consisted of 39 concrete piers 12 ft. on centres, which gives a trestle 468 ft. long. These piers are 18 in. thick 8 ft. wide and 12 ft. 6 in. high, reinforced with ⅞-in. twisted steel bars. The construction above the piers is the same as for a standard coal trestle. On the pier is laid a 10x12-in. hard pine cap, which supports the 8x16-in. hard pine stringers, four in number, two under each track, on which are laid the track ties. Between the piers a thin curtain wall was built to prevent the coal from falling onto the main track. This wall is 9 in. thick, and has a spread base of 3 ft. 9 in. in width.

After the work was started in 1906, it was found that for a part of the way under the wall the bottom was soft, so it was decided to put a pile foundation under a portion of the wall. Four 20-ft. spruce piles were driven under each pier and 9 in. of concrete was laid around the heads of the piles. This was done under a separate contract. The elevation of the coal track was made 4 ft. higher than it was before, and the approach to it is by a 4 per cent. grade. The approach track is laid on an ordinary concrete wall. The clear depth below the coal track rail to the ground beneath it is 12 ft., which gives a chance for teams to be filled by dumping direct from bottom dump cars or, when necessary to unload the cars, they can be dumped direct, and if a greater storage capacity is desired the coal can be shoveled over the sides of the cars. This is the case at the time this is written; coal is piled up on the yard side of the trestle so that it is level with the top of a coal car.

The work was done by contract on a unit price basis for earth excavation, for sheathing and bracing, for concrete, etc. The price for the various mixtures of concrete included the cost of the forms, as estimated by the contractor. The final total quantities on the work were as follows: 33,500 cu. yd. earth excavation; 2,500 cu. yd. rock excavation; 8,000 cu. yd. backfilling; 300,000 ft. B. M. spruce sheathing and bracing, placed and removed; 114,000 ft. B. M. spruce sheathing and bracing left in place; 6,600 cu. yd. 1:3:7½ foundation concrete; 16,500 cu. yd. 1:2½:6 main wall concrete; 1,400 cu. yd.

Constructing a Side Wall with Cableway at Newton Highlands.

1:3:7½ ditch wall concrete; 550 cu. yd. 1:2:4 bridge seat concrete; 230 cu. yd. cut stone for bridge seats.

The work in 1905 was done by Chas. R. Gow and John E. Palmer under the firm name of Gow & Palmer. The work in 1906 and 1907 by the Chas. R. Gow Co., of which company Chas. R. Gow is president. The excavation and all other work done by the railroad forces was in charge of the roadmaster, C. B. Lentell. The work was done under the direction of Mr. Walter Shepard, chief engineer, Boston & Albany R. R.. Mr. William Parker, division engineer, was directly in charge of the work. The detail plans were made by the writer, who also had charge of the line and grade work, estimates and construction work under the direction of the division engineer.

Sewage Purification at Hampton.

The method of sewage purification now employed at Hampton, England, is so favorably regarded by British engineers that some statements concerning it by Mr. Sidney H. Chambers deserve attention. He is the surveyor to the Hampton Urban District Council, and at a resent meeting of the Association of Municipal and County Engineers explained a marked change made in the operation of the system as follows:

The original method of working the Hampton contact beds was to exclude nothing from them, except the screenings, and to endeavor to retain the suspended matter in them, in the confident hope that all would be destroyed. The result was that, in 1902, after four years' operation, so much sludge had been removed from the beds, and so much was retained in them, as to give rise to the opinion that the original suspended solids had either suffered no diminution by biolysis, or whatever diminution had been effected had been made up from some other source. The opinion was confirmed two or three years ago by careful estimations and calculations, and more recently by estimating the total amount of sludge removed in washing the beds.

The present method of working the beds is to exclude from them the largest possible quantity of suspended solids, and as much of the colloidal matter as will readily be removed from solution by large surface contact, while at the same time the beds are so operated as to secure the disengagement and evacuation of as large a proportion as possible of those solids which have entered them, or which may be formed therein from the soluble solids. By this method of working the desolution effect is made evident, since the total amount of suspended matter leaving the beds is in excess of those gaining admittance thereto. The effect of this throwing out of suspended matter is, obviously, to minimize the accumulations, which necessarily must prolong the working efficiency of the beds.

Steel Water Mains 4, 6 and 9 in. in diameter have been used in the new works to furnish an additional supply to Teignmouth, England. The original plans of Mr. C. F. Gettings, the urban district engineer, called for cast-iron pipe, but a considerable saving was made by using steel pipe furnished by the British Mannesmann Tube Co., as the pressures carried are quite heavy, running up to 380 lb. at a river crossing.

Conditions along the Panama Canal.

From the annual report of the Isthmian Canal Commission, made public this week, and the "Canal Record," the official journal of the Commission, it is possible to form a good idea of conditions along the Panama Canal. During this year the entire personnel was changed, and to the vacancies left by the resignations of the former members were assigned three officers of the Corps of Engineers, United States Army; the Chief of Bureau of Yards and Docks, United States Navy; an officer of the Medical Corps, United States Army, and two civilians. Two important changes resulted from a combination of the positions of chairman and chief engineer on March 4, filled by Lieut.-Col. Geo. W. Goethals, and from the requirement that the Commissioners take station on the Isthmus, where they can be in direct touch with the work committed to their charge. The new Commission assumed its duties on April 1, 1907.

In order to utilize the services of the engineer members of the Commission in construction work and to secure a closer supervision of the details of the work, then rapidly expanding, through a head directly responsible to the chairman and chief engineer, the department of construction and engineering was subdivided into departments, each in charge of a member of the Commission, as follows: Department of excavation and dredging, department of lock and dam construction, department of municipal engineering, motive power and machinery, and building construction.

Excavation and Dredging.—This department of construction embraces the Culebra division, extending from the Chagres River to Pedro Miguel, the Chagres division, embraced between deep water in Lake Gatun and the Chagres River, the Colon dredging division, extending from Gatun to deep water in the Atlantic, and the La Boca dredging division, taking in all excavation between the La Boca locks and deep water of the Pacific.

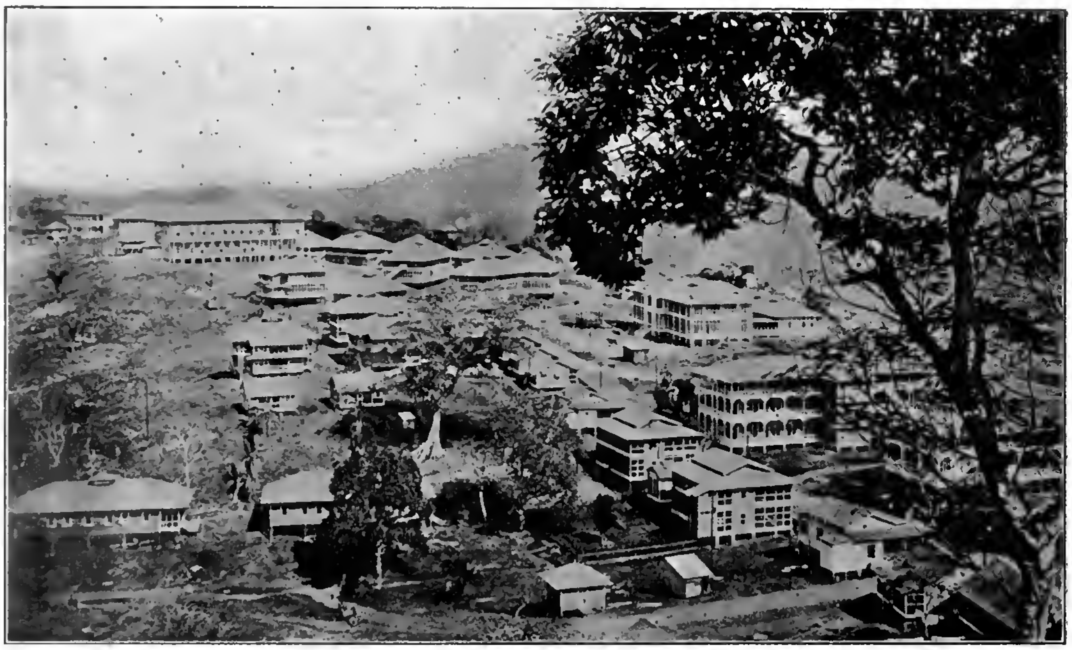
The Culebra division is practically 10 miles in length, and early in the wet season it was recognized that general supervision of all the steam shovels or all the trains of the entire division under one supervisor or superintendent was not productive of the best results in fixing responsibility in case any part of the work was not progressing satisfactorily, consequently a slight change in organization was effected on July 1. This consisted in subdividing the division into five construction districts, each under charge of a superintendent of construction, who is held responsible for the work in his district. Better results have followed with less friction.

The greatest difficulty found in maintaining the output during the rainy season is due to the dumps; the material being loose sinks under train loads after being wetted by the heavy rains causing considerable delay if not entirely preventing the use of the dump until it has dried out.

The total excavation in this division up to November 1 has been 11,221,730 cu. yd. The average haul of the dump trains is about 10 miles at present, but will be increased when the soil goes into the dams, as described later. On June 30 there were 3 45-ton shovels, 28 70-ton and 32 95-ton on the Isthmus. The number of cubic yards excavated per hour, while under steam, by shovels not engaged in preparatory work, averaged 68 for the fiscal year ending June 30, 1906, and 86 for the year ending June 30, 1907. Considering the total output in the Culebra division for the fiscal year, the average cost of the various items of expense have been as follows: Arbitrary, to cover cost of plant, $0.1200; blasting, .1451; excavation by steam shovels, .1081; transportation, .1942; tracks, .0830; dumps, .1548; general expense, .0193; total, $0.8245.

This does not include the material used in the repair of locomotives, steam shovels, and cars, nor does it include the cost of operating the air compressor nor the proportionate cost of administration and general expenses of the mechanical department, which makes repairs on plant for the Culebra division. These items have never heretofore been included in the cost of excavation in the Culebra division, but as they comprise a fair charge against this work, they will be included in the cost of work for the fiscal year ending June 30, 1908.

In the costs just given the total cost of blasting has been distributed among the total number of cubic yards of excavation, but to get the real cost it should be applied only to the material actually mined, 3,291,856 cubic yards, making the cost for blasting $0.2557 per cubic yard. In other words, other things being equal, the removal of rock, due to blasting alone, cost $0.2557 more than that of earth.



General View of Culebra, the Canal Headquarters.

The item entitled "Arbitrary, to cover the cost of plant," is a fixed charge added to the cost of excavation with the idea that this fixed charge added to every cubic yard of material excavated will, by the time the canal is completed, total a sum which will be equivalent to the original cost of the plant, repairs for the plant being included in the cost of operation.

On the Chagres division only preparatory work was done during the year, consisting of surveys and borings to determine the character and amount of earth to be removed. The Chagres River crosses the center line of the canal 23 times within the limits of the division. The differences of level between the river and portions of the division are such that whatever excavation in the dry is undertaken will be subject to more or less interruption from overflow during the wet season. As the rock portion of the cut can be removed or broken up by blasting more economically in the dry than in the wet, it is desirable that work be undertaken without delay; though the amount to be done is relatively not large, the conditions are such as to militate against rapid progress.

The Colon dredging division consists of the Mindi and Colon districts. In the former about 700,000 cu. yd. of material in the vicinity of Mindi Hills will be removed by steam shovels, this method being more economical since the borings made during the fiscal year indicate that a large percentage of rock is found in this locality; the remainder will be dredged. The necessary clearing and other preparations were made and excavation by steam shovel was begun toward the close of the year.

In the Colon district dredging operations were in progress throughout the year, the greater part in the vicinity of the dry dock slip and along the route of the old French canal as far as Gatun. The latter was done to make a navigable waterway for the transportation of the materials that must be taken to the site for the construction of the locks. The machine shop for the Colon dredging division at Cristobal was equipped during the fiscal year with many pieces of new machinery and is in good working order. Steps were taken to enlarge the dry dock so that when completed it will be capable of taking a vessel 298 ft. long, 50 ft. beam, and 15 ft. draft.

On the La Boca dredging division the surveys to determine the line of the canal were completed, and some dredging done. The machine shop at La Boca is fairly well equipped for marine work and has accomplished much in rebuilding and repairing floating equipment, such as clapets, launches, barges, and electric cranes.

Locks and Dams.—This department of construction embraces the Gatun locks and dam, the locks and dam at Pedro Miguel, the locks and dams at La Boca, meteorology and river hydraulics.

The locks are in pairs, each, as now proposed, with usable lengths of 1,000 ft. and widths of 100 ft., which there is some talk of increasing to 110 ft. The adopted project contemplates a flight of three locks at Gatun, a flight of two at La Boca, and one lift at Pedro Miguel. The report on the site of the locks made by Messrs. Noble, Stevens and Freeman, already printed in this journal, stated that all of the locks of the dimensions proposed will rest upon rock of such a character that should furnish a safe and stable foundation. Since this report was made last May careful borings have been continued over the entire area in order to secure a contoured plat of the rock surface with a view to the most economical adjustment of the locks to the site.

Subsequent to the adoption of the project, studies were begun of locks, gates, and sluiceways. From these studies the Commission finally decided upon the method of filling and emptying the locks and the number and type of gates. The gates are in duplicate and of the miter type, except that the rolling gate similar to that now in use on the Ohio River will be substituted for the duplicate set at the lower end of each sum-

mit-level lock. In addition there will be provided an auxiliary pair of gates at the lower end of each flight for use as cofferdams in case it may be necessary to pump out the locks, and it has been determined tentatively to adopt a swing bridge type of dam for emergency use. The designs for the locks and gates are progressing satisfactorily.

Gatun Locks and Dam.—Excavation of the lock site by steam shovels was begun in September, 1906. About 573 acres of the site to be occupied by the dam were cleared of timber, and a pile trestle was partially driven along the 30-ft. contour on the upstream toe of the dam for the purpose of depositing rock from Bas Obispo as an integral part of the dam. Contracts were entered into for two 20-in. pipe line suction dredges for construction use on the lower portion of the dam. The cross section of the dam has been slightly changed and the upstream slope made more gradual than that originally proposed.

Broken stone needed for concrete construction in the locks can not be obtained in the immediate vicinity of the site and a quarry of trap rock suitable for the purpose was located at Porto Bello. Surveys of the property were made, and contracts were entered into for furnishing the necessary rock-crushing plant and barges for transporting the product to Gatun.

At the Pedro Miguel locks and dam, besides the pits and borings to determine the character of the foundation, work was confined to excavating the lock site.

At the La Boca locks and dams only preparatory work has been in progress, consisting of borings at the lock site and along the lines of the La Boca-San Juan dam and the Sosa-Corozal dam, and for locating and constructing the necessary spillway. At the Sosa-Corozal dam preparations were made for the construction of trestles on the two toes of the dam from which material from Culebra cut is to be dumped. Between the two dumps thus made suitable material for the dam is to be placed. Arrangements were made for the construction of a diversion channel for drawing off water which interferes with the construction of the dam so begun.

Division of Municipal Engineering.—The work performed by this division during the fiscal year included the paving of streets and construction of water works and sewer systems in the cities of Panama and Colon, paving, roadmaking, grading, construction of waterworks and sewer systems, and miscellaneous work of a similar nature in the Canal Zone, necessitating an expenditure of $1,741,953, divided about equally between work in the cities of Colon and Panama and work in the Canal Zone.

In general, the work has been but a continuation of the plan inaugurated at the outset of American occupation of the Isthmus—to take such steps as were necessary to make the Isthmus sanitary, so as to further the work of building the canal.

The cost of work done in the cities of Colon and Panama will be reimbursed to the United States under the terms of contract entered into shortly after the expiration of the fiscal year, in which the United States is authorized to collect such water rates as are sufficient to reimburse itself, as above outlined. The cost of these improvements in the cities of Colon and Panama, covering work approved to date, will approximate $1,750,000.

Division of Motive Power and Machinery.—The work embraced the erection and preparation for service of machinery necessary in canal construction and its maintenance in good repair; the installation and operation of air-compressor plants; the performance of work in connection with electrical installations, and the manufacture and repair work for other divisions.

To date the following machinery has been erected and made ready for service: Sixty-three steam shovels, 284 locomotives, 2,076 dump cars, 18 unloaders, 13 bank spreaders, 33 unloading plows, 3 track shifters and 7 pile drivers.

This work has been done largely at the old plants at Cristobal, Gorgona, Empire and Paraiso. Work was commenced on new plants at Empire and Paraiso during the year, in order to provide for increased demands made on this division.

Building Construction Division.—For the accommodation of gold employees 656 quarters, both bachelor and family, were constructed, and for silver employees 335 buildings were erected, consisting of barracks, bath houses, cook sheds, family quarters and kitchens. For the sanitary department 33 buildings were constructed for hospital purposes. Larger office buildings were constructed at Empire and Ancon and additional office space afforded at Cristobal and Culebra. A school building was constructed at Culebra, and other buildings for similar purposes started at Gatun, Cristobal and Empire. Seven mess halls for the accommodation of American employees and 11 for European laborers were completed; a large hotel at Tivoli Hill was also built, together with quarters for help and baggage room. A machine and car-repair shed, machine shop, engine house, pattern shop and other structures for the manufacture and repair of machinery were completed and extensive plants at Paraiso and Empire were commended. Four clubhouses were constructed.

Of the 2,265 buildings which were received from the French Canal Company, 252 were repaired during the year and 113 destroyed. There are 678 of these buildings yet remaining to be repaired, remodeled or demolished.

Division of Material and Supplies.—The division of material and supplies, the head of which reports directly to the chief engineer, is charged with the purchase and the proper handling of all material and equipment needed in connection with the construction of the canal. The diversity of the work necessitates the purchase and use of a very great variety of equipment, material and supplies, including stock for repairs. All departments on the Isthmus rely upon this division to suppply their various wants, and every effort is made to anticipate requirements by frequent purchases in the United States based on estimates submitted by the different divisions or gauged by the rate of consumption of stock on hand at the various storehouses along the line.

A large amount of old French material, consisting of boilers, pumps, Decauville track, cars, locomotives, cranes and other material, has been repaired and placed in service. About 11,000 tons of this old French material were disposed of to dealers in the United States as scrap iron, and 4,000 tons of it were used as ballast by Panama Railroad vessels going north, when there was a shortage of commercial cargo.

Storehouses for the distribution of this material are located at Mount Hope (general storehouse), the dry dock, Cristobal, Gorgona, Bas Obispo, Empire, Culebra, Paraiso, Ancon and La Boca. Larger and more commodious storehouses are under construction at Empire and Paraiso. All storehouses carry as full a line of supplies as is carried at the general storehouse.

The New Panama Railroad.—The completion of the canal will necessitate the abandonment of the present main line of the Panama Railroad, and preliminary surveys for location of a new line on the east side of the canal have been completed. The location of the line was practically determined in March, and involves the excavation of 1,600,000 cu. yds. of material and the placing of 12,000,000 cu. yds. in embankments.

The main line at Gatun now passes over a portion of the site that must be occupied by the dam, and in order not to delay work on this structure it became necessary to commence so much of the new line around Gatun as would enable the abandonment of the existing line and permit construction of the dam upon this portior of the site.

Contract vs. Hired Labor.—The report of tł Commission discusses this subject at much leng' There is no question, the report states, that in t majority of cases in the United States work

Views before and after a Blast Displacing 29,640 Yards of Rock at Bas Obispo.
Four drill holes, 78 feet deep, were used and charged with 9,600 pounds of black powder.

contracted because it can be done cheaper by that method than any other. This is generally due to the fact that the contractor has on hand a construction plant which can be more cheaply hired than purchased anew. Where, in any particular case, either from the nature of the work or its location, the contractor must purchase machinery and appliances which, so far as he can forsee, will be practically useless on the completion of the work, or where the party having the work done can make use of the plant subsequent to its completion, the advantages of the contract system disappear.

As illustrative, the Government secured cheaper and incidentally better concrete work in its fortifications than was obtained by contract. The batteries are heavy concrete constructions requiring machinery for which the contractor could find little, if any, subsequent use. For the same reason the Government, in many cases, especially where the work was removed from commercial centers, was able to construct locks and dams more cheaply than could a contractor. In some instances, to overcome a combination of contractors, the Government purchased the necessary plant and accomplished results more cheaply than by contract; this is notably true in dredging operations, as recent legislation on the subject clearly indicates. It is not uncommon in the execution of comparatively large projects that the contractors have failed and the Government carried successfully to completion, by hired labor, the work undertaken by the contractor. Notable instances of the Government successfully completing work are the State, War and Navy Department building and the Congressional Library, Washington, D. C.

Omitting profits derived from subsistence and general stores, and assuming the hours of labor the same in both cases, it stands to reason that the Government, when warranted in making the necessary outlay for plant, can do work cheaper than a contractor, for no question of profits enters into consideration.

The question of Government work versus contract in connection with the Panama Canal has been discussed, and a conclusion reached in favor of the latter method because of certain stated advantages that are claimed to result. To those familiar with river and harbor improvements, erection of public buildings, lighthouses, etc., and with contracts under the Government the advantages set forth are not so apparent or real, according to the report.

It is claimed that contractors have under their control and at their disposal trained labor forces, and that by a combination of such forces, through an association of contractors, team work will result, thereby accomplishing the desired end more quickly. As a matter of fact, conditions seldom enable a contractor to maintain intact his entire organization on one piece of work for transfer to another; the completion of a job means the disbanding of the force, and though new work may bring to him some of his old men, a new organization must in each case be perfected.

The Panama Canal presents a piece of work unprecedented in magnitude, which must be done under conditions entirely different from similar classes of work in the United States. The work naturally divides itself into dredging, dry excavation, the construction of the locks and dams and the construction of the new Panama Railroad. There is no contractor or syndicate of contractors that by any combination could bring to the Isthmus an organization ready for team work on any of these units. While it is possible for several contractors to combine forces, assuming that a sufficient number of men can be gotten together in that way, there still remains the necessity for whipping this force into shape in order to secure an organization that will produce the team work so advantageous in the accomplishment of results.

From the United States the supply of labor is the same whether the work be done by contract or by the Government, and the character of the labor must be the same. So long as work is plentiful the dread of the Tropics will deter men from seeking work here in preference, and this is equally applicable to the contractor and the Government. An adequate supply of labor from the United States is not possible, and recourse must be had to securing it abroad. The records here show that no contractor can even attempt to recruit labor in the West Indies, and that great opposition will develop to any recruiting by authorized agents of the Commission if the labor procured is turned over to contractors. These island governments cannot be blamed for their hostility toward the latter because of their experience under the French, which left an indelible impression throughout the West Indies. A representative of the Italian Government has recommended to the authorities that Italian labor be permitted here for employment under the commission, but he is not favorably inclined to the control of such labor being vested with a contractor.

It is true that in some cases the contractor may have an acquaintance which will enable him to secure suitable men more easily than a government agent and, again, he may bring to a work a great experience, but, so far as the most important parts of the Panama Canal work are concerned, this advantage is not apparent. In any case, the knowledge of the specialist in the particular work that is to be done is the element that will accomplish the most satisfactory results, and, so far as dredging and lock and dam construction are concerned, the government's experience has been, if not greater, at least as extensive as that of any contractor or association of contractors that can be secured in the United States. For these units of the work the government's acquaintance is equally extensive, and experienced men can be drawn from the engineering force of the government. These three classes of work form the most important parts of the Panama Canal, and in their prosecution the government has the advantage. So far as relates to excavation in the dry by steam shovel and cars, the advantage ordinarily would be with the contractors, yet the government has secured and maintained an organization on the Isthmus that cannot be surpassed by any contractor, and, it is claimed, has perfected this organization in as short a time as, under the circumstances, could have been done by any association of contractors.

When the government does work in the United States the wage scale is determined by the amount paid for the same class of labor in the immediate vicinity; there is no pressure brought to bear on higher authority for any increase over the salaries or amonuts offered, and strikes are unknown. It is true that conditions on the Isthmus are such that demands for increase in pay are frequent, and that to accomplish what was denied by those immediately in charge of the work recourse has been had to higher authority.

Conditions on the Isthmus are peculiar. It is contended, apparently on reasonable grounds, that service in the Tropics saps the energy, and that a man is incapable, after a time, of performing the same amount of work that he would accomplish had he spent the same period in a cooler climate. This creates a desire to accumulate sufficient means to avoid the necessity of relatively harder work on the return to the United States, and it is a question that a contractor would be obliged to face as well as the United States. In some respects the government is in a position to handle the situation more satisfactorily than a contractor, as was plainly shown by the trouble with the steam-shovel men in May last.

Track Throwing Machine on the Tabernilla Dump.

The wage scale on the Isthmus is practically adopted, and a contractor would be obliged to maintain it. Under the recent decision that all questions of pay are to be left with the commission, this body is placed on as secure a basis relative to the constant demands for an increase as any association of contractors.

Experience has shown that continuity of construction is more apt to result in cases where the government undertakes the task than when it is turned over to contractors. This can be easily verified by an examination of the records (the number of failing contractors) to be found in the office of the Chief of Engineers. For all work done by hired labor continuity of work is merely a question of continuity of appropriations. It is true that continuity may be equally insured by turning the Panama Canal work over to contractors, if the contract is so drawn that practically all risks are assumed by the government, but why this should be done, at a considerable increase in cost, is not apparent.

To any one who has had experience with contracts on government work, the claim that letting a piece of work by contract is a reasonable assurance that it will be completed in a definite time is utterly untenable. On public works, including public buildings, it may safely be said

that in the majority of cases the time limit is exceeded. An examination of the contracts for material to be supplied the Isthmian Canal, so far as the time limits proposed by the contracts are concerned, will clearly show that there is no assurance of completion in a definite time of any contract, even though the contractors themselves, when fully cognizant of all the conditions surrounding the work, fix the time for the completion or delivery. It certainly cannot be supposed, therefore, that in an enervating climate, like that on the Isthmus, and with labor below that in the United States in efficiency, this time-failing record for contract work would be changed.

Reasonable definiteness in cost is usually obtained by contract, when based on unit prices and when all conditions of the work are fully known in advance, yet these unit prices are, as a rule, higher than would be the cost to the government should the latter possess the necessary plant. It is true that the contract which was proposed for the construction of the canal provided for the determination of time and cost by a board of engineers, but the conclusions on these points could be upset should conditions be found or met with unforeseen by that board. Experience on all works, even those based on more definite data than can be presented to contractors for the Isthmian Canal work, shows that the unexpected is always happening, and this seems especially true of the work here.

There is no question that there are a number of people who will always believe and contend that any piece of work done by the government could have been done as well and more cheaply if undertaken by contract, but an examination of the records will generally disprove such a contention. On the other hand, there is an equally large class who will contend to the contrary and claim, after the completion of the work that the reverse is true.

Work heretofore has been conducted on a non-partisan basis. The thinking class of American people fully realize the necessity for the Panama Canal and its early completion, and it is generally realized that this can be accomplished only by the application of business and non-partisan methods. This has generally been the case with all government work wherever undertaken, and the fact that the continuation of this policy may not continue along the same lines is hardly an argument strong enough to weigh in favor of contract work.

While it has been noted that contractors can usually do work cheaper because of plant already on hand, thereby saving the cost of new machinery, and because of greater familiarity with the class of work on which they are engaged, there are at times additional ways for securing the same results, namely (*a*) by paying lower wages, (*b*) by working their men longer hours, (*c*) by requiring a greater amount of work per hour from the men, (*d*) by giving them less expensive rations and quarters, in case employees are fed and quartered.

On the Panama Canal a contractor cannot anticipate profits from any of these sources. The work already done and in progress has fixed the wage scale, and a contractor would be unable to retain labor that might be turned over to him, nor could he secure additional men at less salary than already paid by the commission.

The government is now working foreign labor as many hours per day as is practicable in this climate, so the contractor could gain nothing more than the government has already acquired. So far as American labor is concerned, the eight-hour law is applicable, and so long as it remains in force it must be as binding on the contractor as on the government.

It is questioned whether he could get more work out of the laborers on the Isthmus than they now perform for the commission. This is a question dependent entirely upon the character of foremen employed, and he would have exactly the same class of men in this position, since most of the foremen now employed have previously been with contractors, and therefore have had their principal training on contract work. Moreover, the pace set by the laborers under the commission would fix the rate for the contractor.

Were all the work turned over to one contractor, or an association of contractors, the Commission would be obliged to maintain a supervisory force, and the feeding and quartering of these employees would determine the demands that the contractor's men would make upon him for accommodations. Moreover, a number of the dwellings that are now occupied by Commission employees would be turned over for occupancy by contractor's men, and any additional force would expect the same accommodations. Trouble would result, therefore, in case the contractor fed his employees on less expensive rations or quartered them less comfortably than the Commission; no saving could be made, and the Government would be obliged to foot the bills.

The Panama Canal work is naturally divided into—

(1) Excavation in the dry by steam shovel, including all of the Culebra division and part of the Chagres division. The construction of drainage and diversion channels would come under this heading.

(2) Excavation by dredges on the Colon and La Boca divisions and on part of the Chagres division.

(3) The construction of the dams.

(4) The construction of the new Panama Railroad.

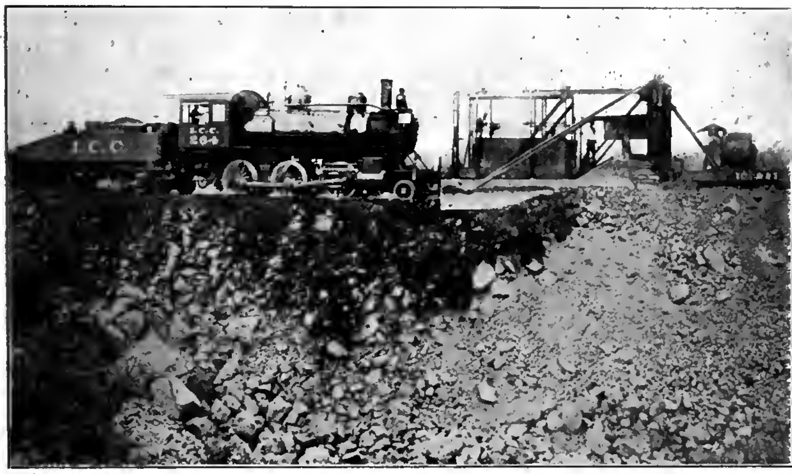
(5) The construction of the terminal facilities, harbor basins and breakwaters, if any.

(6) The construction of locks, gates and spillways.

The excavation of the Culebra division has already been undertaken by hired labor; practically all of the plant required for this work has been secured and paid for; a complete and thoroughly efficient organization for the same has been built up, and the Government is not hampered in any way in procuring the necessary labor for filling vacancies that arise. In the organization that has been perfected the higher grade men were formerly employed by contracting firms, and some of the number have been successful contractors themselves. The conduct of this work, therefore, has been along the lines usually followed by contractors. Under the circumstances no advantage would accrue to the United States by letting this piece of work to contractors, but on the contrary there would be not only additional expense, but a feeling of unrest and dissatisfaction engendered among the present employees materially affecting efficiency. Under existing conditions, therefore, contract work cannot be recommended for the Culebra division.

The Government has on hand, or under contract, all the dredges that will be needed for excavating such parts of the canal prism as can be most economically performed by this class of machinery. Experience in the United States has demonstrated that with such a plant in its possession no contractor or association of contractors can do the work as economically as can the Government. The Government agents are as familiar with this class of work as the contractors, and the necessary dredge crews can be obtained without difficulty. So far, therefore, as dredging is concerned, the Government should do the work and contracts for the same cannot be recommended.

The great problem in the construction of that portion of the canal included in the Culebra division is the disposal of the excavated material. In the main this has been disposed of at various localities favorably situated with regard to the cut. The systematic performance of the work and the necessity for additional material in completing other parts of the work have made it necessary to arrange for such a disposition in the future as will be most beneficial to the work in its entirety. The efficiency of the dams depends upon their having sufficient weight and tightness to impound the water without leakage and without danger to the stability of the structures. The weighty material, or rock, is to be furnished in each instance by material from the Culebra cut and the tightness is to be secured by the selection of suitable material to be obtained from the products of dredging. In other words the construction of the dams is so intimately connected, both with the excavation of the Culebra cut and the dredging, that if these two can be most economically and advantageously done by the Gov-



Spreading Material on the Corozal Dump.

Excavation on the Culebra Cut near Gold Hill.

ernment rather than by contract it naturally follows that the method adopted for the construction of the dams must be the same, namely, by hired labor under Government supervision and not by contract.

The survey of relocation for the Panama Railroad has been completed and it has been necessary to undertake the construction of the railroad in order to permit the removal of the present bed in the vicinity of Gatun, so that the construction of the dam at that point may be begun. The construction of the new line requires, among other things, about 1,600,000 cu. yd. of excavation and about 12,000,000 cu. yd. of embankments. The excess of embankments over excavation, about 10,000,000 cu. yd., is to be supplied largely, if not entirely, from material excavated from the canal prism, the embankments forming dumps for the material trains. Steps have already been taken for the development of dumps which will result in the construction of a part of the new roadbed at Miraflores, Pedro Miguel, Gamboa and Gatun, and plans have been prepared and proposals invited for a bridge across the Chagres at Gamboa. With excavation in the Culebra division to be done by hired labor under Government supervision, with the material therefrom to be used in the construction of the Panama Railroad, the intimate relation between the two necessitates the adoption of the same method of construction, namely, hired labor under Government supervision, in the consetruction of the new Panama Railroad.

The regulating works and spillways of the Gatun and La Boca dams are so dependent upon and intimately connected with the construction of the dams that whichever method is adopted for the latter must be made applicable to the regulating works and spillways, in order to avoid friction and difficulties that would result in case part were done by the Government and part by a contractor.

The Panama Railroad must be maintained and operated as a commercial line, and it must be utilized also for construction purposes in connection with the Culebra cut, the reconstruction of the railroad, the construction of the dams, and in addition it must transport all materials entering into the construction of the Pedro Miguel locks.

The difficulties that would result from a joint use of the Panama Railroad by a contractor and the Government at the Pedro Miguel locks disappear, however, for the locks at Gatun and La Boca, since both are accessible by water. Sand can be procured along the shores of the Pacific, and a suitable quality in sufficient quantity can also be obtained on the Atlantic shore of the Isthmus.

The success of the lock construction depends largely upon the quality of cement used, and there is no question that the Government should furnish all the cement. No contractor, or association of contractors, possesses the necessary plant for handling the enormous quantities of concrete required for these structures. Subsequent to the construction of the locks the contractors could have no further use for the machinery installed, even if the payment of freight for its return to the States were warranted. If the contractor furnishes the plant, the Government must pay for it in its entirety and in addition pay interest on the amount expended for its purchase. This plant can be procured more cheaply by the Government than by a contractor. As previously explained, if the Government furnishes the plant, the advantage of the contract method disappears. The contractor will have greater difficulty in securing the common labor needed than will the United States. The engineering force of the Government that has in the past few years been employed in the construction of such large quantities of concrete in various forms in the United States can be drawn upon to furnish the skilled personnel necessary for concrete work here. The acquaintance with competent men, for this class of work, is more extended on the part of the Government than on the part of the contractor.

These considerations lead to the conclusion that the locks can be more economically and advantageously constructed by the Government than by a contractor or association of contractors.

The gates and operating machinery can, it is believed, best be constructed by contract at the proper time.

The foregoing conclusions do not cover the proposed work on the Chagres division or the terminal facilities, harbor basins and breakwaters, as the surveys for the development of the amount of work and character of material involved in the Chagres division have not yet been completed, nor have the final plans for terminal facilities, etc., been finished.

No account has been taken of the question of sanitation, one very important to the successful prosecution and completion of work on the canal. Proper sanitation can be maintained more easily and satisfactorily with the Government in supreme control of the work than with a contractor, and this adds an additional argument in favor of the Government doing the work itself.

The relative advantages of the contract system versus hired labor under Government supervision in the construction of the Panama Canal are very different to-day from what they were two years ago, and were different then from what they were when the work was first undertaken. To one familiar with conditions on the Isthmus there can be no doubt at this stage of the work as to the advisability of continuing it by hired labor.

It is estimated that 80 per cent of the entire plant needed for the construction of the canal has been purchased or contracted for. Machine shops have been erected and equipped for making all needed repairs to the machinery now on hand or still required for the work. So far, therefore, as the plant and its care and repair are concerned, the Government is better equipped to carry on the work as advantageously and economically as any contractor.

Many thousand employees have been secured, and an effective working organization has been perfected, and the recruiting system put in operation is capable of furnishing more labor than can be advantageously used. The employees are well sheltered and, in general, well fed; the salaries paid are satisfactory and the work is progressing smoothly. A change from these favorable conditions in the method of prosecuting the work would disorganize all existing conditions and would undoubtedly increase the estimated cost and time of completing the canal.

The conclusion that the work can be done better, cheaper and more quickly by the Government has been reached only after free and full discussion by the various members of the Commission and the higher officials connected with the construction work, and after careful consideration of all sides of the proposition.

Labor, Quarters and Subsistence.—This department is charged with securing all skilled and unskilled labor and its assignment, according to the needs of the work. It is the custodian of all living quarters, allotting them to employees according to their standing as gauged by salary earned and in conformity with rules and regulations approved by the Commission.

It supplies furniture to quarters, delivers distilled water to residences, offices and shop, and is in direct charge of the delivery of all food supplies, including ice, bread and cold-storage articles from railroad stations or local commissaries to residences, hotels, messes and kitchens.

It polices the ground around camps and quarters, cleaning up waste and refuse material which is placed within reach of those charged with its final disposition. It also has charge of the lighting of the camps and of roads to and through them.

It operates the hotels, messes and kitchens for the accommodation of the employees of the different grades—the hotels for white Americans, the messes for Europeans, and the kitchens for the natives of the West Indies.

It keeps the service history of each individual employee in the general personnel record of which it is the custodian; issues by direction of the chairman all orders pertaining to leaves of absence, sick leave, resignations, discharges, promotions and reductions. It also authorizes the issuance of steamship transportation and special rates to which employees are entitled.

The skilled labor force is recruited in the United States. The skilled force on June 30, 1906, was approximately 2,500, and on June 30, 1907, actually 4,404. To increase this force 1,904 men and provide for the usual separations, due to sickness, resignations, etc., 3,038 men were brought from the United States during the year.

The unskilled force is brought from the West Indies and Europe. Recruiting agents are located in Barbadoes and Martinique, and a representative in Paris, France, to keep in touch with European labor conditions and with European emigration. On June 30, 1906, there were on the canal work 500 Europeans and 13,625 West Indians. June 30, 1907, there were 4,317 Europeans and 14,606 West Indians. To maintain this force of laborers, and also provide the Panama Railroad force of about 5,000 laborers, 6,899 Europeans and 10,947 West Indians were brought to the Isthmus—an average of nearly 1,500 men per month—to meet the demands of the work for common labor during the year.

At the close of the last fiscal year 1,129 houses were available for quartering employees of all classes, furnishing buildings for offices, hotels, messes, kitchens and storerooms. On June 30, 1907, 2,208 buildings were in use for the same purpose.

There are in operation 23 kitchens for the West Indian laborers, where a day's board is furnished for 30 cents and is made up of such food supplies as they are most accustomed to and prepared by cooks of their own country.

Zone Government.—The department of civil administration embraces the affairs of government of the Canal Zone, the courts, the office of the prosecuting attorney, and the divisions of revenues, posts, customs, lands, administration of estates, police, education, fire protection, and public works.

Governor Magoon left the Isthmus Sept. 25, 1906, when the duties of his office devolved upon the executive secretary until Nov. 17. The Executive order of Nov. 17, 1906, created the department of law and government under the general counsel, after which date governmental matters were handled in Washington by the general counsel through the executive secretary on the Isthmus. On April 2, 1907, an Executive order vested the authority of the chief executive of the Zone in the chairman of the Commission, and by order of the latter the duties were assigned to one of the Commissioners.

Under authority conferred upon the President by existing law to legislate for the Zone, the five municipalities into which the Zone was divided were abolished and administrative districts were created in their stead. The United States patent, trade-mark, and copyright laws were extended to the Zone; provisions were made for regulating insurance companies, for the registration of land titles, and the celebration of marriages. By the order of March 13, 1907, the Commission is authorized to enact, with the approval of the Secretary of War, ordinances relating to police, sanitation and taxation, and matters formerly regulated by municipal ordinances.

The Mechanical Plant of the Boston Herald.

By Howard S. Knowlton.

In the production of a modern daily newspaper time is so valuable that the use of machinery has almost entirely replaced the slow hand methods of publication formerly in vogue. The appearance of an extra edition on the streets a few minutes in advance of a competitor scores a commercial advantage which is made possible only by a mechanical equipment which eliminates so far as possible every doubling back in the production processes between the desk of the writer and the counters where the papers are delivered. The mechanical plant of the Boston "Herald," in its lately completed buildings, affords an interesting illustration of the dependence of such a newspaper upon the engineer in its regular and special output.

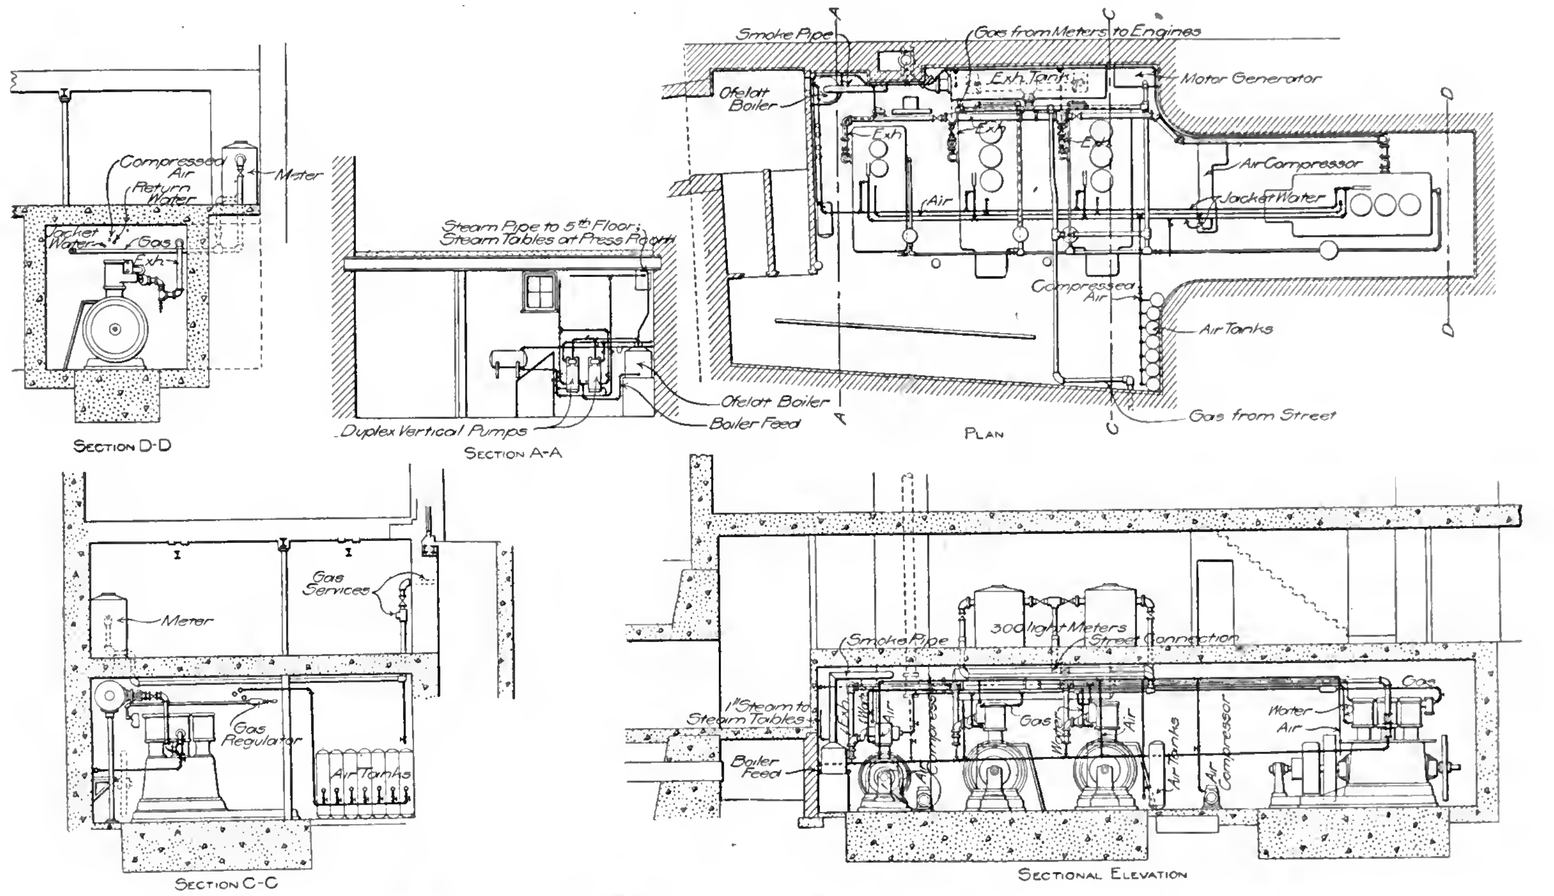
The main offices of the "Herald" are in a five-story building at 171 Tremont street. At the rear of the office or "Administration Building" is the "Mechanical Building," a five-story structure connected with the former by a tunnel and an overhead passageway. The entire mechanical plant, including the production building, the power installation, sub-basement of the administration building, heating equipment, machinery foundations, matrix and newspaper carriers and other apparatus, was designed by Mr. F. W. Dean, of Boston, Mass., mill architect and engineer.

The Administration Building houses a power plant in its sub-basement, the basement being used for the storage of supplies and paper rolls. The office of the mechanical superintendent, Mr. G. S. Ross, is also located in the basement, and a small repair shop is installed under the Tremont street sidewalk. On the street floor are located the counting room and advertising department, and on the upper floors are bookkeeping, auditing, special writing, executive and editorial departments.

The Mechanical Building basement is given up to stereotyping, a press room, a locker room and lavatory. On the street floor are the newsboys' section, the mailing and job-printing departments. The next floor is occupied by the circulation manager, art, engraving and color departments, the next by city and news editors, the reporting staff, department editors and library. The top floor is utilized by the composing room.

To make clearer the relations of the mechanical plant to the production process a brief outline of the order of events in the turning out of an item in printed form is given here. An entire page of 8 columns metropolitan size, including all display, may contain less than half a column set by actual hand labor. Motor-driven machinery is found at every step. As soon as an item has been written by a reporter, it is delivered to the news editor and then carried by an automatic conveyor to the copy-cutter's desk in the composing room, where it is divided into sections which are parcelled out among the operators of the composing machines. From the machines the sections are collected and a proof struck and read; after this the type is corrected and automatically forwarded to the make-up table, where it is inserted in its place in a full page of type. As soon as the form is locked up, it is shifted to a table on wheels, and rolled to a steam table, where an impression of the form, called a matrix, is made on specially prepared paper. In the old days the form left the composing room to be matrixed in the stereotyping room, but in the "Herald" plant the matrix alone is sent down to the stereotyping room between two belts running over opposed sets of pulleys. The form and matrix are subjected to a steam pressure of 80 lb. for 3 or 3½ minutes, which partly removes the moisture. Enough tables are provided to press all the matrices which can be molded in that time. The matrix is then dried for 15 seconds in a rotary gas roaster, and transferred to the stereotyping room in the basement, where a stereotype casting is made from the matrix in a casting box. The plate is then trimmed and routed by electrically-driven cutting tools and locked on the press, from which issues the folded and counted papers. The latter are delivered by a motor-driven conveying equipment to the mailing and sales departments. The operation of the casting boxes and the steam tables, the making-up of the forms and their transfer from point to point are the only hand processes employed from the time the paragraph is given to the compositor until it is in the stereotype plate. A plate may be locked on the press in less than 8 minutes after the form it reproduces is completed.

The power plant in the sub-basement of the Administration Building consists of four Westinghouse gas engines, each direct-connected to 230-volt direct-current generators. There are three 85-h.-p. 11 x 12-in., three-cylinder vertical engines, each driving a 55-kw. dynamo at 300 r.p.m., and one 9 x 11-in., 35-h.-p., two-cylinder engine driving a 25-kw. generator at 310 r.p.m. These outfits deliver current on the three-wire scheme of connections and are provided with balancing transformers. Richardson cylinder lubricators are used. The engines burn gas supplied from the mains of the Boston Consolidated Gas Co., which has a calorific value of about 550 B.t.u. per cubic foot. For starting the engines seven vertical air tanks working at 170 lb. are provided, with a single-acting compressor, chain-driven, by a 3½ h.-p. motor. These tanks discharge into a 1½-in. main with 1-in. branches to each engine.



Arrangement of Gas Engines and Piping in the Mechanical Building of the Herald.

Two gas connections from the street mains are provided, each being a 4-in. line. These are joined inside the plants and carried in a 4-in. line to the middle of a connection between two 300-light meters on the floor above. One meter is used as a spare. From the meters a 4-in. line delivers to the gas engines through 2-in. and 1½-in. branches, a gas regulator being provided on the supply side of each engine. The meters are by-passed with locked valve control for emergency use. The stereotype and composing departments are supplied from an independent street connection through a 3-in. line, and risers distribute this supply to the various floors. The exhaust pipes of the engines vary in size from 3½ to 4 in. and are brought together in an 8-in. connection which leads into a muffler tank in the engine room. From this tank the exhaust is carried in an 8-in. pipe to an outlet over the roof about 115 ft. above the grade of the sub-

basement floor. Each exhaust pipe is separately valved.

The engine-room also contains a 22-h.-p. boiler which supplies steam to the stereotyping beds and the matrix heaters. Water is sprayed into the exhaust pipe of each engine and into the exhaust main for cooling purposes, this water being taken from the jacket outlet pipes through a 3/8-in. line. The jacket supply comes from the city mains through a 3-in. pipe into the sub-basement, and is delivered to the engines through branches averaging 1½ in. in size. The discharged circulating water from the jackets is pumped around the building for use in lavatories.

Special provision was made in the plant for ignition. Each engine is provided with three dry cells and also with two storage battery cells, which are charged through a resistance from the 230-volt circuit at the switchboard. There is also a Westinghouse motor-generator set for ignition, consisting of a 1¼-kw., 110-volt dynamo driven by a 2.2-h.-p. motor. The engine room contains a switchboard 20 ft. long consisting of eight panels, with recording wattmeters, for each department, double-throw switches for each of the two sets of busbars installed on the rear of the board, ammeters, voltmeters and rheostats. Two of the panels are for generators, one is a totalizing panel with ammeter for the entire output, two are power panels, two are lighting panels, and one is a blank. Beside the general motor and lighting loads there are three electric elevators operated by the plant. Service is supplied to the manufacturing building through a reinforced concrete subway equipped with automatic sliding doors at each end.

The Herald buildings are heated by the steam heating plant of the Park Theatre through a 3½-in. underground pipe laid in a box of kyanized plank fastened together with copper nails. The pipe is covered with 85 per cent. magnesia, with a top dressing of Portland cement mortar. The various floors are heated by direct radiation. The returns from the steam heating system are carried back to the boilers through a 1-in. line.

The press room contains four Hoe sextuple presses and one Hoe color press. The floor is a terrazo pavement laid on 4 in. of Portland cement concrete. Each large Hoe press has direct connected to it a 50-h.-p. and a 4-h.-p. motor with Jenney control appliances. Five operations are provided on the push button boards which are located at several places on each press. The first starts the 4-h.-p. motor, turning the press at the slowest speed; the second button increases the speed and cuts in the 50-h.-p. motor, while the smaller motor automatically stops; the third button decreases the speed, the fourth is a bell signal button, and the fifth opens all circuits in emergency stopping. The starting boxes are motor-driven and automatically cut in resistance in case the power supply fails. The switches are mainly of the solenoid type, and seven-pole switches are provided to enable two presses to be run as one unit. The motors are installed in concrete pits below the floor, with trap door covers to enable them to be examined easily, and are compound wound to give the necessary starting torque. The total capacity of the plant is 375,000 eight-page papers an hour. The large double sextuple presses can each turn out a 96-page if necessary and can print one other color in addition to black. The color press is capable of printing seven colors at once, or black, and has a capacity of 75,000 eight-page papers per hour. The total capacity of the installation is 1,530 eight-page papers per hour per rated gas-engine horsepower in the generating plant.

Electric hoists are used in the press room to deliver the paper rolls to the presses, each roll weighing from 1,200 to 1,400 lb. and yielding from 9,000 to 11,000 papers. Rolls are brought into the press room from the storeroom by a traveling, hand-operated hoist, and a narrow-gauge track also connects the two rooms.

In the stereotype room the principal machine equipment is motor-driven. This includes a matrix roaster operated by a ½-h.-p. motor; three tail cutters, each driven by a 5-h.-p motor; two curved shavers, each driven by a 2-h.-p. motor; one flat shaver, driven by a 3-h.-p. Lundell motor; a jig saw and drill run by a 1-h.-p. Sprague motor; a flat router driven by a 1½-h.-p. motor; a bending machine, operated by a 2-h.-p. motor; two curved routers, driven each by a 2-h.-p. motor; and a saw and beveler run by a 1-h.-p. motor. Sump-drained water is pumped to the sewer by a 3-h.-p. Knowles triplex pump driven by a General Electric motor.

The machine shop beneath one of the sidewalks contains a speed lathe back-geared to a ½-h.-p. motor; a circular saw driven by a 5-h.-p. motor; an engine lathe run by a 1-h.-p. motor, back-geared, and an emery grinder driven by a ½-h.-p. motor. All motors are 230-volt Jenney machines unless otherwise mentioned.

In the composing room are 27 linotype machines, each direct-driven by a ¼-h.-p., 110-volt motor, with two sets of fields on each pole piece. These outfits are gear-driven and can be run at 70, 72 or 74 r.p.m. Some of the machines are provided with eight different faces of type, and average setting 8,000 ems per hour, with a maximum of 9,000. They have about three times the capacity of the earlier linotypes, being equipped with interchangeable magazines of type matrices from 5½ point to 12 point. Ten seconds suffices to enable the operator to shift from one magazine to the other. The act of taking his seat on the part of the operator starts the corresponding linotype motor and throws the incandescent lamp over the keyboard into circuit.

The copy carrier in the composing room is driven by a ½-h.-p. motor, and three copy carriers serving the proofreaders' desks are each operated by a ½-h.-p. Holtzer-Cabot motor. There are two matrix rollers, each run by a 3-h.-p. motor. The matrix endless belt conveyor to the basement is driven by a 2-h.-p. motor; a small lathe for linotype work is run by a ⅔-h.-p. motor, and a metal saw by a 1-h.-p. motor. Cuts are handled between the basement and the upper floors by a push-button elevator which automatically stops at any predetermined floor.

The engraving room employs two 220-volt arc lamps in series, taking 8 amperes, for photographic reproductions. There are also two powdering machines and two etching machines, each driven by a 3-h.-p. motor. A saw and trimmer is run by a 2-h.-p. motor and two flat routing machines, making 20,000 r.p.m, are each operated by a 1¼-h.-p. motor. In the mailing room four conveyors are back-gear-driven by 2-h.-p. motors, and in the job printing room are two job presses run by a ¼ and a ⅓ h.-p. motor and a ⅓-h.-p. motor-driven addressing machine. In its use of direct connected motors on separate machines and gas-engine generators supplied from city mains the Boston Herald plant is of peculiar interest to persons watching the extension of power into the field of newspaper production. It is to be hoped that the economy of the plant will be published at some future time by those responsible for its installation and operation.

Independent Fire Protection for its yards and buildings at Pittsburg and Altoona has been secured by the Pennsylvania R. R. by equipping its switch engines in those yards with fire pumps and hose. A system of whistle signals indicates the location of the fire and the engine crews are trained in the use of their fire-fighting apparatus. At a recent fire nine engines were at the fire within seven minutes after the alarm.

Some Disputed Questions concerning Steel Rails.

A discussion of some of the disputed questions regarding steel rails was recently presented by Mr. Franklin E. Abbott, of the Lackawanna Steel Co., in a paper before the Central Railway Club. The first portion of this paper related to the general methods of making rails, from the ore to the finished product, and need not be reviewed here. The discussion of the controversial questions may be condensed as follows:

Composition.—Chemical analyses of average Bessemer rail steel as made at present for heavy rails run about as follows: Carbon, 0.50 per cent.; phosphorus, 0.10; sulphur, 0.08; silicon, 0.12; manganese, 1.00; iron, 98.20.

The quantity of carbon can be controlled by the grade of spiegel used. The makers and users of rails are not exactly agreed as to what the limits in carbon should be. When a 70-lb. rail was regarded as a heavy section, carbon ran from 0.35 to 0.40, but when the weights of rails reached 100 lb. per yard, 0.60 per cent. carbon was called for, and in some cases the upper limit was fixed at 0.65 per cent. The higher carbon steel, 0.55 to 0.65 per cent., was also specified for lighter rails such as 80-lb. and 85-lb. The 80-lb. rail was an increase in weight of only about 14 per cent. over the 70-lb., but 0.58 per cent. carbon often called for in this weight rail was an increase of fully 45 per cent. of this element over the lighter section.

The reason for raising the carbon was to get more elasticity and better wear, which in a degree was obtained, but with it came more failures from breakage. It was then specified that phosphorus should be lowered about 0.015 per cent., making the limit not to exceed 0.085 per cent. This proposition seemed entirely consistent from a metallurgical and theoretical standpoint, but practically it cannot be obtained because of the ore conditions.

It is estimated that the available 0.085 phosphorus Bessemer ores in the United States are relatively small. If all the rail mills in this country were to undertake to fill, from American ores, the annual requirement of about 3,000,000 tons under 0.085 phosphorus specifications for Bessemer rail steel, that grade ore would be exhausted before provisions could be made to meet the yearly demand for rails made by any other process.

If open hearth steel is to succeed Bessemer, it will take a term of years and the expenditure of an enormous sum of money to build furnaces enough to provide the steel needed for rails alone. Before this could be accomplished it is more than probable that the 0.085 phosphorus Bessemer ores would run out, and with an inadequate production of open hearth steel, the railroads would have to either get along with a short supply, or import the tonnage lacking.

To avoid this apparent short cut to the end of good quality Bessemer rail steel, the makers insist that the phosporous limit shall be left as it has been for a number of years past, at 0.10 per cent., and a somewhat modified carbon content be used. It is entirely practicable to use enough carbon with 0.10 per cent. phosphorous ores to make perfectly sound, safe and serviceable Bessemer steel, and with that limit accepted, the manufacturers will be able to produce good quality Bessemer steel rails for many years to come.

The wear of the heavier section rails has not been all that the users expected, even with the proportionally higher carbon, and they are loath to make any recession in this hardening element, fearing that by so doing, there will be still greater loss from rapid wear. But the question

of safety must have first consideration, and neither the makers nor users of rails will be justified in adding hardening properties, to get increased service, that will place the material anywhere near the danger line of breakage.

There is a strong probability, however, that harder steel may be used if the shape of the rails is changed. How this may be brought about will be considered further on.

The next element in order in the steel composition is sulphur. This is of little consequence to the user of rails. Its effect is to make hot steel "hot short" and liable to pull apart, making flaws on the surface of rolled shapes. A limit of 0.10 per cent. can be handled very well, but it is always to the interest of the manufacturer that it should be lower.

Silicon has a quieting influence in molten steel when it is settling and cooling in the molds and makes it dense when cold. A limit of 0.20 per cent. is generally stated in specifications.

The quantity of manganese in rail steel will run from 0.80 to 1.10 per cent. Its effect is to make the hot steel tougher, overcoming some of the bad effects of sulphur, and thereby better adapted to rolling. It also makes the steel harder and better for wear, but if the quantity exceeds very much the upper limit noted it is liable to lead to brittleness.

Discard.—Another clause in standard rail specifications that is a source of some contention between makers and buyers of rails, reads as follows: "Sufficient material shall be discarded from the top of the ingot to insure sound rails." Under that agreement the buyers of rails can get, and do get, perfectly sound steel. The interpretation of the term sound in this case means entirely free from piping or spongy metal. Sound steel rails of standard composition are perfectly safe to use, and when the railroad companies have exercised their rights given by the specifications in their inspection at the mills, while rails are being made, and thereby obtained sound rails, they have done their whole duty toward themselves and their patrons, whose safety and welfare they are bound to protect.

But the question arises why do the railroad people, or so many of them, come up with a demand for more discard, in some instances asking for a fixed amount not less than 25 per cent. of the whole ingot. It is not a question of safety, but one of service. Under present specification, the rail mills must deliver to the railroads safe rails, that is to say, free from the danger that comes from piping. They are obtained by shearing from the top of the ingot sufficient material to insure sound steel. Then what would the railroads gain by doubling the discard if 25 per cent. should amount to that increase? They might get a larger percentage of better wearing rails than they now receive, but the gain would be purely in an economical sense, and not in one of safety. Therefore, the question of more discard after enough has been made to insure sound and safe rails is purely a commercial one, and can be disposed of between the railroads and the steel companies without giving cause for any anxiety on part of the traveling public.

Drop Test.—In addition to the discard sheared off the bloom, a crop end is cut off the long rail when it is finished, taken from the end toward the top of the ingot. This is about 6 ft. long and is used for a drop test. One such test piece is taken from every blow of steel. It is placed on steel wedge-shaped bearings, 3 to 4 ft. apart, and struck with a 2,000-lb. weight, falling 15 ft. to 22 ft., depending on size of rail tested. If the test piece breaks under the drop, all rails from blow represented by that test must be discarded.

This is the most satisfactory proof of the quality and strength of the rails that can be used. If the steel is brittle, it will be discovered by the character of the break. If piped, that condition can be seen in the fracture and will determine at once whether or not sufficient discard has been made at the shears to insure sound steel. If the metal is very soft, it will show by excessive deflection. It can be seen, therefore, that the drop test throws out many safeguards against passing defective or inferior material.

Section.—Another difficult part in the making of steel rails is in the section. In the first place, it has to be very close to mathematically correct. A finished rail is a simple looking thing when it is made, but there are a good many dimensions besides the length to take into account in getting it through the mill in proper shape. The ordinary rail section is made up of 17 separate and distinct dimensions, 9 of which are duplicated, making a total of 26 to be kept in order and held in their respective places when the rolling is under way.

The section is continually checked during the process of rolling. This is done by a steel template made to exact dimensions of one-half the rail divided by its vertical axes. The rail section is tested on both sides by the same template, and therefore each half is as nearly like the other as possible to make it. In checking rail sections, the inspector has to guard against either over or under size and always strives to maintain perfect symmetry. In this detail, a difference of 1-64-in. cannot be ignored and the wonder is how such ponderous and coarse machinery as constitutes a rolling mill can be so nicely adjusted as to accomplish such fine results. It is not easily done, and it should be remembered that the turning or shaping of rolls and the manipulation of steel through them when rolling is under way, is the most intricate part of the rail-making process.

One of the leading advantages to the manufacturer in the Am. Soc. C. E. sections is in the distribution of metal in its different members. In the head there is 42 per cent.; in the web, 21 per cent., and in the base, 37 per cent. There is but five points difference between head and base, and these are so much closer than many of the sections the mills were formerly required to make that they gave the Am. Soc. C. E. sections a cordial welcome and have always tried to further their use.

At the time these patterns were introduced an 80-lb. rail was regarded as a heavy section, and some engineers even doubted whether one so heavy could be used economically. The designers, however, evidently expected railroad track to grow, for they provided for 5 lb. per yard increase in weight till 100 lb. was reached, and then designed a 110-lb. pattern, apparently for a good measure.

Shrinkage.—The period during which the 80-lb. rail was regarded as heavy was not of long duration, for the railroad soon took on 85-lb. and 90-lb. sections and during the past few years a very considerable tonnage of 100-lb. rails have been made. The 90-lb. rail was an increase of about 12½ per cent. and the 100-lb. about 25 per cent. over the 80-lb. The users of rails naturally looked for a proportionate gain in wear for the additional steel bought. But this did not always obtain and led to the criticism that they were not properly worked; that they were rolled too fast and finished too hot. An effort was then made to incorporate in standard specifications what was called a "shrinkage clause." By this is meant that the rails when they reach the hot saw shall be at such reduced temperature that only a certain number of inches and fractions of an inch shall be allowed for the rail to contract in length from the temperature at the sawing down to 70. It was expected that if the mills could comply with this, the steel would come through the finishing passes at a lower temperature, and the colder rolled steel would give better wear.

It would be perfectly reasonable to look for those results from such conditions. But the difficulty of incorporating a shrinkage clause in general specifications and making it operative was found in the fact that rails cannot be brought to the hot saws at the same temperature in every mill. There are no two in which the shrinkage could be kept exactly alike, therefore, any fixed allowance in a general specification could not be made applicable in all places. The opposition to a definite shrinkage clause in specifications is raised on account of the insurmountable difficulties encountered in attempting to fix a temperature at which the finishing work shall be done in unbalanced sections.

As already stated, the Am. Soc. C. E. section, or any other tee-rail thus far made, has greater percentage of metal in the head than in the base. The head is in a mass with less radiating surface than the base. The base is not only smaller, but thinner, besides having a greater radiating surface. It can, therefore, be readily understood why there is considerable difference in temperature between head and base, when the rail goes through the finishing passes. The obect of a shrinkage clause was to improve the rail head by finishing at a lower temperature, but in an unbalanced section the base is likely to get too cold to work, or so hard as to cause damage of cracking the rolls, while the head may still be hot enough to admit of some reductions.

Cambering.—Cambering of the rails is made necessary to counteract the warping that takes place in cooling. The warping is due mainly to the shape of the section, and the rail is rarely perfectly straight when cold. Whatever warp or crook that may be left in must be taken out by cold straightening. This is done in a press under a slow-motion plunger by applying pressure on the rail centrally between bearings for 42 in. apart. The arrangement of this press has lately become part of a general specification, and for that reason should receive some notice in this connection.

It is pretty generally conceded by both rail makers and users that the strain and torture that rails have to endure in cold straightening are the most severe and most objectionable work in the whole manufacturing and finishing process. The impossibility of taking a bend or kink out of a rail without straining it beyond its sectional elastic limit makes the necessity of setting up internal stresses, working at cross purposes with the normally cold tension of the steel, unavoidable. To what extent these may be harmful to the rail after it is put into service cannot be definitely determined, but it is only reasonable to infer that they have some effect. The remaining work in finishing after the straightening is done consists of drilling, chipping, filing, etc., all simple mechanical or hand operations not likely to cause any injury.

Rail Usage.—It is not an uncommon occurrence for a panel of rails in first-class track to carry a load upward of 200 tons over its entire length in half a second of time or less. This enormous weight coming onto the rails in such a short interval causes a shock almost equal to a hammer blow. During this short space of time every foot of the rail throughout its entire section is subjected to alternating tension, compression and torsion and the head to crushing and abrasion. There is not a piece of steel made for any structure whatever that has to withstand such severe treatment as that imposed on a rail.

The users contend that rails fail because of defective material or shortcomings on the part of the manufacturers in the process of making. The manufacturers claim that the users do not specify the grade of steel, nor weight of rail

best suited to their various traffic and climatic conditions; that maintenance of way is not always what it should be; that bad order rolling stock and irregular operations of motive power are responsible for a greater part of rail destruction.

There are nine or ten classifications of rail failures, but more than 95 per cent. can be placed under less than half that number. The remainder are of rare occurrence and little account.

Piping.—First are the head failures which are the result of piping, or caused by the metal actually shearing off at the sides, usually about on line with one side of the web. Piping is a defect adherent in the steel, and the whole responsibility for this rests with the manufacturing. Every practicable precaution is constantly exercised against such material going into rails, but in spite of all that can be done, some with this defect get into use.

To reconcile the fact that piped rails are found, with the claim made that sufficient material is discarded from top of ingot to insure sound steel, it will be necessary to explain that piping in ingots is not confined entirely to the top, but does at times occur all the way down through the center, although it may not be continuous. Such piping will not show at the ends nor give any surface indication of its existence when rails are finished. It ordinarily develops under traffic and then appears by the head flattening or spreading out. Only a very small percentage of piped rails give out suddenly, or without first showing this condition on the head surface and affording time for removal before harm is done. Some railroad engineers say that they do not regard rails showing slight piping as particularly dangerous, and often allow them to remain in use after their condition is known. It is the opinion of the writer, however, that rails which show piping in any degree are wholly unfit for any main line track, and never should be allowed to remain in service.

Split and Crushed Heads.—Split head failures occur mainly on high curvature track and on the inside or low rail of the curves. These are apparently due to irregular bearings of worn wheels and cross strains thrust into the rail head by tread of false flanges, on extreme outside corner. This leverage brings the maximum stress at top of rail heads, about on line with side of web, where such breaks are generally found.

Another type of failures resulting from rail and track conditions, similar to that just mentioned, is in the metal flowing or crushing off the corners of the head. The inside wheel of a train passing around a curve, not only rolls but slips over the rail, and when the track gauge is wide, it slides across the head, causing the metal to flow or shell off in long, ragged strips. This kind of giving out is sharply criticised and often causes considerably anxiety among railroad engineers, on account of the seeming weakness. Such rails have an extremely bad appearance and ordinarily show excessive wear, but they are not unsafe to run over and may be retained in service without any unusual risk, until completely worn out.

Breakage.—By far the greatest number of failed rails are due to breakage, that is to say, complete fracture of the entire section. These are not only most numerous, but most dangerous of any in the whole classification. There are three distinctive characters—breaks that may be described and in a measure accounted for as follows:

First: The square break in which the fracture is almost at right angle with the axes of the rail and is often quite as regular as a saw cut. The fractured surface may be fine, close, homogeneous texture, but the shape of the break indicates excessive hardening properties in the metal, bringing it close to the point of brittleness, hence, easily ruptured by shock and therefore poor quality steel for rails.

Second: The angular, or shearing break, which generally passes through the section at an angle of 45 deg. or less, with longitudinal axes. This shows that the rail stood a deflection and elongated before breaking, indicating ductility and a perfectly good grade of steel, but probably broken by severe shock or excessive overloading.

Third: The base break. There are more failed rails from breaks of this character than from any other cause. It is found in varying degrees on all railroads and in rails from all mills. The principal peculiarity of this break is that it starts at the center of the rail base, directly under the web, and develops longitudinally, extending from 6 in. to 18 in. and will then run out to the edge of the flange, resulting in a "half moon," or flange break, and in many cases also extending upward through the rail, causing a complete fracture of the entire section.

As a girder the rail seems to be theoretically and practically correct in shape. But it has always been shown that the roadbed and ties, which constitute the rail foundation, are unstable, and yielding and that the solidity of tie bearings are at times widely variable, making the bearing surface of the whole rail base quite irregular and uneven. These conditions are generally worse when the roadbed is frozen. In consequence, the base member of the rail section has to sustain excessive compressive strains at the higher or more solid points of its bearings.

The rail base in compression will, on account of its shape, buckle, drawing the edges of the flanges upward, thereby causing a cross strain with maximum tension at the center directly under the web, and this is the point where base break begins. Therefore, it appears that the base member of the girder tee-rail as now made is deficient when subjected to compressive strain and for that reason fails.

Improvements.—Just at the present time we seem to have reached one of the transition periods in the manufacture and use of steel rails, in which the rails as made do not quite balance with the railroad traffic as it exists. A correction must be found.

The manufacturer is held by certain limitations in character of raw materials that prevent meeting all that might be desirable in changes of composition of steel for the improvements needed. The railroads cannot recede in the matter of heavy loads and fast trains, and must by some means get rails that will hold up to changed conditions as they are.

It is believed that a remedy can be obtained by the co-operation of the manufacturers and railroads in bringing out a revised rail section. This will embody certain cardinal principles and be designed with a view to overcoming detail deficiencies found in the present sections, at the same time be a better shape to roll. It is suggested that, in comparison with the Am. Soc. C. E. sections, both head and base shall be reenforced, and that the distribution of metal be nearly balanced, making that in the base equal or slightly greater than in the head. It is also proposed that width of base shall be less than height of rail, which will admit of forming thicker flanges.

The advantages of a balanced section, with comparatively thick base are:

First, lower temperature of the whole section at the final pass, hence a colder finish of the rail head, giving denser and better wearing material.

Traveling Derrick for Trenching for 15-Foot Sewer, Borough of Queens.

Second, less cambering and better hot straightening, reducing as much as possible the objectionable cold straightening work.

Third, a reinforced head to provide against splits and other head failures.

Fourth, a reinforced base to overcome the weakness that seems so prominent in present pattern rails.

It is expected, also, that with this pattern rail the higher carbon steel from grades of ores now available may be made with safety, and by longer service prove a benefit to the railroads. The balanced sections can be made easily and economically, and will thereby contribute to the interests of the manufacturer.

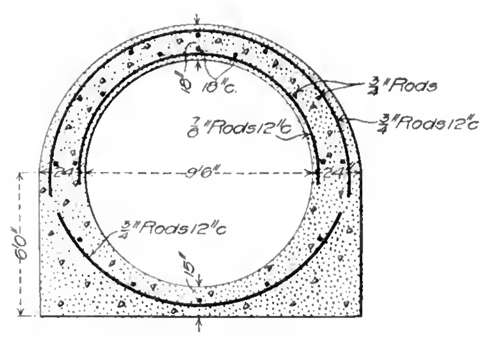
A STEEL STACK over 100 ft. high and weighing 22 tons was erected recently in a single piece at the works of Messrs. Brown, Bayley & Co., Sheffield, England. The stack is 10 ft. in diameter at the base and 7 ft. at the top and serves a 20-ton open-hearth furnace. It has no stays or braces but the brick base is founded 20 ft. below ground, and the iron base plate is anchored to the brickwork by eight 16-ft. bolts. The stack was raised in slings by a high derrick and the base was then guided into the flanged base plate to which it is securely bolted.

A Large Reinforced Concrete Sewer in the Borough of Queens, New York City.

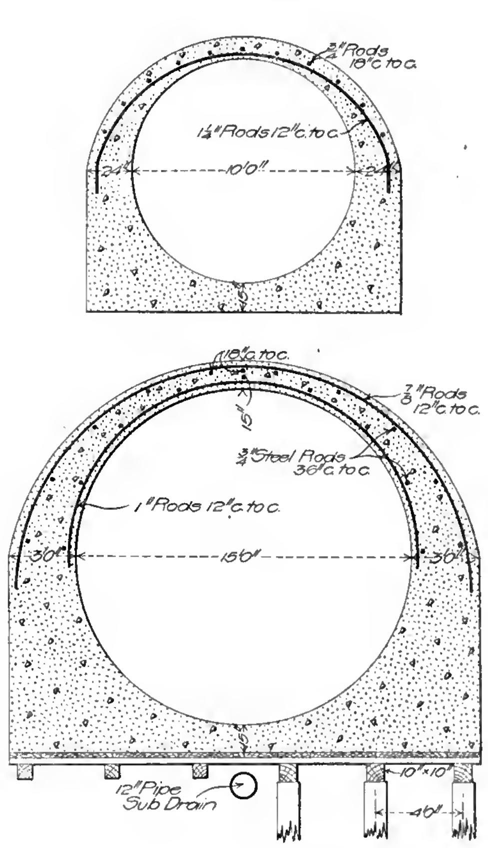
A circular reinforced concrete trunk sewer, varying from 2½ to 15 ft. in diameter, is now being built in Myrtle and St. Nicholas avenues, in the Borough of Queens, New York City, to serve a 2,150-acre area in the southwestern section of that borough. This work is part of a general sewerage system planned for the southwestern part of the Borough of Queens. This borough, while the largest of the five that make up Greater New York City, covering an area of 127 square miles, is, at the same time, the most sparsely populated, having less than 250,000 inhabitants, collected in scattering settlements. The water front totals 116 miles, but the length along which sewage may be discharged is limited to 27 miles by laws prohibiting the discharge of crude sewage into Flushing and Jamaica bays and Newtown creek. This complicates and makes difficult the problem of sewerage, and in the case of the system mentioned necessitates carrying the flow to the East River, through a 16-ft. continuation in the Borough of Brooklyn. The work in Brooklyn has not yet been put under construction.

The approximate quantities of work included in this contract in Queens are: 1,355 ft. of 15-ft. sewer; 690 ft. of 11¼-ft.; 1,335 ft. of 10-ft.; 2,070 ft. of 9½-ft.; 2,000 ft. of 5 and 5½ ft., and 2,190 ft. of smaller sizes. The total length under contract, including 255 ft. of 24-in. pipe sewer, is 9,845 ft., and the total fall is 46.73 ft. The grades are: 0.002315 in the 15-ft. section; 0.00296 in the 11¼-ft. section; 0.00442 and 0.00412 in the 10-ft. and 9½-ft. sections; and 0.0052 to 0.00425 in the smaller sections. The cover over the larger sections is fairly uniform, being in general about 15 ft. At one point, however, the cover over the 9½-ft. sewer is 22 ft. deep. The smaller sizes, from 5½ ft. down, have, in general, 8 to 10 ft. of cover. The excavation is mainly in sand or sandy soil, and practically no water has been encountered.

The sewer now under construction in the Borough of Queens has the same general sectional form in all sizes, the outer sides of the invert being tangent to the extrados of the arch at its springing line and carried down vertically to meet the plane of the foundation. The concrete below the springing line is a 1:2:4 mixture of Atlas Portland cement, sand and bank gravel, having a maximum size of 1½ in., and is without reinforcement. Above the springing line all sizes are reinforced laterally and longitudinally with "new style" Johnson corrugated bars. The concrete of the arch is the same as that below the springing line, except that the stones larger than ¾ in. are screened out. The sections of sewer smaller than 4½ ft. in diameter have ¾-in. lateral rods, 12 in. on centers, and three lines of ¾-in. longitudinal rods over the crown and haunches; the arch in all these sections is 6 in. thick at the crown and 6 to 9 in. thick at the springing line; and the lateral rods are equidistant at all points from the intrados of the arch. The sizes from 4½ to 5½ ft. in diameter, inclusive, have ¾-in. lateral rods, 12 in. on centers, and ¾-in. longitudinal rods, 18 in. on centers, but the lateral rods are placed on a three-centered curve, being near the intrados at the crown and near the extrados at the springing line. The longitudinal rods rest directly on the lateral rods. The arch ring in these sections varies from 6 to 8 in. thick at the crown and from 12 to 15 in. thick at the springing line. The 9½ and 10 ft. sections are much like those just described. The lateral reinforcement is three-centered, and the thickness at the crown and springing line is 12 and 24 in., respectively, for both sizes. The 10-ft. section is shown in the accompanying illustration. The 11¼ and 15 ft. sizes have two series of both lateral and longitudinal rods, one series being parallel to the intrados and the other parallel to the extrados of the arch ring, as shown in an accompanying illustration of the 15-ft. section, on which the important dimensions are indicated. The arch ring of the 11¼-ft. section is 12 and 27 in. thick at the crown and springing line respectively, and the reinforcement is like that of the 15-ft. section, except that the outside lateral rods are ¾ in. instead of ⅞ in.



Section under Tracks.



Sections of Large Sewer, Borough of Queens.

In designing the larger sizes it was assumed that the covering material, which is in many places clean sand, would, when saturated with water, transmit live loads very readily, and the sections are accordingly liberal. Moreover, the magnitude and permanency of the work warranted no doubtful economy of material, and the minimum thickness of protective covering of concrete over the reinforcing rod is accordingly in general about 2½ in. Pile foundations of the form indicated in the illustration are specified, to be used where required, but the excavation so far has been in good, dry, sandy soil, and no piles have been necessary.

The tracks of the Long Island R. R. cross the sewer over the 9½-ft. section, necessitating extra heavy construction for a distance of about 70 ft. Here the thickness of the arch ring at the crown and springing line is increased to 18 and 24 in., respectively, and the ring is reinforced with two series of lateral and longitudinal rods, one parallel to the extrados and the other parallel to the intrados, as shown in an accompanying illustration. A third series of lateral and longitudinal rods placed parallel to the surface of the invert reinforces the section below the springing line.

Along the line of the main sewer several junctions with tributary sewers are required. Of these, the one at Myrtle and Cyress avenues, where a 7-ft. sewer enters the 11¼-ft. section, is typical, and illustrations of it are given. The drawings of this intersection also show a reducer from 11¼ to 10 ft. just above the junction point.

Manholes are provided throughout the length of the sewer at intervals which do not in general exceed 250 ft. On the sections larger than 5 ft. the manholes will be placed at one side of the axis of the sewer, so that the vertical axis of the manholes will be about tangent to the barrel of the sewer. Center manholes on sewers as large as these make it difficult and dangerous for workmen to enter the sewers. The arrangement adopted will in a great measure remove this difficulty. The bottom of the manhole is usually at or a little below the springing line of the arch, and steps are provided leading down the side of the invert to the bottom. Up to a point about level with the crown of the arch ring the manhole is built of concrete reinforced with ¾-in. rods, which are bent into the arch ring wherever possible, as indicated in an accompanying illustration. Above the concrete the manhole is carried up to the cast-iron cover with brick work in the usual manner. A double-track street car line, which traverses the part of Myrtle avenue occupied bya section of the sewer 10 ft. and less in diameter, has influenced the position of the manholes somewhat, but they are placed either between the rails or outside the tracks, as the case requires.

The sections of the sewer 5½ ft. or less in diameter are built without the use of much mechanical equipment. Two-inch hemlock planks, 6 to 8 in. wide, are carefully driven to serve as sheeting and as boxing for the vertical walls below the springing line. The excavation is carried on with pick and shovel, the spoil being hoisted and delivered along one side of the trench in small buckets by a portable horse-power derrick mounted on a heavy four-wheel truck. The street car track, which is operated as a single track line where the work is in progress, is shifted over to the side of the trench not occupied by the spoil bank, and it has been possible to maintain the operation of cars constantly. Sand, cement and gravel are stored in convenient piles in vacant lots beyond the street car track and are delivered to the work in wheelbarrows. The concrete is hand mixed on a plank platform spanning the trench.

In building the smaller sections a slab of concrete is first laid on the bottom of the trench, its top surface being kept a little below the grade line of the finished invert. A narrow strip along the center of the top of this slab is then built up carefully to the grade line, and the cradle forms are rested on it, being braced from the sides with wooden struts against the sheeting, and internally with rods and struts supplied with turnbuckles and screws. The concrete is then poured up to the level of the springing line. Before it has set the ends of the lateral rods of the arch ring are thrust into it at the proper point, the weight of the rods being carried by a ridge pole previously fixed at the proper height. The placing of the concrete of the arch ring is carried on in the usual manner. Sheet-steel forms, made by the Blaw Collapsible Steel Centering Co., are used for all sizes of the sewer.

On the larger sizes of the sewer the excavation is also carried on by pick and shovel, but more elaborate equipment is required to hoist the spoil and deliver it as back-fill. In Myrtle avenue, near its intersection with Cypress avenue, the section of 10-ft. sewer is now being built; here the cover

is about 14 ft. The sides of the trench are retained, as in the smaller sizes of sewer, with narrow 2-in. hemlock sheeting, driven by hand in 16-ft. lengths and carefully supported by waling pieces and struts. Here again the sheeting serves as boxing for the vertical outside walls of the invert.

The spoil is shoveled into 1-yd. Haywood buckets, which are hoisted by two stiff-leg derricks, with 25-ft. booms, and masts short enough to clear the overhead trolley construction above the street. These derricks, with their hoisting engines and boilers, made by National Hoisting Engine Co., are mounted on a large platform traveler, which spans the trench, with three wheels on each side running on heavy railroad rails. These rails are laid on 6 x 8-in. timbers, laid across the trench about 3 ft. on centers and extending far enough beyond the sheeting to secure a good bearing.

The derrick mounted on the front end of the traveler handles the top surplus spoil not required for back-filling. This material is delivered to Troy dump wagons and hauled away, to be used in filling neighboring lowlands. The derrick on the rear end of the traveler handles the back-filling material, which is delivered to 1-yd. Koppel cars, operated by hand on track laid on the 6 x 8-in. timbers spanning the trench, which have been before referred to. These timbers are left in place behind, as the traveler proceeds, to carry the narrow-gauge track and are taken up as the back-filling progresses.

At Cypress avenue a street car line crosses Myrtle avenue, and when the traveler was on one side and the unfilled trench on the other side of this car line it was necessary to run the dump cars across it. This was accomplished by means of a turn-table of heavy bar-iron rails, arranged so that when a street car passed the turn-table could be turned, with its axis parallel to the car track, so that the turn-table rails would clear the car wheels. The car track was supported over the trench by lines of timber stringers.

The order of procedure in constructing the larger sizes of the sewer is much the same as has been described for the smaller sizes. The bottom slab is laid first and brought up to the grade line of the invert along its center, to carry the cradle forms, which are braced both from the sides of the trench and internally, as shown in the accompanying illustration. Before the placing of concrete is begun the cradle and arch forms are carefully trued up under the direction of an inspector. Wooden pegs are inserted in the key-holes at the free end of the steel forms, to hold the wooden bulkhead in place. The turn-buckles and screws are covered with cloth or paper to prevent their becoming fouled with concrete.

The concrete for the 10-ft. section is mixed in a 1-yd. Smith machine, mounted on a low truck, which is moved alongside the trench as the work progresses. The mixer delivers through a short chute into a small hopper, which rests on horizontal timbers, laid parallel to the axis of the sewer on the series of transverse sheeting struts second from the surface of the ground. From the bottom of this hopper a 10-in. sheet-iron pipe leads down to a point a few feet above the crown of the arch ring. Here open chutes are provided, which lead the concrete to one side or the other, as required. The concrete is mixed wet and exerts a heavy pressure on the forms, which have to be braced very securely. In the larger sizes of the sewer the curved lateral rods are not put in place until the arch ring is about to be constructed. To provide for their support, holes are formed in the top of the sides of the invert while the concrete is still green, into which the rods are securely grouted later.

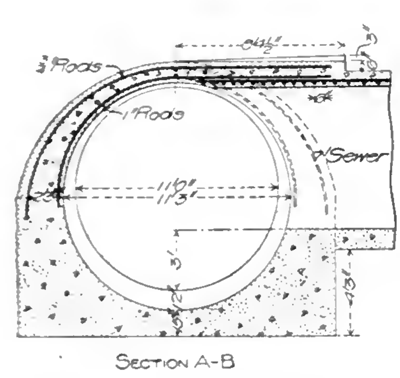
The lateral rods are bent at very little expense on the work by unskilled laborers. For this work a heavy plank platform is provided on which are nailed sticks 3 or 4 in. square and about 2 ft. long, placed radially so that their outer ends around which the bars are bent form a horseshoe-shaped curve. This curve, which is, of course, quite different from the curve of permanent set which the rods take, had to be determined by experiment. A separate series of blocks is necessary for each size of sewer but two or three curves can be formed on one platform by imposing one series of blocks upon another.

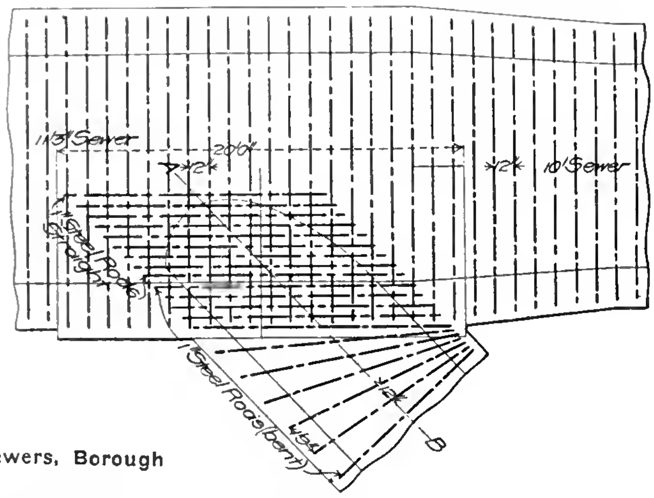
In St. Nicholas avenue, where the 15-ft. section is under construction, the same general methods of excavation and placing of concrete have been used as have already been described. Here, however, only one derrick is mounted on the traveler platform. It is of the stiff-leg type and is operated by a National hoisting outfit. The boom is 35 ft. long. A blacksmith's equipment is carried on the traveler platform where picks are sharpened and repair work is done with minimum delay.

A large part of the excavated material in St. Nicholas avenue is sand, which is available as concrete material. This is stored in convenient piles along the work and as the storage space was limited, the piles are high. In order to maintain the operation of the dump cars from the derrick to the storage piles by hand the track is raised on timber cribs placed about 20 ft. on centers between which are lines of timber stringers on which the Koppel track rests directly.

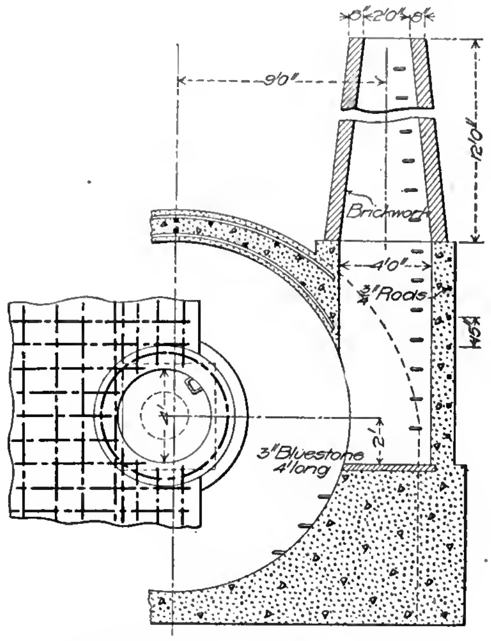
The double-track elevated steel structure of the Ridgewood division of the Brooklyn Rapid Transit R. R. crosses St. Nicholas avenue with too little clearance to allow the passage of the traveler and derrick. When the excavation reached the east line of the railroad structure, the derrick was dismantled, the traveler moved to the west side of the railroad track, and the derrick mounted again. Two short lines of narrow gauge track were then laid within the limits of the trench excavation under the steel structure parallel to the axis of the sewer. The dump bodies of two of the regular Koppel cars were then taken off and low wooden platforms substituted. One car was placed on each line of track with a Hayward 1-yd. bucket on its platform. As the buckets were filled by the shovellers, the cars were run forward to the west side of the elevated structure where the derrick could reach them. The tracks were lowered as the excavation progressed and when the portion of the trench under the elevated railroad was finished both cars and track were hoisted out by the derrick.

The four steel columns of the elevated structure in St. Nicholas avenue are placed two on each side of the pavement, just outside the curb lines. As the footings of these columns are close to the trench it was thought to be dangerous to depend on the trench sheeting to sustain the lateral pressure due to passing trains. Accordingly, part of the weight carried by the columns has been transferred to four timber towers, each made up of four 10 x 10-in. timbers, placed under the girders close to the property lines and wedged up to a solid bearing.





Junction of 7-Ft. and 11-Ft. 3-In. Sewers, Borough of Queens.



Special Manhole for Large Sewer.

When a section of forms is to be drawn forward into its new position the traveler platform is anchored in place and the hoisting engine is utilized. The forms are oiled carefully before each new section of concreting is begun and no difficulty has been experienced in drawing them. The invert and arch surfaces secured are very smooth and require no plastering or patching. The forms for the arch ring and invert of the 15-ft. sewer are handled in 30-ft. lengths. The hoisting equipment and traveler is moved forward with its own power by means of tackle attached to any convenient anchorage.

The work is being prosecuted under the direction of Mr. Joseph H. De Bragga, superintendent of sewers, and Mr. J. H. Johnson, chief engineer. The plans and specifications were prepared by Mr. Alberto F. Schreiner, assistant engineer, and Mr. Elmer W. Firth, assistant engineer, is in immediate charge of construction. The Sigretto & Manino Co., Brooklyn, N. Y., is doing the work, the total cost of which is $393,743.75. A surety bond of $155,000 was required and 400 working days are allowed for the completion of the work. The progress made so far indicates that the work will be completed within the specified time.

Longer Drill Rods than an ordinary air drill tripod will take were used recently by suspending the cylinder between the guides of a small pile driver frame.

New Mechanical Equipment of the Enlarged Tribune Building, New York.

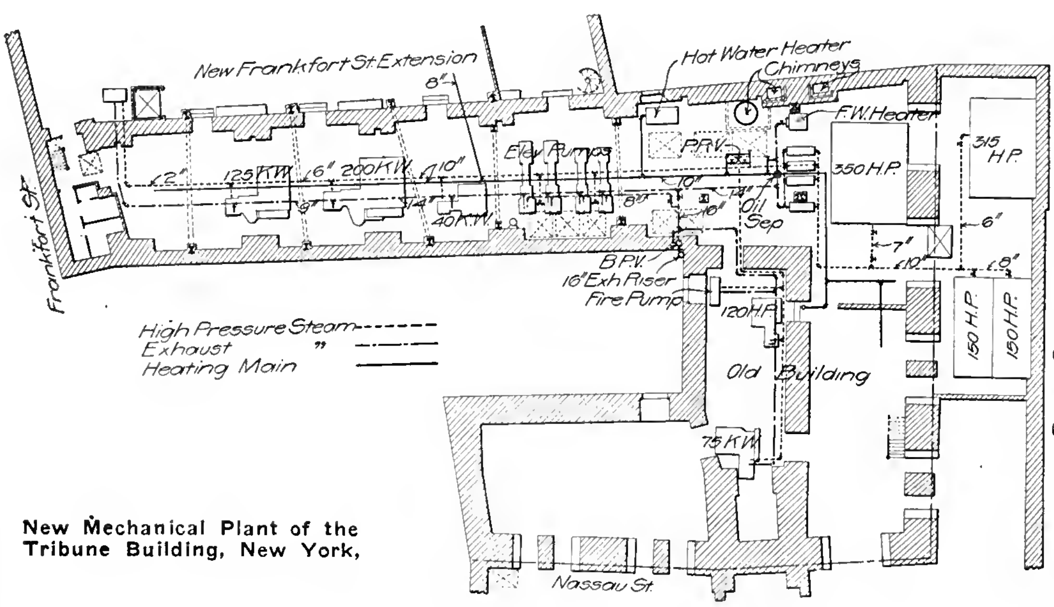
The ten-story building of the New York "Tribune," at Nassau and Spruce Sts., New York, has recently been raised and remodeled into a twenty-story office structure and increased in floor plan by a 60x116-ft. extension of similar height. The interesting and unusual engineering problems involved in this reconstruction were described in The Engineering Record of June 1. With the reconstruction of the building, extensive additions to the power and mechanical plants became necessary and as the equipments of the original building were entirely incapable of extension to the capacity desired, an entirely new layout was designed, providing the increased capacity required and ample accommodation for future growth. The power plant had consisted of an equipment of four small boiler units and of both Corliss and high speed automatic engines for the operation of the printing presses and dynamos, while the heating system was designed for operation with high pressure steam, a usage now practically extinct. The original elevators were of an early Crane design and incapable of extension. After a study of the requirements of the building as extended, it was decided to abandon the greater part of the original mechanical equipment and replace it by new equipment of modern design, which should be accessibly located and have sufficient reserve capacity for emergency requirements. While the new plant and its equipment involves many features of interest, its installation is of peculiar interest for the reason that the equipment is installed largely in the basement space occupied by the original apparatus, all of which it was necessary to keep in operation until the new apparatus had been placed in running order. Owing both to greatly congested space in the basement and to the necessity of entire rearrangement of the plant, the work was attended throughout by many temporary arrangements and connections, which hampered the work a large part of the time, but the new installation was finally completed without accident or interruption of any of the building services.

The basement space allotted to the power plant in the original structure consisted of a 16x40-ft. passage under the front portion of the building and the 24x170-ft. space under the rear portion, extending through between Spruce and Frankfort streets, with, in addition, the 18x63-ft. space under the Spruce street sidewalk, in which the boilers were located. In the remainder of the space under the front portion of the building were located the printing presses, pressroom and other portions of the Tribune's printing plant, with the exception of the stereotyping department, which shared with the power plant the basement space in the rear extension. With the extension of the Frankfort street frontage, however, a greatly increased basement space was there afforded for an enlarged printing plant, and also a division of that space was devoted to the requirements of the stereotyping plant, thus entirely freeing the central basement space for the power plant equipment. The rearrangement of the power plant consisted in the main of remodeling the boiler plant, the removal of the engines and the electrical generating equipment from the front portion of the Frankfort street end to the original basement in space formerly occupied by the stereotyping department, and the location of the new elevator equipment in the central portion of this section, next to the boiler plant. In the latter there was also added later a fourth unit of 350 h.p. capacity, just within the building wall from the original boilers. The plant has always been limited as to space available for fuel storage, and no increase in storage is as yet available from the new arrangement, although when the presses and the printing plant are moved from their present location in the front portion of the basement to the new basement space under the Frankfort street extension a large amount of space will become available under the front portion of the building for coal storage, additional mechanical equipment and rearrangement of the boiler plant if need be. Access is had to the basement for machinery parts and supplies by conveniently located sidewalk lifts on both the Spruce and Frankfort street fronts.

The steam generating equipment had originally consisted of two 60-h.p. horizontal return tubular and two 150-h.p. Babcock & Wilcox water tube boilers, which were located in the Spruce street sidewalk vault, but early in the course of reconstruction the return tubular boilers had been replaced by a single Babcock & Wilcox water tube boiler of 315 h.p. rating, to provide needed additional capacity. As the other water tube units were of comparatively recent installation they were retained for the new plant and merely supplemented by a new unit of the same type and make, which is of 350 h.p. capacity, giving thus a total steam generating capacity of approximately 1,000 boiler h.p. This capacity will enable the maximum power demands of the enlarged building to be carried with one unit always in reserve. The new unit was installed alongside of the 315-h.p. boiler, just within the building wall, so that the same firing floor serves all four of the boiler units and also a considerable space is afforded between these units for the storage of fuel. The only other change in the boiler plant was the erection of a steel smoke stack to supplement the two 24x36-in. flues in the rear wall, which served the four original boilers; the new stack is a 48-in. cylindrical steel stack, rising through the building in a 5x8-ft. shaft enclosure to a point some 260 ft. above the grates, and is connected by a breeching on the basement ceiling to the two larger boiler units, while the two 150-h.p. boilers are served by the wall flues through the original underground flue connections.

The boilers are of the standard Babcock & Wilcox inclined tube construction, designed for 125 lb. working pressure, the two larger units being arranged in single settings and the smaller units together in one setting, as shown in the basement plan of the building. The largest unit is of the longitudinal drum type, having three 36-in. drums and 189 4-in. tubes, 16 ft. in length, giving a total heating surface of 3,527 sq. ft., and has a furnace of 88 sq. ft. grate area. The other boilers are all of the cross-drum type, the larger unit having 144 4-in. tubes, 18 ft. in length, giving 3,100 sq. ft. of heating surface, while the two small units have each 84 4-in. tubes, 18 ft. long, with 1,500 sq. ft. of heating surface each. The two larger units are fitted with Thompson dumping grates for burning low grade anthracite coal and are hand fired, coal being dumped directly from wagons in the street into the storage space or on to the firing floor. Ashes are removed in the usual way, in cans upon the adjoining sidewalk lift. The boilers are fed by two $9\frac{1}{2}x5\frac{1}{2}x12$-in. feed pumps in duplicate, one a Knowles type A simplex pump, which was used in the old plant, and the other a new Davidson pump, either one of which is of capacity sufficient to operate the entire boiler plant. The pumps draw from a Webster open feed heater of 1,000 h.p. capacity, which has been installed at the rear of the boiler room for heating the feed by exhaust steam, and delivers to the boilers through a $2\frac{1}{2}$-in. main, with $2\frac{1}{2}$-in. and 2-in. branches to each unit. The greater part of the feed water supply is condensation returns from the heating system and other steam apparatus, with make-up from the city water supply, all of which is filtered through a building service filter equipment installed by the New York Continental Jewel Filtration Co. The boiler blow-off system consists of a 3-in. main with $2\frac{1}{2}$-in. blow-off connections to each boiler, which delivers the discharge into a blow-off tank under the firing floor for partial cooling, from which it is subsequently raised to the sewers in the adjoining street by a small steam pump.

Owing to the general rearrangement of apparatus, practically all of the piping of the plant had to be reconstructed and enlarged, and as, on account of the importance of the service, all new work had to be erected and placed in service before any of the original piping could be dismantled, all systems were laid out on as simple an arrangement as could be devised. The high pressure steam system consists of a single 10-in. main leading from the boiler room directly to the engine room, with an 8-in. branch into the old section of the plant in the front portion of the building. It has double-valved supply connections to each of the boilers, which are graded to drain condensation into the mains, while the latter has all steam delivery connections made from the upper side, so that condensation will accumulate in the main; this condensation is removed from the main by connections to the feed and vacuum pumps, which are connected from the lower side, and by steam traps at the ends of the main run and of the branch. In the 8-in. branch to the old division of the power plant connection is made with a low branch from one of the 150-h.p. boilers, which serves as a by-pass to the 75-h.p. generating unit, permitting lighting service to be maintained in the building if the main



New Mechanical Plant of the Tribune Building, New York,

generating plant be shut down for repairs. Drainage from this line is facilitated by both a connection to a steam pump and to a steam trap. The exhaust main practically parallels the high pressure main, consisting of a 14-in. line in the engine room, with an 8-in. branch from the engines in the front portion of the basement, and it has connection through a back pressure valve into a 16-in. atmospheric riser to a roof exhaust head and through an oil separator, to the low pressure heating main and the feed water heater. This line is also similarly drained by steam traps and the connection to the feed water heater. There has also been installed a supplementary exhaust main, consisting of an 8-in. line having duplicate connections to the exhaust outlets from the elevator pumps, which supplementary main has a direct valved connection to the atmospheric relief riser branch; the purpose of this is to permit of a sub-division of the exhaust main and allow the elevator pumps to exhaust direct to the atmosphere, independent of the disposal of the main exhaust, when little steam is required for heating purposes. The new low pressure heating main follows the general arrangement of the original heating main, except that it is enlarged to a 10-in. line in the engine room and with a 9-in. branch to the old portion of the basement; this is supplied with steam through a 14-in. connection direct from the exhaust main, with also a live steam supplementary connection from the high pressure system through an 8x12-in. pressure reducing valve.

With the reconstruction of the plant, the power scheme has been entirely remodeled, with a view of electrically driving all the machinery in the building. The machinery of the pressroom and other departments of the printing plant had formerly been operated through shafting and belt drives from a large Corliss engine, with the fly-wheel of the 75 k.w. American-Ball generating unit lined up for a belt drive connection in reserve, and there were, in addition, two direct-connected electrical generating units of 40 and 50 k.w. capacity each, for operating the electric lighting service in the original building. As the Corliss engine was located in the space now occupied by pumps and the elevator equipment, it was removed early in the course of the reconstruction work, and the press load carried by the simple automatic engine, and an electrical generating equipment of nearly 500 k.w. capacity has been installed with provisions for easy enlargement in view of the possibililty of eventually replacing the belt drives if the printing plant is remodeled. For the present, however, the original presses, located in the front portion of the old basement, are still in operation, but a large space has been provided in the basement of the new Frankfort street extension to amply accommodate the proposed new printing plant. Two of the original electrical generating units, namely, the 40 and 75 k.w. machines, have been maintained in the new plant, and in addition two larger units with compound driving engines installed, which are of 125 and 200 k. w. capacity respectively. The two large new units and the 40 k. w. unit are located in the newly arranged engine room at the Frankfort street end of the basement, as shown in the basement plan, while the 75 k .w. unit was left in its original location, where it had been so placed that it might also be utilized to operate the printing plant shafting from its fly-wheel, and thus serve as a reserve power unit, while still available for generating electric current supply. The 200 k.w. generator is driven by an 18 and 28x18-in. American-Ball compound engine, which, operating at 200 r. p. m. and with a boiler pressure of 120 lb., has a rating of 325 h.p., while the 125 k.w. unit is driven by a 14 and 22x16-in. engine of similar make, that operates at 230 r. p. m. and has a rating of 200 h.p. The 40 k.w. unit that was moved to the new engine room has a 12x12 simple Ames engine, operating at 300 r. p. m. and rated at 60 h.p., and the 75 k.w. unit a 15x12-in. simple American Ball engine that operates at 285 r.p.m. and has a rating of 100 h.p.; both of these engines were designed for the steam pressure originally carried at the plant, namely, 80 lb., and accordingly are now supplied through reducing valves which reduce the pressure from 120 to 80 lb. at the throttle. The power unit by which the presses are normally operated is a 11½ and 13½x12-in. American Ball compound engine, which operates at 250 r. p. m. and is rated at 120 h.p. The two larger engines are of the improved duplex compound type, with piston valves and balanced inertia governor, built by the American Engine Co., Bound Brook, N. J.

The 125 and 75 kw. electrical generators were supplied by the American Engine Co., in both cases direct-connected to American Ball engines, while the 200 and the 40 kw. units are General Electrical generators, the 40 kw. unit direct-connected to the Ames engine. These generators are all compound wound multipolar machines, wound to deliver 120 volts direct current, and are all designed with very liberal ratings, having capacities for 50 per cent. overload for 2 hr. continuously and for 100 per cent. momentarily. The distribution is on the two-wire system throughout the building, being controlled on a handsome five-panel switchboard of Vermont marble. The board is of double bus-bar construction and has the usual arrangement of switching and indicating apparatus, and, in addition, recording apparatus so connected that the current consumptions for both power and lighting purposes may be recorded separately. Two panels are devoted to the generator circuits, a feature of the equipment of which is the use of I. T. E. reversite circuit breakers, which are designed to open the circuits in cases of a very slight amount of reverse current in paralleling the generators, and of the remaining three panels two are used at present, the two lower rows of switches being on the lighting, while the upper row is for power and the third is held in reserve for future circuits to the proposed new printing plant and other new departments. The power load of the plant is already of considerable size, there being seven individual motor drives operated in the stereotype room, using motors from ½ to 5 h.-p. capacity; two small motors in the engraving room; in the composing room four motors operating job and proof-presses and 35 ¼ h.-p. Sprague motors individually connected to linotype machines, while there are one 15 h.-p., two 5 h.-p. and two 2½ h.-p. motors operating ventilating apparatus. The lighting system will consist of a connected load of 6,000 to 7,000 16-c.p. lamps in the offices, and, in addition, 76 Cooper-Hewitt mercury vapor lamps distributed throughout the different departments of the Tribune; four of these are 700 candle power lamps, located in the clock tower for illumination of the clock's dial.

The new elevator plant that has been installed consists of eight high-rise passenger and one freight elevator machines of the plunger type, which are operated on the back-pressure discharge system, and a high-duty pumping equipment with ample reserve capacity. The machines all have full travel to the twentieth floor of the building with the exception of one passenger machine, which has a rise to the eleventh floor only, and three of the passenger machines are operated for express service, while the remaining five passenger machines are for the local service, making stops at all floors. The passenger machines are all designed for capacities of 2,000 lb. each, the three express cars to travel at a speed of 600 ft. per minute, and the five locals at 400 ft. per minute, and the freight elevator for a capacity of 3,000 lb. at 200 ft. per minute, while in addition the freight machine is fitted with a jack pump attachment, by means of which its capacity can be raised to 6,000 lb. in special cases, when lifting heavy machinery, safes, etc. These equipments were supplied by the Standard Plunger Elevator Co., New York, and embrace apparatus of the standard construction of this company, with the exception that closed discharge tanks are used in connection with the back pressure discharge system, instead of the usual open tank discharge. The plunger cylinder valves and the control apparatus for the machines are, owing to the location of the corridors in the building, arranged in the central portion of the engine room, and for convenience of piping connections, the tanks and pumps have been here located also. There are four tanks used in the operation of this system, two for the pressure supply system and two for the discharge, in all of which air space is maintained in the usual manner by means of compressed air supplied from a Westinghouse locomotive type air compressor. The main pressure tank is located in the attic of the building, a 7½x24-ft. cylindrical steel tank, to which pressure is delivered from the pump through a 15-in. delivery main and stand pipe, while the auxiliary pressure tank, a 5x10-ft. vertical cylindrical steel tank, is located in the basement, at the foot of the stand pipe, and from this tank the delivery connections are made to the control valves of the elevator machines. The discharge tanks are horizontal cylindrical steel tanks, 6¾ ft. in diameter, one 16 ft. and the other 28 ft. in length, which are mounted on a structural steel platform 6½ ft. above the basement floor level, and into these the control valves discharge through independent grouped connections. The two tanks are interconnected by a 10-in. main, to which is attached a 7-in. line that is carried up alongside of the stand pipe to a point 68 ft. above the cellar floor level to an open discharge outlet, for the purpose of securing the desired back pressure effect. The pumps are located directly underneath the discharge tanks and consist of Davidson compound duplex pumps of the separable type, so that either unit may be worked to its full or half capacity, as required by the elevator service. The larger unit is a 16 and 30x14x24-in. pump, while the smaller unit has 12 and 22x10x24-in. cylinders. The jack pump which is located alongside of the freight elevator in the rear end of the building, and is used for that machine only, is a 10x5x12-in. Davidson simplex pump.

The heating system of the building has been entirely remodeled and converted into a low pressure system, operating with exhaust steam from the power plant and with a vacuum system of condensation return. The original system in the old building was of the high pressure type, using steam at about 10 to 12 lb. pressure, with small size mains and risers and gravity returns, so that the original basement piping was entirely unadapted for extensions, and a new basement distributing system was installed. This consists of a 10-in. header that extends longitudinally through the central portion of the basement and has a 9-in. extension into the front portion of the basement, to connect with certain portions of the original heating system which have been retained in the new plant, and an 8-in. extension into the new Frankfort street extension of the building, with numerous branch connections to nearby risers in the central portion. The header has a 14-in. supply connection from the exhaust main near its central point through a Webster oil separator, and has, in addition, a live steam make-up connection from the high pressure system consisting of a 6x10-in. Kieley reducing valve with by-pass. The supply connections to radiation throughout the building are made in the usual way through 43 wall risers which receive steam directly from the basement heating header

above referred to, and for the greater part are carried up to the top of the building, with anchorages to the building framework at the fourth and thirteenth floors, and expansion joints between at the eight or ninth floors. An exception to this arrangement occurs in the old Nassau St. front portion of the building, in which portion a minimum of building changes were made, and it was thought desirable to utilize the original small size risers that were used in the high pressure heating systetm; this was accomplished by running an overhead distributing main in a mezzanine space above the twelfth floor, in which are located the series of distributing and equalizing beams that carry the steel work of the new upper stories, and feeding from this main both into the new wall risers that are carried up to the new upper stories and also back down into the small old risers from the top. In this way the old risers, which were not disturbed and which are as small in some cases as ½ in. at the top, are successfully operated by feeding in at both top and bottom, in conjunction with the use of the vacuum system of returns. This distributing main above the twelfth floor is a 5-in. line, which is supplied by a direct 8-in. riser from the basement heating header, and from it 1 or 1½ in. connections are run to the tops of all of the old risers below, while the new risers above it are designed and connected in the usual manner. Condensation from the heating system is returned from the power plant by the Webster system of vacuum returns, return risers being run to parallel each of the steam supply risers throughout the building; these connect in the basement to a 3½-in. gathering main, which is in turn connected in the engine room through suction strainers to two vacuum pumps installed in duplicate. These pumps are Davidson 8x12x12-in. simplex pumps, which deliver the condensation first into an overhead separating tank, in which entrained air and vapor is allowed to escape, and from thence it is delivered into the feed water heater for return to the boilers. The total amount of radiation operated in the extended building is about 35,000 sq. ft., which is divided into about 1,000 heating units.

An interesting result of operation with the new plant has been obtained in a considerably reduced coal consumption. The fuel consumption of the old plant was, from records made for six months, from April 1 to October 1, approximately 1,815 short tons, in both 1903 and 1904, which amounts to a daily average consumption of 9.92 tons of pea anthracite during a period when 226 h.p. hours were produced on an average per 24 hours. On October 1 of this year a summary of the plant records for the same six months period indicates a total fuel consumption of 2,212 tons, or a daily average of but 2.16 tons, and this with the building increased to about three times its former size. The electric lighting and power load is now about 75 per cent. greater than before, while the total combined car travel of the present nine elevators is 2,030 ft., as compared with the combined rise of 360 ft. of the former three elevators in the original 10-story building, which indicates a power production on a much more economical basis—due, it is thought, to the use of compound engines and pumps and the operation with 125-lb. steam instead of 80-lb., as formerly.

In the installation of the power plant machinery in the central portion of the basement, difficulty was experienced in obtaining satisfactory foundations without interference with the grillages of the new building framework, and in order to prevent communication of disagreeable vibrations to the upper portions of the building, an interesting arrangement of sound-proof foundation construction was devised. As above stated, reinforcing framework was necessary in the rear portion of the building above the engine room, in order to carry the increased weight of the ten stories added, which consist of balanced columns carried up from new footings in the basement to the thirteenth floor without intermediate loading, at which point the weight of the new upper stories is distributed upon them by a system of equalizing girders. These columns, which were erected through the floors within the old building walls, are carried in pairs on distributing girders placed below the basement floor level, which rest on I-beam grillages that were set in excavations between the original building wall footings, in order not to disturb the original structure. The grillages consist of 15-in. I-beams 12 ft. in length, which are set longitudinally of the basement space, and as the distributing girders supported are but 20 to 24 ft. apart, it will be seen that very little space was afforded between grillages for foundation purposes. It was finally decided to locate the pump and engine foundations directly upon the grillages, taking such precautions as possible to prevent the communication of vibration from the reciprocating machinery to the upper portions of the building framework. For the latter purpose sand-bed insulation was used, there being 8-in. sand-beds provided underneath all foundations and 6-in. sand packed spaces between the edges of the foundation and any adjacent footings, beams or other building construction. This construction is shown in the accompanying detail of the elevator pump foundation, which was built in a single unit for both the larger and smaller separable compound pumps. In this case almost the entire space between adjacent distributing girders is occupied, the block of concrete overlapping the grillages on either side by nearly 4 ft. in either case.

In the construction of the foundations the spaces between the ends of the grillage beams were in all cases excavated to some distance and then concreted to an even surface, level with the tops of the grillage beams, and upon this the sand bed was placed, preparatory to the construction of the foundation blocks. The block was then constructed by erecting forms for the side and placing a water-proofing course over the sand-bed in order to prevent contact of the concrete with the sand and subsequent solidification of the latter. Upon completion, the forms were drawn at the sides and the spaces there packed with sand, the floor being finished directly across the side sand spaces. This construction was found successful, as no vibration is communicated to the upper floors, and this without sacrificing any of the stability of the foundations.

The design of the new mechanical and electrical equipment is due to Mr. Arthur S. Vincent, the mechanical engineer for the Tribune Association, under whose supervision the entire equipment was installed. The general contractors for the building reconstruction were D. C. Weeks & Sons, New York, while the heating and ventilating equipment was installed by Baker, Smith & Co., New York. The architects of the building were Messrs. D'Oench & Yost and L. Thouvard, New York.

Trade Names for Malleable Cast Iron.

A trade misnomer relating to malleable cast-iron is mentioned by Prof. Bradley Stoughton in the "School of Mines Quarterly." On account of its fluidity such iron may be cast very cheaply in small sizes, and therefore the temptation to use it as a material for "cast-steel hammers," "hard-steel" bevel gears, "semi-steel castings," and even automobile "steel" drop-forgings, is a strong one. Engineers are warned to be on their guard against a deception of this kind, for legal redress has been sought many times in vain. A clever lawyer may easily confuse a judge or jury with the involved definitions and technical descriptions necessary to make the distinction clear. It is usual for the manufacturer when putting material of this kind upon the market to qualify the name "steel" with some other letter or name, such as "P. Q. steel"; but they all differ from true steel in that they were not "cast into an initially malleable mass." Some are made by melting a large proportion of steel with cast-iron, after which the cooled metal may or may not be annealed in iron oxide. Others are made by a long or thorough annealing of ordinary malleable castings in iron oxide, by means of which the metal is decarburized to some depth, and is then carburized again by a cementation process. This makes a very good material for some purposes, such as small bevel gears not requiring strength or much ducility, but it ought not to be called "steel."

A Large Coal-Storage Wharf at Superior, Wisconsin.

A coal-storage wharf, which has recently been placed in service at Superior, Wis., by the Berwind Fuel Co., is served by three electrically operated tramway bridges, for unloading coal from vessels and reloading it into railway cars, that are believed to be the largest and heaviest structures of this type thus far built on the Great Lakes. The site of the wharf is on St. Louis Bay, in the harbor of Duluth and Superior, adjacent to a number of other large coal-storage wharves, over which the immense coal traffic passing through Duluth and Superior is handled. This traffic reached a total of over 5,000,000 tons in 1906 and is increasing at a remarkable rate. Many of the large vessels which carry iron ore to the lower lake ports from the Messaba and Vermillion mining districts, northeast of Superior and Duluth, return with cargoes of coal. A small part of this coal is used locally, but a very large percentage of it is unloaded on wharves in Superior and transshipped by rail to the Northwestern part of the United States and Southwestern Canada.

The property on which the new wharf is located is 455 ft. wide and has a frontage of 2,700 ft. on a slip of that length, which has been dredged at nearly right angles to the dredged channel in the bay. The fuel company also owns two strips of land, one 75 ft. and the other 82.5 ft. wide, which extend from the wharf site to right-of-way of a belt-line railroad that connects with all the railroads entering Duluth and Superior. A portion of the wharf site, 1,500 ft. in length, at the shore end, has been developed as a coal-storage wharf during this year, making 682,500 sq. ft. of developed area, which should store 350,000 tons of coal. The remaining offshore undeveloped area covers 546,000 sq. ft., and when the wharf is extended over it the total storage capacity will be about 700,000 tons.

The water was from 4 to 8 ft. deep over all of the wharf site, except for a narrow strip at the shore end where the ground rose from 20 ft. above the level of the bay. The developed portion of the site that was inundated has been reclaimed by a fill confined by tight timber bulkheads; the high ground at the shore end has been cut down to the level of this fill; cuts have been made through the narrow strips of land extending from the shore end of the site to the belt-line railroad, and two tracks have been laid in each of these cuts to provide switching connections for the wharf. The three bridges for unloading coal from vessels in the slip and for rehandling it into cars on the railway tracks span the wharf and travel the full length of the developed area, reaching out also over vessels in the slip.

Wharf Construction.—The fill which was required to develop practically all of the wharf site was carried up 5.5 ft. above mean low water in the bay. It is confined on the slip side, where the minimum depth of water is 21 ft., by a timber crib, 1,500 ft. in length, which is of unusually heavy construction, as may be seen from the accompanying illustration showing the details of it. The crib is 18 ft. wide and 28 ft. high. The sides of the crib are each formed by a row of 12x12-in. timbers, in 12, 14 and 16 ft. or greater lengths, all thoroughly drift-bolted together. The row of timbers on the slip side also has 1x6-ft. battens over the joints between the timbers to prevent the fill from filtering through these joints. The cross bracing between the two sides of the crib consists of 10x12-in. timbers, placed transversely in vertical rows, the rows being spaced 8 ft. apart on centers, the timbers in the rows being 14 in. apart. Between each two of these vertical rows of cross braces are three pairs of 6x8-in. diagonal braces, the first pair 6 ft. from the top of the crib, the second 8 ft. below the first and the third 10 ft. below the second. The cross braces in each vertical row have 12x14x48-in. blocks between them on the slip side, and also 12x14x16-in. blocks at the middle. The crib is protected on the slip side by a row of round piles, 36 to 40 ft. long, which are placed 8 ft. apart on centers, alternating with the cross braces. These piles are blocked against the side of the crib and carry two 8x12-in. oak waling fenders. Above the waterline the crib is built of white pine and fir, and below that of hemlock.

After enough of the row of protection piles had been driven to permit work to be started on the crib the latter was built up in sections, 600 ft. long, directly over the site it was to occupy. These sections floated 6 to 8 ft. out of the water when finished. They were sunk and anchored in position by material placed in them by a dipper dredge. The bottom was previously prepared, where necessary, so each section settled into place evenly and to proper alignment.

The water is 4 to 8 ft. deep on the side of the fill opposite from the slip. The fill is confined along that side by a sheet-pile bulkhead, 1,350 ft. long, which is continued along the off-shore end the full 455 ft. of the width of the wharf to a connection with the crib on the slip side. This bulkhead consists of a row of triple-lap Wakefield sheet-piling formed of 3x12-in. Norway pine in 16-ft. lengths. A row of round piles, 30 to 70 ft. long, is driven on the outside of the sheet piling as a brace and protection. These round piles are 3 ft. 10½ in. apart on centers for 250 ft. from the shore, and 2 ft. 3 in. apart on centers in the balance of the bulkhead. They are anchored to round piles, 20 to 30 ft. long, which are driven 16 ft. apart on centers in a row 50 ft. back in the fill from the row of protection piles.

The extremely heavy loads on the towers of the tramway bridges are carried by rows of heavy piling, thoroughly braced and capped. These piling foundations for the bridges are entirely independent of the crib and the sheet-piling which confine the wharf fill. They were driven ahead of the work on the fill and are cut off at the surface of the latter.

The crib and bulkhead work was done under contract by the Barnett & Record Co., of Minneapolis, Minn. The piling was driven with a hydraulic jet and a drop hammer.

The fill contains about 250,000 cu. yd. of material, 180,000 cu. yd. of which were pumped into the property by the hydraulic dredge "Enterprise." This dredge is owned and operated by the Duluth-Superior Dredging Co., of which Mr. Edward Clifford is president and was in charge of the operations. It is equipped with a 22-in. special centrifugal dredging pump, and has a 20-in. discharge line. The fill for the wharf was made by the dredge in a remarkably short time. When the Berwind Fuel Co. contemplated the construction of a wharf at the head of Lake Superior it was generally conceded by those conversant with such work in the locality that it was impossible to build a wharf of the projected size and fill it with sand in twelve months. At the time the contract for making the fill was awarded the dredge "Enterprise" was on the St. Lawrence River at Messena, N. Y., so had to be brought through the Welland Canal and up the Great Lakes. On account of the backward spring, which caused the Welland Canal to be two weeks late in opening, the dredge did not arrive until May 19, but was started in service on May 26 and practically completed the fill about August 15.

The remaining 70,000 cu. yd. of material in the fill, in addition to that supplied by the dredge, was obtained in cutting down the land at the shore end of the property and from the cuts

View of Coal-Storage Space.

made through the narrow right-of-way strips for the railroad connections. Two steam shovels were installed to do most of the cutting, while some of the lighter work was done by grading machines. The material excavated by the shovels was hauled out on the fill in trains of dump cars running on narrow-gauge tracks. The grading machines were served by dump wagons in which the material was also carried out on the fill. This excavation was all made in a peculiarly difficult clay, which, when frozen, could scarcely be loosened in any quantity by blasting. The erection of the three traveling bridges and the other construction work also complicated the grading considerably, but the large amount of plant installed enabled it to be finished along with the other work.

Coal-Handling Equipment.—The coal-handling equipment consists of three traveling bridges, two screening towers and two locomotive cranes. Each traveling bridge is 506 ft. in length, from end to end, and is carried by two towers, one at the front, traveling along the slip, and the other toward the opposite end of the bridge, the clear span between the two towers being 295 ft. A section of each bridge, 64 ft. long, projects out over the slip from the front tower, and is hinged so it can be raised and lowered to permit the passage of boats with spars. The other end of the bridge is a fixed cantilever, extending 125 ft. beyond the tower leg toward that end. The front tower of the bridge has two legs, 35.5 ft. apart on centers. Each of these legs is carried by two narrow-gauge four-wheel trucks with double-flanged wheels running on rails laid on the heavy pile foundations. The other tower of the bridge is a shear leg, with two vertical posts each carried by a four-wheel truck. The following loads on these various trucks convey an impression of the size of the bridges: the total load per truck on the front leg of the front tower is 177,000 lb.; on the rear leg of this tower, 215,000 lb. per truck; and on the rear tower, or shear-leg, 336,000 lb. per truck.

Each bridge is equipped with a 3-ton clam-shell bucket carried by a trolley having an extreme travel, from end to end of the bridge, of 474 ft. These buckets are self-filling and will handle either bituminous or anthracite coal. Each bucket is arranged to handle coal in several ways. It will unload coal from the hold of a vessel in the slip and place it in storage piles between the two towers of the bridges; or in a hopper on the front tower of the bridge, from which cars on the switch track are loaded; or in the hopper of the screening tower under the cantilever end of the bridge beyond the shear leg. It will also handle coal from the storage piles into the reloading hopper, or into the hopper of the screening tower, and will convey screenings from the piles at the screening towers to either of these hoppers.

One of the salient features of the arrangement of the bridges and of the operation of the bucket carried by each of them is the provision of a hopper on the front tower through which run-of-mine coal may be loaded directly into railroad cars from the vessel. This hopper is so close to the slip that the bucket trolley is required to travel a very short distance, thus enabling a large unloading capacity to be maintained. The hopper is also built to handle large quantities of coal, and as a box-car loader is provided in connection with it, the cars can be filled from the hopper without delaying the operation of the bridge when the latter is working to full capacity.

The buckets have a guaranteed hoisting speed of 300 ft. per minute and a trolley travel of 1,000 ft. per minute. On an average of a round trip a minute and 3 tons per trip, the three bridges should handle 5,400 tons in 10 hr.

The buckets are each operated by an electric hoist, with its hoisting and holding drums controlled, respectively, by means of a hand brake and a friction clutch, the latter being shifted by a General Electric solenoid controller. The hoists are each driven by a 3-phase 25-cycle 440-volt 225-h.-p. General Electric alternating-current induction motor, which has double-reduction gearing to the hoisting and holding drums. The trolley carriage of the bucket is moved by a cable on a trolley drum driven by a 3-phase 25-cycle 440-volt 75-h.-p. General Electric alternating-current induction motor operated by a controller. The motor and hoists for each bridge are placed in a house on the bridge just in the rear of the front tower. The motor and friction clutch are arranged for remote control, the operator being in a cab on the slip side of the front tower when a vessel is being unloaded, or when coal is being delivered to the reloading hopper; and in a second cab at the shear leg when other operations are in progress.

The bridges are moved along the wharf at a speed of 50 ft. per minute by means of a 75-h.-p. General Electric alternating-current induction motor, connected to the axles of the track wheels on the front and rear towers by cast-steel gears. These motors are also arranged for remote control from either of the operator's cabs.

The two screening towers are self-propelled, and are entirely independent of all other coal-handling equipment. They are built of structural steel, each having an overhead conveyor carried by a four-leg tower at one end by shear leg near the other end. This tower and the shear leg are on wheels traveling on rails laid on the wharf. The tower carries a loading hopper and a screening pocket. The screens in this pocket are arranged with interchangeable bars, which permit practically any grade of coal to be prepared with each tower. The screenings are dropped into a hopper which deposits them on a traveling belt-conveyor, and are delivered by this conveyor to storage piles under the extreme end of the bridges, where they can be

East Right of Way Showing about Half of Leads.

reached by the 3-ton bucket carried by each of the latter. The screenings can also be dumped from the conveyor directly into cars on a track under the bridge of the screening tower. Each screening tower is designed to handle 4,000 tons of coal in 10 hr., and can be used in connection with the traveling bridges, or with either of the two locomotive cranes, which travel on a track under the bridges of the screening towers. These locomotive cranes are intended to be used exclusively for loading commercial coal when the traveling bridges are unloading a vessel, or are otherwise engaged. They are thus expected to preclude the chief objection previously made to a large traveling bridge, namely, when unloading any particular grade of coal from a vessel it was impossible to load out another grade without taking the bridge from the vessel.

Most of the coal is shipped to the Northwest from Superior and Duluth in box cars. Two portable box-car loading machines, each driven by a 100-h.-p. General Electric motor, are used in loading the cars. One of these machines travels on a track parallel with the track which serves the hopper of the screening towers; the other is on a track on the opposite side of the wharf next to the track for cars supplied from the reloading hoppers on the front towers of the bridges.

The electric power to operate the various coal-handling equipment is delivered to the dock as 25-cycle 3-phase alternating current at 13,200 volts, by the Great Northern Power Co. of Duluth. The current is received in a fireproof transformer house containing three General Electric 3-phase oil-cooled 500-kw. transformers for stepping the current from 13,200 volts down to 440 volts. Each transformer has four 2½ per cent. primary taps and two 4 per cent. secondary taps. A five-panel switch-board is also provided in the transformer house. One panel of this board, which is equipped with indicating and recording instruments, is for the high-tension incoming line. An automatically motor-operated oil switch for this line is placed in concrete cells. A multiplex lightning arrester is also provided for the high-tension line. The other four panels of the board are each for a feeder circuit, each panel being equipped with an ammeter, a circuit breaker and a main-line switch.

The following four buildings were also erected in connection with the dock: a machine shop, equipped with a traveling crane, planers, lathes, drill presses and forges, permitting all necessary repairs to the equipment to be made in this shop; a store house, equipped with a traveling crane of sufficient capacity to handle any piece of machinery or extra parts for the dock equipment; an office and service building, divided into two parts, one for the necessary accounting, and the other for toilet, running water and comforts for the laborers; and an oil storage house, isolated from the remainder of the buildings. All of these buildings and the transformer house are thoroughly fireproof, having brick side walls and book-tile roofs; the machine shop also has a steel frame.

The contract for the three traveling bridges, the two screening towers and the two locomotive cranes was awarded to the Dodge Coal Storage Co. of Philadelphia. Coal was unloaded from the steamer Joe S. Morrow by all three bridges on August 13, two days prior to the date originally contemplated. The wharf and all of the equipment were practically complete at that time, six months after the contract was awarded. The early completion of the work was largely due to the efforts of Mr. C. J. A. Morris, of St. Paul, Minn., who was appointed chief engineer of the project for the Berwind Fuel Co., and personally supervised the construction from its inception. The structural steel work was all fabricated and erected under a sub-contract by the Morava Construction Co., of Chicago, which company completed the work in contract time, although erection was not commenced until April 23.

This journal is indebted to Mr. F. G. Hartwell, president of the Berwind Fuel Co., for permission to visit the wharf and collect the data from which these notes have been prepared.

Macadam Roads in King County, Wash.

A short resume of the principles and methods of macadam road construction and the cost of a number of roads, formed the subject of a paper by Mr. A. L. Valentine, county engineer of King County, Wash., before the last convention of the Pacific Northwest Society of Engineers, Seattle. The paper was printed in the September, 1907, issue of the proceedings of the Society, from which these notes have been taken.

The broken stone used in King County is graded into three sizes, No. 1 passing a 3-in. ring, No. 2 a 1½-in. ring, and No. 3, which contains all the dust of fracture, including stone passing a ½-in. screen The bottom course of the road is made of No. 1 stone, and the course of No. 2 contains only a sufficient quantity of stone to fill the voids of the lower course. Experience in King County has shown that an allowance of one-third of the desired thickness of the completed roadbed is necessary in the loose stone, to allow for shrinkage in rolling, so that 9 in. of loose stone are used where a completed bed of 6 in. is desired. The work is started at the end farthest from the source of supply, so that in the earlier stages of construction there will be no traffic to form wheel ruts in the first and second courses, which may be easily injured even though they have been rolled.

The costs and quantities which follow are given by Mr. Valentine for macadam roads in King County.

One road 6,600 ft. long, with 16-ft. stone bed 6 in. deep, contained, including turn-outs, 12,006 sq. yd. Total number of cubic yards used was 3,048. In this instance one cubic yard covered 3.93 sq. yd. The proportion of stone was 66 per cent. of No. 1, 25 per cent. of No. 2, and 9 per cent dust. The cost per square yard was as follows: Stone, 0.44427 cents; rolling, 0.03823 cents; sprinkling, 0.01388; spreading, 0.04043; hauling, 0.08536; total cost, 0.62217 cents. Adding 25 per cent. for contractor's profit, gives 0.7777 cents per square yard, or a cost per mile of $7,300 for the stone bed only. This represents the cost after the roadbed had been shaped and was ready to be rolled. The stone was delivered at station 24, making the greatest haul 4,200 ft., station 0 being the beginning.

Another section of road, 4,800 ft. long, was constructed during the wet season and contained 1,869 cu. yd., used in the following proportions: Seventy-eight per cent. No. 1, 18 per cent. No. 2 and 4 per cent. dust. It will be noted there is considerable difference in the quantity one course bears to the other, as compared with the previous figures. This difference is caused by using just enough of course No. 2 and the binder to fill the voids. Taking the number of cubic yards actually used (1,869), and at the rate for carload lots, delivered, $1.75 f. o. b. cars, we have the following costs per square yard: Stone, 0.381 cents; rolling and sprinkling, 0.084 cents; hauling and spreading, 0.166 cents; total cost, 0.631 cents. This cost represents a maximum haul of 4,260 ft. in one direction and 3,700 ft. in the other, the stone being delivered on the road between these points. In this instance, one cubic yard of stone covered 4¼ sq. yd.

This also includes the following labor cost: Foreman, $4.00; rollerman, $3.50; spreadermen, $3.00 and $3.50, and teams at $7.00 per day of ten hours. No superintendence, interest on money invested or contractor's profit is added. Adding a contractor's profit of 25 per cent. we would have 0.788 cents, or a cost per mile of $7,400, for the stone bed only.

Another road exactly one mile long was constructed during dry weather. The road had been built two years and was but 10 ft. wide, with a 6-in. stone bed. It had been entirely covered with water during floods, and the roadbed exposed to the wash of the river current. This washed away the binder and softened the bed so that it was badly rutted. Owing to these conditions it was considered best to increase the width to 16 ft. This meant an increase in the crown and practically an entirely new road, both as regards quantity of material and labor. The entire bed was scarified by hand; that is, laborers were employed at $3.00 per day of ten hours to pick up the stone bed before the first course was spread. This cost would about offset the cost of rolling the sub-grade of a new road, so that the item of sub-grade rolling shows in the summary of cost, but is really included in spreading and scarifying, and the cost of rolling is reduced in that proportion.

The total number of cubic yards of stone used was 1,792, in the following proportions: 72 per cent. No. 1, 22 per cent. No. 2 and 6 per cent dust. The longest haul was 3,970 ft., the stone being delivered at stations 39 plus 70 and hauled each way; that is, to stations 0 and 52 plus 80. Cost of stone delivered f. o. b. cars at station 39 plus 70 was $1.75 per cubic yard; wages of foreman, $4.00; rollerman, $3.50; teams, $7.00, and laborers, $3.00 and $3.50 per day of ten hours; cost of water, 15 cents per tank of 600 gal.; coal for roller at $6.50 per ton. The cost per square yard was as follows: Rolling, 0.0333 cents; sprinkling, 0.0269 cents; hauling, sprinkling, spreading, 0.1695 cents; stone, 0.3340 cents; total cost, 0.5637 cents. Adding 10 per cent. to cover shrinkage and incidentals necessary on a new road on an ordinary foundation, or $5,820.59 for one mile, and 25 per cent. for contractor's profit, we would have 0.770 cents per square yard, or $7,275 per mile.

On this road there was used 1,792 cu. yd. of stone. Had it been an ordinary foundation, allowing one-third for shrinkage, we would have used 2,080 cu. yd. One tank of water covered 64 sq. yds., or 9.33 gal. covered one square yard. figuring each tank at 600 gal. One ton of coal was sufficient for rolling 383 sq. yd. Each cubic yard of stone covered 5.23 sq. yd.

From these figures it appears safe to estimate the stone bed at 80 cents per square yard, or $7,500 the mile, haul not exceeding 4,200 ft. and stone costing $1.75 per cubic yard.

THE NEW SHIPBUILDING PLANT of Yarrow & Co., Ltd., on the river Clyde, is now nearing completion, the buildings being finished, though much of the machinery is not installed. The plant is entirely new and when in full operation the old works on the Thames will be closed, the reason for the removal being the high cost of coal, material, property and labor at the latter point. The new works will be operated almost entirely by electric, hydraulic and pneumatic systems, the pumps and compressors being motor driven. Several unusual features are introduced, notably the installation on each machine in the shops of a gas jet in addition to the regular electric lights. The firm's experience, according to "The Engineer," London, is that workmen, on the whole, work under better conditions as to light and general convenience with gas than with incandescent or arc lamps. Another unusual feature is the use of bare copper wiring in the shops wherever it can be safely used.

Experimental Purification of Boston Sewage.

The Sanitary Research Laboratory and Sewage Experiment Station of the Massachusetts Institute of Technology was founded in 1902 by an anonymous donor for the purpose of making experiments upon improved methods of sewage disposal, especially those adapted to large cities. A large part of the work of the staff has been devoted to the study of the more purely scientific problems, chemical, bacteriological, and hydraulic, which underlie the practice of sewage analysis and sewage purification. These has been carried on, however, along with these theoretical investigations, an experimental study of the immediate local problems of sewage disposal as seem likely some day to confront the city of Boston, and on November 15 a paper on this study and some deductions from it was presented to the Sanitary Section of the Boston Society of Civil Engineers by Messrs. C. E. A. Winslow and E. B. Phelps. An abstract of this paper follows:

The sewage of the metropolitan district of Boston is at present discharged untreated into the waters of the harbor at three different points. The main outfall sewer of the North district carries some 50,000,000 gal. daily and discharges continually off Deer Island. The sewage from the High Level district passed out to Peddock's Island, near the southeastern limit of the harbor; this amounts to about 20,000,000 gal. The main outfall of the south metropolitan district is at Moon Island, nearer the center of the harbor, and here the sewage is stored in masonry tanks and discharged only on the turn of the tide. The daily flow in this sewer is in the neighborhood of 100,000,000 gal. The Massachusetts State Board of Health investigated the condition of Boston harbor in 1905, and found no serious damage from this method of disposal. The town of Wellesley has, however, recently been refused admittance to the metropolitan system from fear of overtaxing the purifying power of the harbor; and it can scarcely be doubted that the progressive increase of population within the drainage district itself will ultimately bring the problem of sewage purification to the fore. The present agitation in regard to the pollution of New York harbor, under somewhat similar conditions, is an indication of what must some day be expected in Boston.

Under these circumstances it is important to form a general idea beforehand of what a proper purification of Boston sewage will involve; and the investigations at the Technology Station have reached a point at which this can approximately be determined. The detailed results of the work will shortly be published in full in the "Technology Quarterly." The general conclusions, as reported to the Sanitary Section of the Boston Society of Civil Engineers, are as follows:

Trickling Beds.—The main result of this investigation has been to show the feasibility of treating Boston sewage on trickling beds so as to secure organic stability. In the experiments conducted, the filters were operated at a rate of about 2,000,000 gal. per acre per day, which would call for 50 acres of stone beds for the treatment of the sewage now discharged at Moon Island. A comparison with the problem of constructing 133 acres of contact beds, or 1,000 acres of sand beds which would be necessary for other processes, indicates clearly that for this city the trickling bed offers the most practical method of treatment.

It has been found that with good distribution, a trickling bed 8 ft. deep will operate successfully at all seasons, under local weather conditions. It removes about half the soluble organic matter, yielding an effluent which is somewhat turbid, but stable and well oxygenated. The organic matter present has been so worked over and purified by the bacteria in the filter as to be non-putrescible. Judged by the methylene-blue reduction test, 90 per cent. of the samples of the effluent are of such stability as to undergo no putrefactive change when kept closed up from the air for four days. Under ordinary conditions of discharge into open water such an effluent would be entirely unobjectionable.

The proper distribution on trickling beds can be attained either by the use of fixed sprinkler heads of the Columbus type, so arranged as to discharge intermittently at frequent intervals, or by the use of the splashing gravity distributors designed at the experimental station for this purpose.

With good distribution the trickling beds show no appreciable tendency to clog. During the greater part of the year solid matter accumulates on the surface of the stones throughout the bed, but when this storage reaches a certain point, usually in the early spring, the solids break away and come off in the effluent in a stable condition. In a period covering two years, the total amount of solid matter coming off balanced that going on. The filtering material at the end of the experiments was in excellent condition and showed no storage of nitrogen.

The results point strongly to the advantage of operating trickling beds under conditions as uniform as possible. Resting periods proved distinctly detrimental to the work of the beds, and constant operation is recommended rather than any process which involves alternate working and resting periods.

Septic Tanks.—It appears from the experiments that Boston sewage may be treated in the septic tank with excellent results, and that a period of 7 hours is a sufficiently long one. Thus operated, an open tank will remove 40 per cent. of the total suspended solids and 60 per cent. of the fixed suspended solids; its effluent shows a decrease of about 25 per cent. in organic nitrogen in solution and a corresponding increase in free ammonia. The septic action on the stored solids is an active one, four-fifths of the organic solids deposited disappearing in solution or as gas. Fixed solids gradually accumulate so as to render it probable that tanks would require cleaning about once in two years.

On the whole, however, the experiments indicate that the septic tank need not be used at all in the treatment of Boston sewage. Since November, 1906, when the distribution system was put in order, crude sewage has been treated on one of the trickling beds with perfect success. On the whole, the effluent from this filter was less frequently putrescible than that from the bed which received septic effluent. Furthermore, the filter taking septic effluent showed a deposit on its floor, due to secondary reducing changes, which was absent from the crude sewage bed. In addition, the absence of the odors produced by spraying septic sewage is an advantage of considerable moment in favor of the process of treating fresh sewage. Combined with the saving of the cost of tanks, in the neighborhood of $250,000, these argments seem to indicate the treatment of crude sewage directly on trickling beds as most desirable. Modern devices for ensuring a thorough preliminary screening should, however, be installed.

Sedimentation of Trickling Effluents.—The suspended solids which appear in the trickling effluent, though inoffensive, are unsightly and in many locations might require removal. By a sedimentation of two hours it has been found possible to remove about half the suspended solids. This clarification was accompanied by an improvement in stability.

In the case of Boston, the currents of the harbor would be amply competent to care for the solid matter discharged if that matter were of an inoffensive and non-putrescible nature. Experience with the system at present in use has indicated this quite clearly. For a comparatively slight improvement in stability, it does not appear justifiable to go to the expense of installing secondary sedimentation tanks. The sludge accumulating in such tanks would amount to 2 or 3 cu. yd. per million gallons of effluent, a serious problem in itself. It is therefore considered by Messrs. Winslow and Phelps that the effluent from the trickling beds may best be discharged directly into the harbor as it comes from the beds. A stable effluent under such conditions could cause no nuisance and if a submerged discharge were provided its presence would scarcely be detected.

Disinfection of Trickling Effluent.—The problem of bacterial purification still remains to be considered, since the trickling bed produces organic stability without destroying pathogenic bacteria. In the case of Boston harbor, with its large contiguous population, its bathers, and its shellfish industry, this aspect is an important one. The experiments carried out during the last two years have made it clear that the effluents from trickling beds may be so purified bacterially by disinfection with chloride of lime as to be of much better quality than the present stream entering Boston harbor. This bacterial purification requires about five parts of available chloride per million gallons and the cost of treatment would be within moderate limits.

The process of disinfection with chloride can be applied to crude sewage, as well as to trickling effluent, although experiments carried out at the station indicate that about double the amount of chloride is needed on account of the reducing action of the organic matter in the sewage. Pending the construction of a trickling filter plant for the treatment of the organic matter in Boston sewage, it might well be purified bacterially by this process at the present Moon Island outfall.

General Plan for Treatment.—The sewage outfall of the South metropolitan district at Moon Island is the one which threatens most seriously to menace the purity of Boston harbor; and it is this sewage which will certainly first require some different method of treatment. Messrs. Winslow and Phelps have therefore considered in a general way the practical problem of dealing with this sewage in the light of the results of their experiments.

The most convenient location for a trickling filter area would be at the Calf Pasture in Dorchester, near the present pumping station. This is objectionable, however, on account of its proximity to the thickly settled portion of Dorchester. Furthermore, the necessity for excavating about 10 feet of mud and refilling in its place would greatly increase the cost of construction at this point. The same objections apply to certain waste areas on the Neponset marshes which suggested themselves as possibly available. The headland of Squantum would offer an ideal opportunity for building trickling beds, but the difficulties of obtaining land in another town militate against the use of this site.

The southern portion of Thompson's Island would furnish a location free from all the objections to which the other sites are open. On an embankment 1,500 ft. long the sewage could be carried from Squantum across to the island, the effluent flowing back along the same embankment to the existing outfall sewer. The pumping station at Dorchester and the tanks and outlet at Moon Island could thus be used without substantial changes. Preliminary estimates of the cost of building 50 acres of trickling beds, 8 feet deep and equipped with the gravity distribution system, including the embankment with its two sewers, an efficient grit chamber, a reasonable purchase price for the necessary land, grading, stone filling brought to the island by water, con-

crete construction, and sprinklers, are in the neighborhood of $1,800,000.

If this capital sum were borrowed at 5 per cent. on a 25-year loan, the annual expense for interest and sinking fund would be $126,800 a year, paying off the entire cost in the 25 year period. As a matter of fact, the authors of the paper see no reason to suppose that at the end of this time the plant would not be good for another 25 years without substantial reconstruction. The cost of operation, including extra pumping and supervision would amount to $70,000 a year, bringing the total cost to about $200,000 a year, or $5.50 per million gallons of sewage treated.

The effluent from the trickling beds, wherever situated, could be further bacterially purified by disinfection with chloride of lime, at a cost of approximately $1.50 per million gallons, or $55,000 annually.

Pending the construction of filters for the removal of putrescible organic matter from Boston sewage, if it should seem desirable to secure bacterial purification, this may be effected by direct treatment of the crude sewage with chloride of lime, which could probably be done for $3.00 per million gallons, or $110,000 annually.

Experiments are now in progress at the Experiment Station to test the practicability of higher rates of filtration and shallower beds than those used in the experiments on which these calculations are based, as well as on the treatment of sewage and effluents by electrolytically produced chloride. It it hoped that these experiments may lead to a material reduction in the estimated cost of the purification processes. It seems clear, however, that the combination of trickling filters and chemical disinfection will solve the Boston sewage problem satisfactorily; and in the light of present knowledge these two methods are the most efficient and economical available for the purpose.

Book Notes.

A little pamphlet which will prove particularly useful to mill architects and others who use tin roofs to a considerable extent has just been issued by the joint committee on tin plates of the National Association of Master Sheet Metal Workers of the United States. The pamphlet gives a brief history of tin roofing, discusses its advantages, and then gives an excellent set of standard specifications, well illustrated, prepared by the trustees of the association after long study for the purpose of indicating the best method of securing the highest grade of material and workmanship in such roofs. There are also practical hints regarding methods of carrying on construction, published for the benefit of contractors. Copies of this pamphlet may be obtained by addressing the president of the Association, Mr. E. L. Seabrook, 2,213 Chestnut St., Philadelphia, Pa.

A second edition of "Tables for Engineering Calculations," which has recently been brought out by Mr. Richard C. Powell, is a revision and amplification of a hand-book which he compiled with Mr. Wm. E. Hawley some years ago. The new edition is about twice the size of the first and contains additional tables which the experience of the author and the criticisms of other engineers have indicated to be useful. The section on hydraulics has been compiled in large part by Professor LeConte, of the University of California, while the tables of rolled steel sections have been furnished by the Cambria Steel Co. The book is likely to be particularly useful to engineers engaged in hydraulic power work. About half of the book is made up of natural and common logarithms of numbers and trigonometrical functions, functions of natural numbers, an excellent collection of conversion factors, and other mathematical tables and formulas. The remainder is made up of information relating to the strength of materials, the properties of steam, and electrical and hydraulic data. Special care has been taken to arrange this information in a handy shape, and to check it to avoid errors. The object of the author has apparently been to bring together in a compact form the tables and formulas likely to be of general use in the office of a designing engineer, and to leave for the reference library such rules and tables as are required but rarely. (Berkeley, Cal., R. C. Powell, $2.00.)

A good many readers of The Engineering Record are probably aware that the French methods of designing walls, dams and barrages have received much study by specialists. A well-written presentation of the current opinions in that country on this subject will be found in the volume on "Barrages en Maconneric et Murs de Reservoirs," by Mr. H. Bellet, an engineer whose visit to this country about eighteen months ago will be recalled by a number of readers. The author first takes up the general problem of calculating the cross-section of a masonry dam and in the second chapter there is a brief discussion of the advantages and drawbacks of dams of different materials. Seven chapters are then devoted to a historical review of masonry dam design, beginning with the early works in Spain and France and then taking up in detail the profiles planned by eminent French engineers and carried out in one or more structures. This portion of the book is equally explicit regarding theory and actual construction, and will be found of particular interest to those who desire to become acquainted with the views that have been developed in France. Next there is an elaborate theoretical analysis of dams both straight and curved in plan, in which the author refers to similar work done by other French engineers and thus rounds out his own analysis in a comprehensive manner. This theoretical study is followed by a description of a large number of structures, mostly European, but including some American examples and a few from Great Britain. The practical design of dams is next taken up and attention is given to those features of design and construction not previously discussed. The volume closes with the regulations of the French government controlling the construction of dams and demonstrations of a number of the more important formulas in the work. It is unnecessary to critically review the mathematical work of the author in this volume, as it follows very largely the accepted French practice. Design of masonry dams of considerable height in France is based rather more completely on methematical analysis than is the custom in the United States, and for this reason the volume under review will be found a particularly interesting one. (Grenoble, France, A. Gratier & J. Rey, 8.25 francs.)

Letters to the Editor.

Sheet Piling and Earth Pressure.

Sir: In your discussion on Nov. 16 of the paper by Mr. J. C. Meem on "The Bracing of Trenches and Tunnels, with Practical Formulas for Earth Pressures," it seems to me that you have misunderstood his views in two points. You state that in the case of dry, sandy material he would employ "the generally accepted theory of earth pressure, the law of whose variation with the depth below the surface is similar to that of liquid pressure." As a matter of fact, Mr. Meem's paper does not admit at any time that earth and aqueous pressures are allied, although it agrees with the common theory of hydrostatic pressures in saturated soils. The opinion of the author of the paper also seems to be that the drier the sand the more it tends to wedge itself between the sheeting and the natural slope line and throw a series of arches to hold itself up. This also applies to the "internal cohesion" of the particles. It will be noticed that the author does not make much use of this arch action, except as increasing the factor of safety, but depends on the tightness of the sheeting and bracing to hold the upper masses of material in place while working below. Of course, there must be a theoretical movement, which gives what the author terms "external coherence" by tending to produce the wedging action above mentioned.

It seems to me that the theory of Mr. Meem gives results more in harmony with observed conditions than the older theories based upon assumed conditions in the earth that very rarely, if ever, exist. It is directly at variance with the theories of high authorities, approved by long use, but why should it not be accepted if it accords best with those conditions observed in practical work? Foundations.

Garbage Reduction in Toledo.

Sir: Referring to Mr. Cook's interesting article in your issue of Oct. 12, on the "Garbage Reduction Process at Toledo," I beg to suggest that, instead of saying "the garbage at Toledo, Ohio, is treated by the reduction process, etc.," you should change this to the past tense. Mr. Cook comments upon the commercial aspect of garbage reduction by mentioning the fact that a receiver had to be appointed to take charge of the company's affairs; but concerning the sanitary aspect of the system it may be of further interest to your readers to know that, in spite of the elaborate precautions which were taken to prevent offense from the workings of the plant, it was enjoined by the courts as a nuisance and went out of commission last July, since which time the city has returned to the primeval method of dumping garbage on farm lands.

When the city entered into this reduction contract (some three years ago), it looked as if it were a very favorable arrangement, as the reduction company agreed to receive and dispose of the garbage free of charge. But, owing to the fact that the reduction system was to be employed, it was found impossible to find an advantageous location for the plant, which was finally built so far from the center of production that the average cost of hauling the garbage to it has been, I am told, about $1.30 per ton; in contrast with which other cities have found it possible to conduct centrally-located incinerating plants at a less cost per ton, including both the collection of the garbage and its final destruction by a process which also enables the city to dispose of combustible rubbish, waste paper, etc., which a reduction plant cannot receive.

In my opinion, it is to the principle of destroying municipal refuse by fire that we must look for a satisfactory solution of this knotty problem, at least in all except our very largest cities, which still show some possible promise of producing organic garbage in sufficient quantities to cover the heavy expense and depreciation incidental to a reduction plant, when all conditions are distinctly favorable.

Yours very truly,

Toledo, Nov. 19. George V. Rhines.

Graphic Solution of a Problem in Hydraulics.

Sir: In a recent test in the Engineering Department of the University of Montana it was necessary to determine beforehand the exact distance to one-hundredth of an inch that a wooden ball, as shown in the sketch, would sink when placed in a measuring tank, as the gauge attachments for measuring the outflow of water were connected to this float. The ball was carefully designed and trued up to a 4-in. radius. The material of which it was made was wood found to have a specific gravity of 0.62. The dis-

tance z to which the sphere will sink when placed in water will be such that the exact weight of the displaced water will just equal the weight of the wooden sphere. The solution of this, however, leads to a cubic equation and a method of attack was then sought for that did not involve higher mathematics. The method as shown in detail will be found useful not only in solving any cubic equation, but, in fact, an equation of any degree whatsoever.

Let r be the radius of the sphere, which is 4 in.; w will be the weight per cubic foot of water, W be the weight per cubic foot of wood, and s be the specific gravity of the wood, which is 0.62.

The volume of a segment of a sphere of depth z is $\pi\ (rz^2 - \frac{1}{3}z^3)$. The volume of a sphere is $\frac{4}{3}\pi r^3$.

Since the weight of the sphere is equal to the weight of the displaced water, $\pi\ (rz^2 - \frac{1}{3}z^3)\ w = \frac{4}{3}\pi r^3 W$.

Clearing fractions and cancelling $z^3 - 3\ rz^2 + 4\ r^3\ s = 0$.

Substituting our particular values for r and s we have the following cubic equation:

$$z^3 - 12\ z^2 + 158.72 = 0.$$

The easiest way and the way that is sufficiently accurate for handling equations of this sort and of higher degree is to divide the equation into two parts, thus:

$$z^3 = 12\ z^2 - 158.72 \ldots\ldots\ldots\ldots\ldots \text{I.}$$
$$-y_1 = z^3 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \text{II.}$$
$$y_2 = 12\ z^2 - 158.72 \ldots\ldots\ldots\ldots \text{III.}$$

Now it is easily seen by looking at equation I that if we find a value of y_1 that makes equation II reduce to zero and an equal value of y_2 that makes equation III reduce to zero, this value when substituted in equation I will make it also reduce to zero. In other words this is one of the values of z we are looking for. In the diagram the two equations II and III have been plotted to the same scale with values of y as ordinates and z as abscissas. Now by looking carefully at the plot, we see that the two curves cross each other at three places. Hence each one of these values is a solution of equation I.

Scaling these off we find: $z_1 = -3.23$, $z_2 = +4.65$, and $z_3 = +10.58$.

As a check that these values are correct their sum should be equal to the second term in equa- I which is +12. As the sum of the above three values gives +12 we conclude that they are correct as far as they have been carried out, since there are no exact roots in the above equation.

The only possible value for our float is thus seen to be 4.65 in.

Robert Sibley.

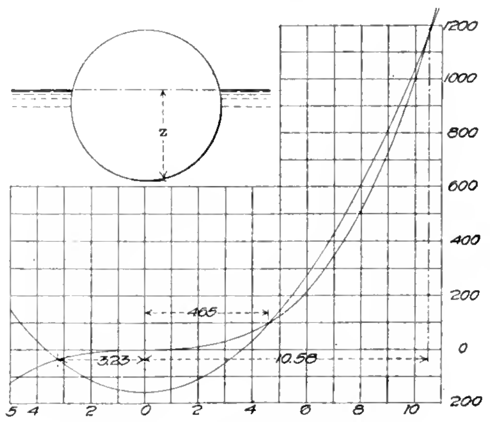
Missoula, Mont.

Treating Wood Paving Blocks.

Sir: In the paper on "Requirements for Treating Wood Paving Blocks" in your issue of Nov. 16 I find several valuable suggestions on a matter which, at this particular time, is attracting considerable attention in New York City, and I would like to add a trifle on this subject and also to correct a statement which appears in the paper to the effect that Brooklyn is using, or has used recently, the specification which is referred to in the table showing the comparative requirements of several cities as to class of timber used, treatment, etc.

Early in 1906 I found this Brooklyn specification for wood block, as quoted, in vogue. It was, I believe, Mr. Tillson's own specification, having been compiled for the borough in 1903. This old specification I promptly concluded to be defective, in that (1) No provision was made for seasoning timber for paving blocks; (2) "All heart" long leaf pine was required, which was not procurable except with great waste of material in cutting blocks; (3) In allowing no other class of timber to be used in competition with this high-priced timber; (4) In calling for treatment of unseasoned blocks with an antiseptic waterproofing mixture, of which 50 per cent. might be creosote of uncertain quality or specific gravity; (5) In using in this mixture 50 per cent. of resin, which is more costly than creosote and not of equal value as a preservative; (6) In allowing a variation of only one inch in the length of the blocks, thus adding to the cost and waste in cutting from merchantable timber and in allowing blocks as thin as 2½ in., which would tend to warp and check under traffic; (7) In making no provision for waterproofing the joints; (8) In bedding the blocks on an unstable mortar bed, composed of only one part of cement to four parts of sand; (9) In providing a concrete base only 4 in. in thickness.

In taking this matter up in Brooklyn I advocated the use of Southern black gum as a cheap alternative for long leaf yellow pine, and urged as a substitute for a light or volatile creosote oil a heavier creosote oil unmixed with resin, advocating also a waterproof joint between the blocks, which were to be laid on a thoroughly mixed and richer mortar bed, carried on at least



Solution of Hydraulic Problem.

5 in. of concrete as a minimum foundation, and I had the department chemist conduct tests of the heavy creosote oils so as to determine their value and permanency as a substitute for the lighter oils and resin called for in the old specification. Through my efforts in this direction, with the co-operation of Mr. Tillson, a specification was compiled in 1906, which has been in print for some time, containing the following requirements for wood paving blocks:

1. Well seasoned timber of long leaf pine, Southern black gum or tamarac.

2. An allowance of 10 per cent. for maximum volume of sap wood in blocks (which restriction should not, however, be applied to the black gum).

3. No blocks shorter than 6 in. or longer than 8 in., and no variation from the depth of the block or the width, so as to secure an even surface and close transverse joints throughout.

4. A straight creosote of 1.12 specific gravity at 68 deg. F., of which not less than 20 lb. to the cubic foot of timber is required.

5. A maximum absorption by a treated block of 3 per cent. when dried at 100 deg. F. in a ventilating oven for 24 hours. (This requirement, as Mr. Tillson says, is a valuable test.)

6. No burden on the contractor for cost of inspection at the works, the city to assume this expense directly.

7. A strong mortar bed of one part of cement to two and a half parts of screened sand, all carried on a 5-in. concrete base.

The comparison with the so-called Brooklyn specification seems unfair, as it had been obsolete for more than a year.

After many inspections of pavements of this class and visits to several block plants, it would seem that the defects in wood block pavements as produced to-day for the several boroughs of New York City are due in a great measure to the lack of selection and seasoning of the timber before treatment and to the steaming and softening of the fiber under a continuous high temperature, to which the raw block is treated under what the old Manhattan Borough specifications peculiarly designated as "dry heat, i. e.:

"In preparing the blocks to receive the creosote mixture they shall be placed in an air-tight cylinder, in which dry heat, or heat produced by superheated steam, is maintained and raised to a temperature of 215° Fahr., for one hour, for the purpose of expelling moisture; the heat is then to be increased until it has reached 285° Fahr., this heat being maintained for a period of three hours, or until the block is completely sterilized. Application of heat is then to be stopped and the temperature of the cylinder allowed to fall for one hour, or until the same has been reduced to 250°.

Some instructive tests on railroad ties and samples therefrom, conducted under Mr. Pinchot of the U. S. Forestry Service, indicate that in wood block treatment as practised by several of our producers to-day, where high temperatures are maintained in the impregnating cylinder carrying the green blocks, the great amount of comparative free water carried in the blocks gives a soaking or steam treatment for this long period of five hours, which has a permanent and deleterious effect upon the fiber. It must in effect be practically a steam treatment.

At the Yale Forest School this deterioration in strength of the timber has been noted, and it is found that if "the steam process has not been excessive" subsequent seasoning by a drying process will restore the greater part of the strength of the timber lost by the high steam treatment.

In the tests also of the Forest Service at the Louisiana Purchase Exposition it was found, with the original strength of loblolly pine ties taken at 100, the strength after 10 lb. steam pressure for a period of four hours, was reduced to 89 lb., and with 100 lb. steam pressure for four hours it was reduced to 41 lb. The increase in strength of seasoned or kiln-dried timbers is too well known to need comment. Re-soaking with water lowers the seasoned timber to a very material extent, but on thorough soaking with creosote the strength is but slightly reduced.

I note these features and the need of getting some more definite information on this subject than is at the present time at hand, and believe that radical changes will shortly ensue in the process of manufacture of city paving blocks. What we require is a thoroughly seasoned, thoroughly sterilized and waterproofed block of high compressive strength, but not too smooth on the end of fiber, with low cost as a first and last requirement.

I am of the opinion that Southern black gum will fill fairly well the need for competition against high-priced long leaf pine and greatly reduce the cost, with good results in durability on the street. Yellow pine specifications must be adapted to this new timber as to the amount of heart or sap, and as the specific gravity is less a properly treated block may not sink in water. Anything more than 20 lb. of heavy oil would seem to be an extravagant treatment, except for very heavy traffic streets, and some less expensive and perhaps inactive filler might be found as a substitute for resin, to be mixed with heavy creosote oil.

In some averages taken by me at the works, comparatively green long leaf pine and black gum timber, said to have been cut three months and exposed to dry weather, showed weights per cubic foot respectively of 51 and 59 lb. These

weights would be reduced in the pine from 51 lb. to perhaps 43 or 44 lb. and in the gum from 50 lb to about 38 lb. if blocks were actually seasoned before injection of the creosote. Tests we now have under way will shortly throw more light on the comparative weights of (1) green, (2) steamed and vacuum drawn, and (3) treated blocks.

A wise move has been made by the Municipal Engineers in an attempt to establish uniform highway practice throughout the city, several engineers of the boroughs acting ex-officio on this committee, and it is hoped that a thoroughly practical standard specification will be given out during this winter for the coming season, which will be alike beneficial to the city and to the manufacturer, in settling several vexing questions as to the necessary seasoning for raw timbers before treatment—as to the amount of resin, if any, and the quantity and quality of creosote oils necessary for the several classes of timber suitable for paving blocks.

Respectfully, R. W. CREUZBAUR,
Consulting Engineer of Public Works.

BROOKLYN, NOV. 20.

HYDRAULIC DIAGRAM FOR CIRCULAR PIPES.

SIR: In the accompanying diagarm, the results of the Hazen-Williams formula for flow in pipes, $v = c\ r^{0.63}\ s^{0.54}\ 0.001^{-0.04}$ are represented graphically. It is the writer's opinion that a properly prepared diagram has decided advantages over tables or even slide rules specially made for the formula. The relations of the discharge, slope, diameter and velocity are presented in the diagram instantly and clearly: and the effect of a modification of one of the factors on the values of the other factors is readily obtained.

In the above formula, c is a constant, the value of which is dependent on the character of the material of the pipe or conduit, and is independent of the mean hydraulic radius and the slope. It is, therefore, different from c in Kutter's modification of Chezy's formula. The other symbols of the formula are the same as in Chezy's formula; v = velocity in feet per second, r = mean hydraulic radius, and s = sine of slope.

A few problems will be given to illustrate the uses of the diagram. These will be followed by a brief discussion of the method of plotting the equation. Along the horizontal line, the grade of the pipe is given in percentages or in feet drop per 100 ft. of distance, along the vertical line the discharge for pipes flowing full is given in cubic feet per second; one set of inclined lines gives the diameter of the pipe; the other set gives the velocity in feet per second.

The diagram is based on a value of c equal to 100, and values of c for different kinds of material are given in the accompanying table. Judgment is required in the selection of the proper value of c.

TABLE OF VALUES OF c IN HAZEN-WILLIAMS FORMULA.

Class of pipe	c
Very best cast iron pipe	140
Good new cast iron pipe	130
Tuberculated cast iron pipe	80 to 110
New riveted steel pipe	110
Lead, brass, tin and glass pipe	120 to 140
Smooth wooden pipe	120
Brick sewers	100
Vitrified pipe	110
Smooth, clean masonry	140
Slime-coated masonry	130
Ordinary good masonry	120

It is required, for example, to find the size of a brick sewer flowing full for a discharge of 250 cu. ft. per second and a grade of 0.55 per cent. In this case $c = 100$. The intersection of an interpolated line of 0.55 per cent. grade with a 250 discharge line gives a diameter of about 5 ft. 8 in., and a velocity of 9.8 ft. per second.

What is the size of a vitrified pipe for a discharge of 45 cu. ft. per second flowing full at an 0.8 per cent. grade? In this case $c = 110$. It is evident that a smaller size than the one obtained from the diagram for 45 cu. ft. per second will suffice. Divide 45 by 110/100 and 41 will be obtained. Using 41 instead of 45 for the discharge in the diagram and a grade of 0.8 per cent., a diameter of 2.7 ft. and a velocity of 7.5 ft. per second will be obtained. The nearest commercial size of vitrified pipe would, of course, be used. The velocity 7.5 is to be multiplied by 1.1, for the real discharge is 45 and not 41. The velocity will, therefore, be 8.25 ft. per second.

A 6-ft. circular masonry conduit of ordinary good work at a grade of 0.3 per cent. is to discharge into three cast-iron pipes, two of which are to be of the same size, determine the sizes of the cast-iron pipes. For the masonry conduit $c = 120$, and for the cast-iron pipe $c = 130$. The discharge through the masonry conduit flowing full is $210 \times 1.2 = 252$ cu. ft. per second. The discharge through one 42-in. cast-iron pipe at a 0.4 per cent. grade is $60 \times 1.3 = 78$ cu. ft. per second; and through a 48-in. at the same grade, the discharge is $83 \times 1.3 = 108$. Therefore, two 41-in. pipes and one 48-in. will give a discharge of 264 cu. ft. per second. This combination of cast-iron pipes will more than take care of the flow from the masonry conduit.

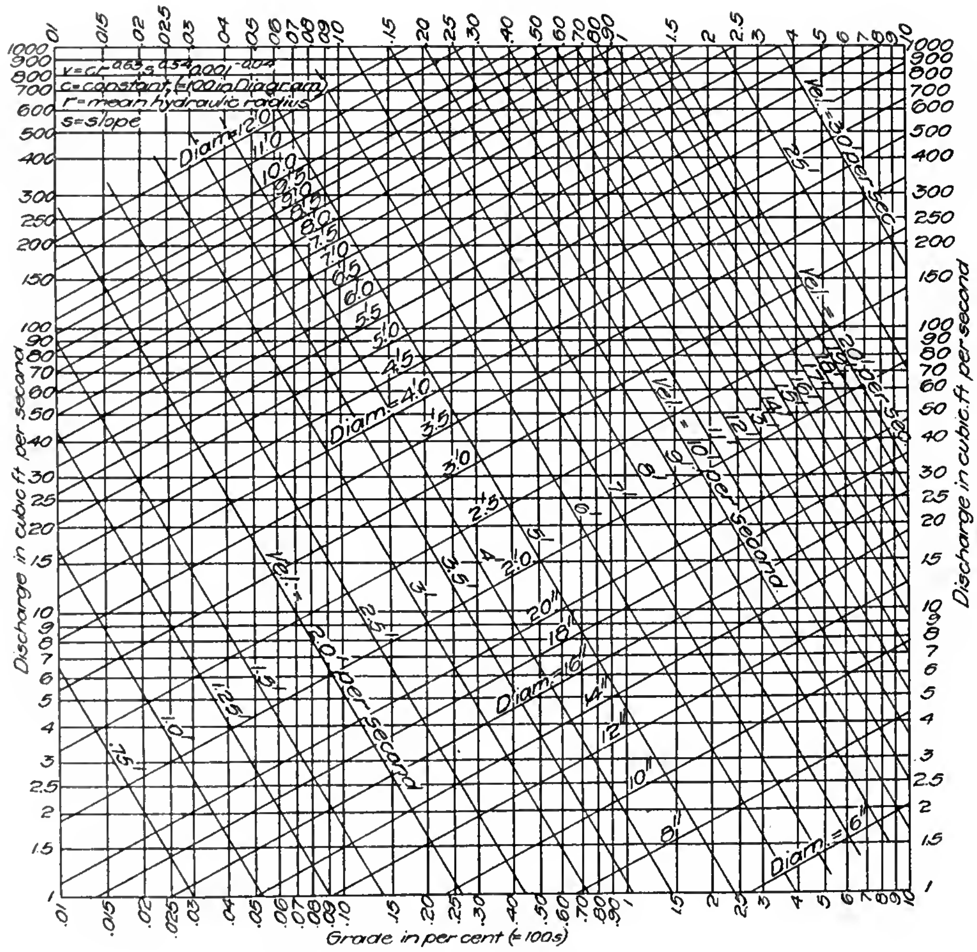
It will be noticed that the Hazen-Williams formula is exponential in form and lends itself readily to logarithmic computations. Advantage has been taken of this to employ logarithmic cross-sectioning for the diagram so that all lines will be straight and in parallel groups.

Multiplying the velocity v by the area A of the conduit in square feet, the discharge Q will be obtained in cubic feet per second. It is to be remembered, that the mean hydraulic radius r equals one-fourth of the diameter D of a circular pipe. $A = \frac{1}{4}\pi D^2$, $r = \frac{1}{4} D$, $Q = Av = \frac{1}{4}\pi \times 0.001^{-0.04}\ 0.25^{0.63}\ c\ D^{2.63}\ s^{0.54}$ in which D is given in feet.

The above equation reduced becomes, with $c = 100$, $Q = 43.23\ D^{2.63}\ s^{0.54}$. The logarithmic form of this equation $\log Q = 1.63580 \times 2.63 \log D + 0.54 \log s$.

This equation is linear in form. If, therefore, cross-section paper be ruled to a logarithmic scale in the same manner as the ordinary slide rule is divided, the relation between Q and s on this kind of ruling will be a straight line for any diameter. To obtain the straight line for $D = 3$ ft., substitute this value of D in the logarithmic equation, and compute two sets of values for Q and s. Plot these points on the logarithmic cross-section paper and connect them by a straight line. This line is the 3-ft. diameter line.

For instance, $\log 3 = 0.47712$ and $\log Q = 2.89063 + 0.54 \log s$.



Discharge of Round Cast-Iron Pipes.

For $s = .0001$; $\log s = -4$.
$\log Q = 0.73063$; $Q = 5.38$.
For $s = 0.10$; $\log s = -1$.
$\log Q = 2.35063$; $Q = 224$.

Plot the points ($s = .0001$, $Q = 5.38$) and (.10, 224) and connect them by a straight line to obtain the line for a diameter of 3 ft. The other lines can be obtained in the same manner. It will be noticed that all these lines should be parallel.

The velocity lines can be obtained in a similar manner from an equation giving the relation of Q, v, and s. Or the diameter lines can be used to obtain the velocity lines by help of the relation $Q = Av$. The velocity lines will also be parallel to each other.

Very truly,
SAMUEL D. BLEICH.

NEW YORK, NOV. 16.

[Similar diagrams giving the discharge in gallons were printed in The Engineering Record of June 20, 1903.]

THE ENGINEERING RECORD
PUBLISHED WEEKLY BY THE
McGraw Publishing Company
James H. McGraw, Pres.; Curtis E. Whittlesey, Sec. and Treas.
MAIN OFFICES:
239 WEST 39TH STREET, NEW YORK.
BRANCH OFFICES:
CHICAGO: Old Colony Building.
PHILADELPHIA: Real Estate Trust Building.

SAN FRANCISCO: Atlas Building.
LONDON OFFICE: Hastings House, Norfolk St., Strand.

SUBSCRIPTION RATES.

United States, Cuba and Mexico..........$3.00 a year
Canada ....$4.50 a year
Foreign subscription.....................$6.00 a year
25 shillings. 25 marks. 31 francs.
Foreign subscriptions may be sent to our London office.

NOTICE TO ADVERTISERS.

Changes in advertisements intended for a particular issue should reach the office of THE ENGINEERING RECORD on Friday of the previous week. New advertisements can be received up to noon of Wednesday of the week of issue.

NOTICE TO SUBSCRIBERS.

REMITTANCES.—Remittances should be made by check, New York draft, or money order, in favor of THE ENGINEERING RECORD.

CHANGE OF ADDRESS.—The old address should be given as well as the new, and notice should be received a week in advance of the desired change.

BACK COPIES.—No copies of issues prior to July, 1906, are kept on sale, except in bound volumes.

DATE ON WRAPPER indicates the month at the end of which subscription expires. The sending of remittances for renewal prior to that date will be much appreciated by the publishers.

CLUB RATE.—In acknowledgment of assistance rendered by subscribers in the securing of new orders, a club rate of $2.50 per annum is quoted. This rate applies to subscriptions in clubs of two or more, at least half of the names in the club to be those of new subscribers.

Entered at the New York Post-Office as Second Class mail matter.

Of this issue of THE ENGINEERING RECORD 16,000 copies are printed. Total circulation for 1907 to date 718,000 copies, an average of 14,653 copies per week.

TABLE OF LEADING ARTICLES.

The Abuse of Cost Data.

A contractor of many years' experience on large work, whose father and grandfather before him had also been contractors, recently declared publicly that if a man could prognosticate accurately the cost of proposed construction undertakings, that man could command remuneration which would soon make him a prince even among the very wealthy. In the same connection it was also affirmed by more than one man of wide experience that it was absolutely impossible for any man to tell the cost of any large proposed engineering work until it was completed, and even then it was not always possible to determine the cost accurately in detail. Such statements doubtless will at once excite the interrogatory convolution of the brain of many a younger member of the profession, and of some also who can count some score of years since first they carried the rod. In these days there is a growing tendency in some quarters to place dependence upon cost analysis methods and records of cost data, to an unwarranted degree.

As a commentary upon methods of making estimates for proposed civil engineering works the testimony presented at hearings concerning the Ashokan dam contract now in progress in New York City has more than passing interest. As explained in some detail last week in The Engineering Record, this contract was awarded on the basis of unit prices and the engineers' estimated quantities to a bidder whose tender was about two and a third million dollars higher than the lowest bid. Although within the clearly prescribed power of the Board and by no means an unprecedented act in principle, the award elicited criticism from local newspapers, and in course of time the investigation now progressing was instituted by the Commissioners of Accounts. Investigations are an inevitable and necessary feature of public affairs, and their value in showing good as well as bad administration is important, provided the examination is a fair one. That the present investigation of the Board of Water Supply is proceeding along questionable lines seems to be the opinion of those who have attended the meetings and do not judge the testimony from the incomplete newspaper reports solely.

The engineers of the Board believe that the lowest bid was much below the reasonable probable cost of the work, and the investigation practically hinges on the value to be placed on their judgment. The Board held that the low tender of the lowest bidder and its inexperience in the class of work covered by the contract, consisting largely of rolled earth embankments for large dams, was deemed sufficient reason for the award made to a higher bidder, for records of many cases under similar circumstances showed that delay, additional expense and much other trouble had resulted from giving the contract to the lowest of all the responsible bidders. The construction of the dams within the time stipulated in the contract is highly important, because the additional water is urgently needed by the city. The president of the company which made the lowest bid, who was abroad at the time of the bidding, subsequently stated that he believed his tender was too low, but his engineer stood by his figures and testified that he estimated there would be something over two million dollars gross profits.

Quite naturally the technical features of the controversy hinge upon the ability of engineers and contractors to estimate with some degree of accuracy the cost of large works extending over a period of years; there may be political considerations back of the investigation that have not yet been made public. The three engineers hired by the Commissioners of Accounts to help them in the investigation are strong advocates of the cost-analysis method of estimating. On the contrary, the chief engineer of the Board testified that he believed published cost data, with their usual meagre statements of conditions, were exceedingly unreliable bases for important estimates. For work like that under discussion, he could make a safe estimate only by exercise of judgment trained by his long experience in this class of work, guided by a knowledge of the total unit costs of the most important items, gained from completed works with which he had been personally connected or with which he had intimate knowledge. He further testified that he had made many estimates of the cost of work in this way which had been closely confirmed by the actual total cost of the work when completed.

According to testimony during the investigation, the lowest bidder's estimate seems to have been made by one engineer and to have been merely reviewed by two other persons, one of whom checked it by aid of published cost data. In sharp contrast were the methods of the second bidder to whom the contract was given. Great care was exercised to have the work studied thoroughly, but quite independently, by several members of the associated concerns and their engineers, one of whom was specially retained for this purpose. On the fourth day prior to the date for receiving bids by the Water Board, a meeting of these parties was held and six independent bids submitted to the president of the company, just as if he were to award the contract. All of these bids were higher than the bid finally submitted to the Board. Then followed a discussion, with very brief interruptions for sleep and food, lasting until the morning of the day for depositing the bids. The reduction made in the final bid, as compared with the preliminary estimates, was determined upon principally because the company had over a million dollars' worth of suitable plant immediately available. The successful bidders testified that they had used only records of cost of completed works done by themselves or with which they had been connected, comparable to the work in hand, and that even these records had been applied with very careful exercise of judgment after learning as much as possible of the conditions surrounding the proposed work.

Altogther much testimony of a very positive tone was given by men of great experience as engineers and contractors as to the great hazard in using published cost data or similar information borrowed from other persons unless one had thorough personal knowledge of the works to which the information referred. Only the contractor, except in rare cases, can know the total cost of completed undertakings, and he frequently does not keep sufficiently complete records to permit detailed analysis of unit costs. Much less can a young engineer or inspector, by occasional observations or daily force account records, get at the real cost of the items of any large work on which he may be engaged, although he has the closest personal contact with it. There are a number of elements of cost, large in the aggregate, that cannot be detected by such observation. Contractors bid on much work which they do not get; it frequently costs thousands of dollars to prepare a safe bid on a large undertaking. At least a small nucleus of an organization has to be kept constantly, whether there is much business or little in the office, for such men are selected largely for compatibility and other personal qualities and cannot be easily replaced. Interest on deferred payments and on investment in plant, insurance of men and plant, losses due to delays or failures of supply dealers, and accidents must all be covered. And there are many other elusive factors in the total cost. To these must be added the so-called general office and administration expenses of the particular work. In view of these facts, refined analysis of the cost of labor and materials for masonry or earth work, for example, when labor and materials constitute but fifty to seventy per cent. of the total, is of questionable service, since the remaining and large element of the price to be used in the bid or estimate is not susceptible of close determination and is inevitably a matter of judgment, in large part.

The gathering of information about the cost of engineering works in detail is to be encouraged, but the notes must contain very complete

statements of conditions if they are to be used for estimating the cost of proposed construction. The likelihood is that, after all, they will be safely useful only to the men connected with the work on which they were made. In many lines of manufacturing and in a few kinds of engineering, the cost in detail of the various processes or acts entering into the finished product can be determined, by suitable records, with all necessary accuracy; but the number of dips a minute a steam shovel can make may have very little to do with the rate of progress or the cost of a large job of excavating, and the number of feet a minute a steam roller can travel may have still less to do with the cost of a large rolled earth dam. Such information is useful for the suggestions it gives concerning methods of increasing the efficiency of a working force, but it should no more enter into estimates of the cost of great undertakings like the Ashokan dam and dykes than the cost of lead pencils should be considered in the expense of preparing the plans for such works.

Improved Waterways.

The cry that is going up from most parts of the country for improved waterways would indicate that there are a number of people who must have water on the brain. If the history of means of transportation teaches anything it is that waterways are unexpectedly costly to construct and peculiarly uncertain as to returns. Those who talk so glibly about constructing canals and improving rivers at the public expense in order to supply competition to railways, overlook the fact that the railway has one tremendous advantage. It can overcome grades and force itself across country in a way that no canal possibly can. The grades that are possible for a canal are necessarily flat, it is often extremely difficult to provide locks where they are most needed, and in some cases the problem of supplying enough water for navigation has itself proved an insuperable obstacle to construction. Then, again, when the waterway has been completed it is unsuited for handling anything but slow freight. It is out of the question to make fast time on such narrow channels; even if boats are put upon them which have the power to make good speed, the wash they set up is so great that the banks are severely injured. On wide rivers this condition does not exist, but there is a limit to speed there which is set by the necessity of providing enough cargo space to make the boat pay a profit. This condition has practically done away with the old river packet which made fast time, and it is only in a few localities, where the travel is large in volume and can be done at night, that boats can hold their own for transporting passengers in competition with railways. The internal waterways problem is, therefore, essentially one of transporting freight, and must be approached from this point of view.

A great deal has been said about the competition which waterways will offer to railroads. This really seems more theoretical than actual. The trunk line railroads to-day are hard pressed to handle their business, at least those lines which would be, in a sense, paralleled by improved waterways. If much more business comes to them they will have to spend enormous sums for further improvements. It seems to be the general belief among railway men at the present time that what is most needed is the improvement of existing facilities, more side tracks on single-track lines, better terminals, the elimination of dangerous grade crossings, improved rolling stock, and things of this nature. Such improvements will enable the roads to take care of all the high-grade freight requiring fast movement that is likely to come for some time. The increase in this kind of freight seems likely to be steady. If waterways can be constructed which will handle the low-rate bulk freight which is actually a burden on some roads, so much the better for the lines in question. Leading railway officers unquestionably express their full belief, without reservation, when they endorse reasonable projects for internal navigation improvements, as they have done with practical unanimity during recent years.

Although these internal waterways can be considered only as partial competitors of railroads, and their merits on that score are problematical, they nevertheless have such important advantages as to merit the attention they are receiving from those who are approaching the subject from a sane point of view. The construction of an improved waterway is like any other transportation problem. It is necessary to look far into the future, to estimate the growth of the population in all the regions tributary to this waterway, to forsee the character of the products which will be produced there and the nature of the goods which must be imported into this region. It is necessary to study the types of vessels which seem likely to be suited for carrying freight on the waterway. Finally, it is necessary to go into the cost of the proposed work in careful detail, in order that the expense of providing the waterway may be fully understood before any work is done. When a project is approached in this thorough manner, it becomes one of such complication that most of the advocates of improvements of this nature either lose heart or are contented to deal in mere generalities. Most of the agitation which is being conducted at the present time has reached this stage. It is now a matter of either hard work or hot air. The Engineering Record is a sufficient believer in the value of improved waterways to hope that hard work will be done. We really know very little, speaking generally, in this country, concerning the important details of improved waterways, vessels best suited to navigate them, and such technical matters. Whatever work of this sort is done should be conducted, in most cases, by the Government, and this journal believes that Congress would do well to give the Chief of Engineers, U. S. A., an ample appropriation for a thorough investigation of the problem. This would require capable assistants, some of whom would have to make careful studies in Europe, and it would entail several years of investigation. The importance of the result, however, fully warrants the expenditure. Without some such thorough investigation, we are all groping in the dark at the present time.

The Evolution of Interurban Lines.

The growth of electric interurban lines in the last ten years has been of the most extraordinary character. Starting as mere extensions of urban lines, the electric roads felt their way out into the suburbs and then, growing bolder, began to take up the work of ordinary railways. There has been no sudden creation of an interurban species; it has developed by orderly evolution into what it is. A road which went into operation about a month ago, the Milwaukee Northern, is an excellent example both of the resulting product and of the variations which, unless suppressed by natural selection, may form a further stage of the evolutionary process.

To begin with, the road has reached out northward from Milwaukee about 30 miles and extensions are in prospect that will carry this distance to more than 100 miles. The country thereabouts is, as everyone knows, rich in small cities and large towns capable of giving large local and through traffic, just such a country, in fact, as twenty years ago would have tempted the capitalist to the construction of another steam railway line. To-day the motive power is changed, but in other respects the work has gone on by the usual methods of railroading. In other words the time has come when, given the economic need for a railway, it is built up to the proper standards of construction and the motive power is chosen on its merits.

The Milwaukee Northern owns its right of way, save in passing through cities, and has put in a good straightforward piece of railway construction, differing in no essential features from the standards of the best steam railway practice. It has a solid, well-ballasted roadbed, laid with standard 70-lb. rails in the main, and has kept rigorously to low curvature and low grades. The day has past when electric railway builders went in for sharp curves and 10 per cent. grades just to show that the motor cars could negotiate them. There is, too, a general absence of grade crossings and all the difficulties they entail. The electric construction along the line presents nothing out of the ordinary.

The most striking feature of the road is its power station at Port Washington. It is the first considerable electric plant for railway purposes worked with gas engines and producer gas —indeed the only large one which relies solely on this source of power. The only other gas engine railway stations are the Warren & Jamestown plant and the auxiliary stations of the Boston Elevated Railway, and these are not only much smaller than the Port Washington station but are not essential features of the Boston system. Indeed, from all accounts, it is rather likely that the latter are considered unimportant, for, while fairly successful, it has been no small task to get them into working condition, and there are no symptoms of any increase in capacity of this particular kind. The Port Washington station has its experience yet to acquire, and it is to be hoped that it will be altogether satisfactory. The plant consists of three 1,000-kw. Allis-Chalmers generating sets, designed for a large over-load capacity.

The engines are of the twin tandem horizontal double-acting type, with an ultimate capacity of more than 2,000 h.-p. each. One of them was described in the Current New Supplement of this journal on Aug. 24 of this year. The cylinders are 32x42 in., and operate at 107 r.p.m. The engine frames are arranged for side cranks instead of double throw cranks, a plan very unusual for large gas engines. These engines are supplied with gas from two Loomis-Pettibone units, each including a pair of producers with their accessories and rated at 2,000 h.p. per unit. The coal employed is Hocking Valley bituminous slack, having a thermal value of about 11,500 B.t.u. per pound. The resulting gas as drawn from the holders is of about 125 B.t.u. It is claimed that the producing system delivers in the gas 80 per cent. of the thermal value of the coal. If this figure is substantiated, it puts the producer on a considerably higher plane than the steam boiler as a thermal intermediary between fuel and engine.

No details of engine performance are yet available. Experience with big gas engines in this country has been quite varied, but upon the whole fairly encouraging. The opinions of engineers are much divided, some holding that gas engines are the coming motive power and others that they are uneconomical unless waste gases are available. Abroad a good degree of success seems to have been the rule, and the number of installations now going in on our own side of the sea shows that confidence is not wholly lack-

ing here. Yet there is a singular lack of definite data from American practice, which gives one a certain feeling of insecurity. Recent steam turbine performances have come so near to the best gas engine figures for fuel consumption per kilowatt-hour as to leave very little room for difference in fixed charges and maintenance as against the gas engine. It is to be hoped that figures from this big new plant will soon be available to show whether the gas contingent has been able to peg up the record a notch.

The Milwaukee Northern is doing by electric traction and from a gas-driven generating plant the regular work of the older steam railroad, and so far as all appearances indicate it is doing it better. Certainly it is doing it better from the standpoint of the patron, since the highest cash fare is but 2 cents per mile and mileage books bring the rate down to 1.3 cents per mile. An interesting feature of the traffic situation is that under the franchise provisions the Milwaukee Northern is obliged to sell eight tickets for 25 cents, good within the city limits. Cash fares are 5 cents, as usual. Now the company runs its city cars about a mile beyond the city limits and it has promptly toed the mark by making these tickets good for the whole city-car service, which extends to 4.3 miles. This comes pretty near to a record low fare and it certainly is enough to give a steam railway man the cold shivers. Of course the proposition is not so formidable as it looks. There are at present but four strictly city cars in service and the through cars can be depended upon to show ample earnings. It has often been the experience on interurban lines that the near suburban and urban work amounts to very little, and on a road like the present, with a long run and good population along it, the lowered fare within the city should cut a comparatively small figure in the balance sheet. As far as American data go eight tickets for a quarter is a figure just too low to be practicable even for strictly city work. Fortunately the Milwaukee Northern is unlikely to suffer much from this cause and has ample traffic in sight.

Working Stresses for Long Span Bridges.

It has never been an easy matter to determine properly the greatest permissible unit stresses in the members of bridges and other structures of moderate spans and ordinary dimensions, to say nothing about those structures of such unusual magnitude as to make that determination still more difficult. The stresses in an ordinary bridge structure for any prescribed moving load are easy to determine with a high degree of accuracy, if the load be considered static, and it is easy to go still further and fix a reasonable allowance for shock or the assumed effect of a rapidly moving load. After having determined these stresses, however, the real difficulty begins. While we may assume the greatest permissible stress per square inch in the material for both tension and compression members, the rational defence of such stresses against reasonable criticism requires far more consideration than at first sight seems necessary.

In the early days of bridge building the greatest working stress was ostensibly one fifth of the ultimate resistance, but that was a technical fiction which quickly disappeared in favor of a so-called safety factor of four; and even this latter value has attached to it considerable doubt. In order that a fractional value of the ultimate resistance of a member of a structure may acquire significance, that ultimate resistance must be known. There has been almost an endless number of tests of eye-bar tension members, but almost none at all of steel compression members or columns. As a matter of fact, the tests of eye-bars, even those up to 15 in. in width, and of other tension pieces, have disclosed fairly full and accurate knowledge of this class of structural members, showing that one-fourth of their ultimate resisting capacity is generally materially less than the allowed working stress. This difference, however, is not of great importance, a sufficient margin of safety existing in any event, but the case is radically different when compression members, as well as some important details are involved. So much investigating attention has been devoted to the testing of tension members that it has been quite forgotten that we know comparatively little about the ultimate carrying capacity of both upper chord sections and intermediate and end posts of the ordinary truss bridge. The failure of the great compression members of the Quebec bridge has directed public attention so intensely to this whole matter of the carrying power of built columns that experimental investigation as to this particular feature of design is likely soon to develop results of the highest value. In the meantime, nobody actually knows what safety factor exists in the built columns of any railroad bridge, even of moderate span. It is reasonably certain that the actual carrying power of these members, instead of being four times the greatest load coming upon them, is somewhat less, and possibly it does not exceed three times the actual load carried in some cases.

While these observations are directly pertinent to short-span bridges they bear with special force on the design of long-span structures. This arises from a number of causes. In the first place, the magnitude of the members required for a great bridge truss so far exceeds that of the ordinary bridge member that it is an open question whether inferences as to actual carrying capacity can be accurately drawn from tests of small sections for the larger. It is generally assumed that such inferences may safely be drawn, and that process seems reasonable. At the same time every thoughtful engineer who has this duty to perform frequently reflects most seriously whether, after all, he is proceeding along lines which can be effectively defended. And this statement is made entirely without reference to the fact that the elastic and other physical properties of the thick metal and heavy shapes and plates of the long-span pieces justify materially less working stresses than the thinner and lighter sections of short-span structures. This latter consideration is probably never permitted to affect the value of long-span working stresses, although probably no test of full-size structural pieces ever failed to indicate its importance. If a testing machine of great capacity ever becomes available for tests of compression members of comparatively great area of section, the importance of this feature of heavy section design will be fully recognized.

On the other hand, it is obvious that the long-span structure is far less likely to receive frequently its full loading than the short-span bridges. This condition in itself justifies the use of higher working stresses than would be permissible for a bridge whose length is so short as to cause its maximum loading possibly many times a day. While this is clear enough, it is not sufficiently obvious just how far the influence of this condition may be permitted to reach.. This, like many other highly important engineering questions, must rest wholly upon the judgment of the responsible engineer. The prevailing practice in the past, both in completed structures and in the design of some great projects not actually executed, appears to indicate that no main piece of any long-span structure should, under any conditions of loading whatever, be stressed more than one-third of its ultimate carrying capacity. When the many exigencies of manufacture, erection and use after completion are kept in view, such a limit certainly does not provide more than reasonable safety. When it is further reflected that engineers at the present day really possess little exact knowledge of the actual carrying capacity of one of the great classes of bridge members, the danger of adopting a working stress of but little less than half what may reasonably be anticipated to be the ultimate resistance can be appreciated, especially when one large element of the moving load is entirely neglected. Some fundamentals of long-span working stresses require most careful consideration and re-statement, and there is need of further experimental investigation as to the carrying capacity of large compression members.

The New York Subway report, which Mr. B. J. Arnold submitted to the Public Service Commission, is a particularly interesting document to the engineer. The subway trains are now jammed full of people during rush hours, and from time to time assertions are made that this crush is due to defective engineering work in designing the road or to negligence of the operating company to run enough trains of enough cars to handle the traffic. When the Public Service Commission assumed office and first investigated subway conditions, it decided that more cars were needed and directed the Interborough officials to buy them. When it was discovered that the company had already ordered these cars some months before the Commission was appointed, the latter body recognized that the problem was a pretty big one. It accordingly determined to supplement the advice of its own engineers with the counsel of Mr. Arnold, whose long study of intricate transportation problems in Chicago made him particularly fitted for such duties. In his preliminary report, printed on another page of this issue, he has nothing but praise for the subway and its operation, a decision to be expected but none the less gratifying as the judgment of a well-qualified critic never before connected with the enterprise in any way. The subway has almost reached the limits of its capacity, and the problem of carrying more people in it is one of policy and not of engineering. This journal believes that very rarely has an engineer so concisely and clearly demonstrated such a condition. If more people are to be carried, it will be necessary to reduce the number of seats, make more people stand in the cars, and manage the crowds on the station platforms more strictly. The Public Service Commission must accordingly make a serious decision itself, the responsibility for which cannot be delegated to its engineers. It is gratifying to see such a problem put directly into the hands of that body. But the main lesson of the report is that New York greatly needs more rapid transit lines, a fact reiterated many times by those familiar with transportation in the city. The tremendous cost of these roads is such that the city cannot well finance them for some years with its other great obligations, while no terms yet proposed by the city will attract private capital. The problem is a serious one to those who are obliged to struggle to and from their work in the present packed cars, and if the city cannot afford relief it would be wise to allow private capital to build at least one line even if the terms are not so favorable to the city as the municipal authorities desire. The necessities of the public should receive some consideration in discussions of such a complicated problem. At present the crowds on the trains are so great as to offend every sense of public decency.

Main Locomotive Shop, Missouri, Kansas & Texas Ry., Parsons, Kan.

SOME ENGINEERING FEATURES OF THE PARSONS SHOPS OF THE MISSOURI, KANSAS & TEXAS RY.

The Missouri, Kansas & Texas Ry. operates over 3,000 miles of track from St. Louis and Kansas City to an important Gulf terminal at Galveston. The company has over 20,000 cars and between 600 and 700 locomotives, the greater part of which is good equipment. Its maintenance is conducted at two small shops in Texas, at the Sedalia car shops and at the locomotive repair shops at Parsons, Kan., a city favorably located for division headquarters of the lines north of Texas. The old shops there became entirely inadequate for their work, and an entire reorganization of plant and methods was ordered. It was decided to locate the new shops on a 30-acre triangular tract close to the old site, so that when the latter was abandoned, the buildings could be utilized to a certain extent at least for car repairs.

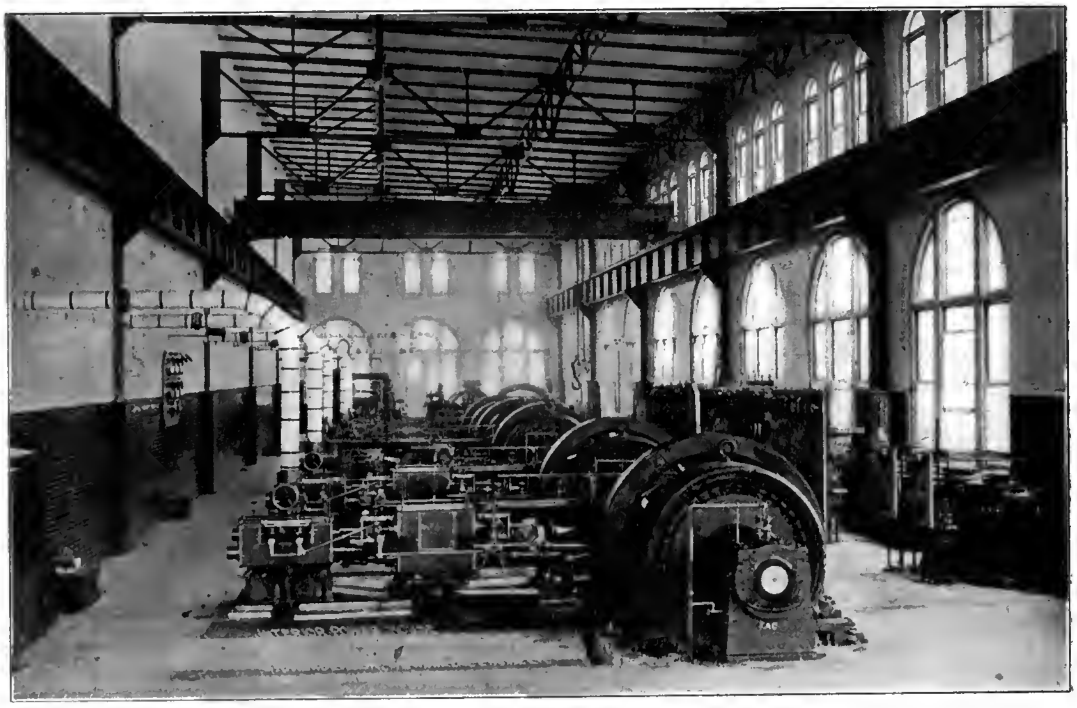
The shops provide for the maintenance of all locomotives of the lines north of Texas and also for a limited amount of manufacturing for other departments, together with ample provisions for considerable future growth. There are now operated on these lines between 350 and 400 locomotives, a considerable portion of which are large heavy-powered engines. The repair-work schedule on which the shops were designed provides for a general overhauling of approximately one complete engine per day, together with a considerable amount of manufacturing and auxiliary work. It was decided that this can be accomplished most efficiently in a single large shop building for the dismantling and erecting of both engines and tenders and also for all machine shop work, while a separate building is used for the blacksmith work. The longitudinal pit-track type of erecting shop was chosen as best adapted to the available yard lay-out and best suited to the character of the work to be handled. The improvement scheme does not include a reorganization for the present of the car repair shops of the northern lines, which are located at Sedalia, Mo., but the new organization and power scheme will permit the addition of large car shops without change.

The large main building is a steel structure 860 ft. long with a 78-ft. center bay and two side bays 153 ft. 9 in wide. The blacksmith shop is a 100x250-ft. steel structure, the power house is 84x215 ft., and the store house and office building, 60x150 ft. There are several small auxiliary buildings, a 500,000-gal. 50x150-ft. water storage reservoir, and a group of fuel oil tanks. The space actually occupied by the entire shop group is 450x1,300 ft. over all, which is exceptionally small for a plant of this capacity. The longitudinal track arrangement of the main shop simplifies the yard lay-out considerably, the total length of yard track devoted to shop purposes amounting to only a little over 3,000 ft.

Fire Protection.—The building layout has been studied with considerable care for fire-protection and provisions made for dealing with a fire very effectively before the city fire apparatus arrives. Direct pressure in the mains is furnished by pumps in the power house drawing from the city works, with the 500,000-gal. reservoir in reserve, and delivering through 8-in. mains encircling the shop group, with hose reels within the buildings and hydrants and hose houses distributed over the yard. Local fire signals have been arranged and provisions made for quickly raising the pressure in the mains. Fire roadways run throughout the yard surrounding the main building and lead to all large hydrants having steamer nozzles, to enable the city fire engines to be put in action rapidly. Special orders are given the yard crews to keep these roadways always clear of cars.

There are 18x10x12-in. Fairbanks-Morse duplex steam pumps in the engine room of the power house. The main source of water is an 8-in. metered service to a 10-in. city main leading to the reservoir, and there is also a suction connection to the reservoir. The suction main is 16 in. in diameter and has a by-pass to the 12-in. pump discharge to permit admitting city water into the shop mains in case it is desired to shut down the pumps. One pump is always kept in operation on the shop service, being fitted with a Fisher governor set to maintain the water pressure at 100 lb. The other pump is fully connected up and kept with its throttle valve open a mere crack. By this arrangement the pumps will continue in motion very slowly, but at such a rate as to insure their being kept hot and always ready for instant service. In case of fire the throttle on the second pump is opened and the governor disconnected from the first, allowing both pumps to furnish their maximum pressure.

The pumps discharge into the yard mains through a 12-in. pipe which connects about 50 ft. from the power house with a 10-in. main that feeds three longitudinal 8-in. service mains, one on either side of the main shop, and the other at the rear of the blacksmith shop, the power house and the store house. The central 8-in. line is extended several hundred feet beyond each end of the main building and all three lines are cross-connected at each end of the large shop. From the southerly end of the system a 6-in. connection is extended across the yard to connect with the water system of the round house and old shops, which are now to be used for car repair work only. There are sixteen hydrants installed along the line of the fire roadways to the yard, eight of which are plain two-way hydrants for hose while each of the remainder have two 2½-in. hose nozzles and one 4-in. steamer nozzle.

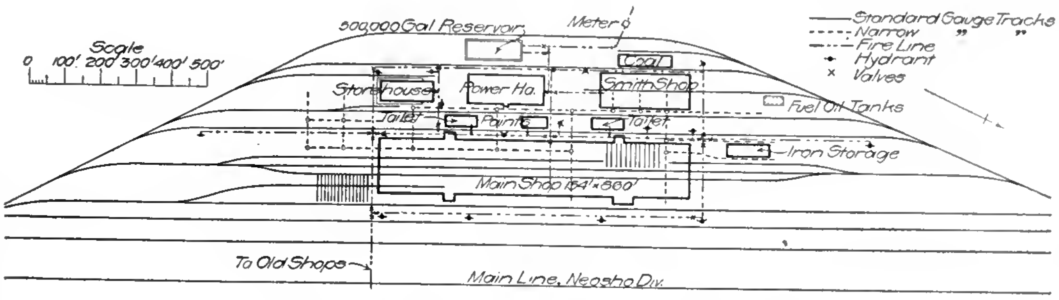


Engine Room of the Power Plant at the Parsons Shops.

Heating.—The buildings are heated with low-pressure exhaust steam from the power plant, supplemented by live steam at reduced pressure, when necessary, with hot-blast heating in the main locomotive shop and direct radiation in the store house, office building and auxiliary buildings. The heating requirements are, however, comparatively moderate at Parsons owing to its southerly location, for which reason no direct radiation was installed in the main shop or in the blacksmith shop, and, in fact, no heating of any kind was provided in the latter shop for service in the daytime owing to the warmth from the forges and furnaces; in this building a limited amount of heating is provided for use at night-time and on holidays, to prevent freezing in severe weather, by diverting the hot blast delivery from one of the heating stands of the main shop. The low-pressure steam supply is distributed by mains through the underground piping tunnels which connect the power house to various buildings, a 5-in. heating main extending from the exhaust header in the power plant to the store-house and office building and a 16-in. main to the main locomotive shop building.

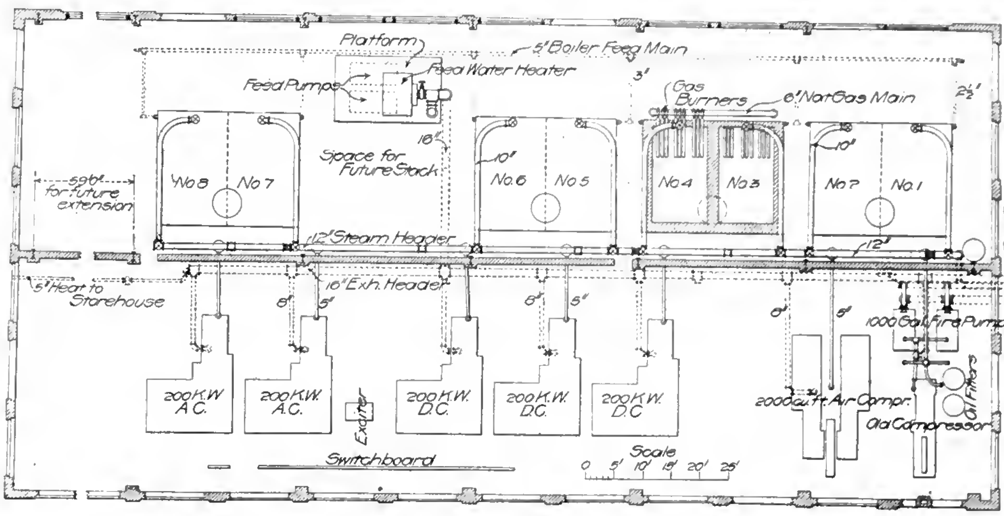
The main shop is served by four separate hot blast equipments. The blowers and heaters are of unusual size, and located in 20x26-ft. fan houses outside the walls of the building, there being two on each side at quarter points of the building. These houses open directly into the main shop, from which the fans draw their air; large windows are provided to supply fresh air when it is desired to run the fans for ventilation during hot weather. Sturtevant steel plate centrifugal fans are used with three-fourth down-

ward discharge housings and 9-ft. wheels 44 in. in width. Each is direct-driven by a 9x12-in. Sturtevant horizontal engine running at 180 r.p.m, at which speed the blower has a capacity of 57,000 cu. ft. per minute. Each engine receives steam through a 3-in. connection to the high pressure pipe from the power house and exhausts through a 3½-in. connection directly into the main which supplies low pressure steam to the heating stack. There is also an auxiliary 3½-in. connection for carrying the exhaust from the engines to the outside in case it is desired to operate the engine when heating is not required. The heating stacks are located in 10x12-ft. casings connecting with the fan intakes and each consists of four sections of Sturtevant heaters, containing 8,000 lin. ft. of 1-in. pipe.



Plan of the New Locomotive Shops at Parsons.

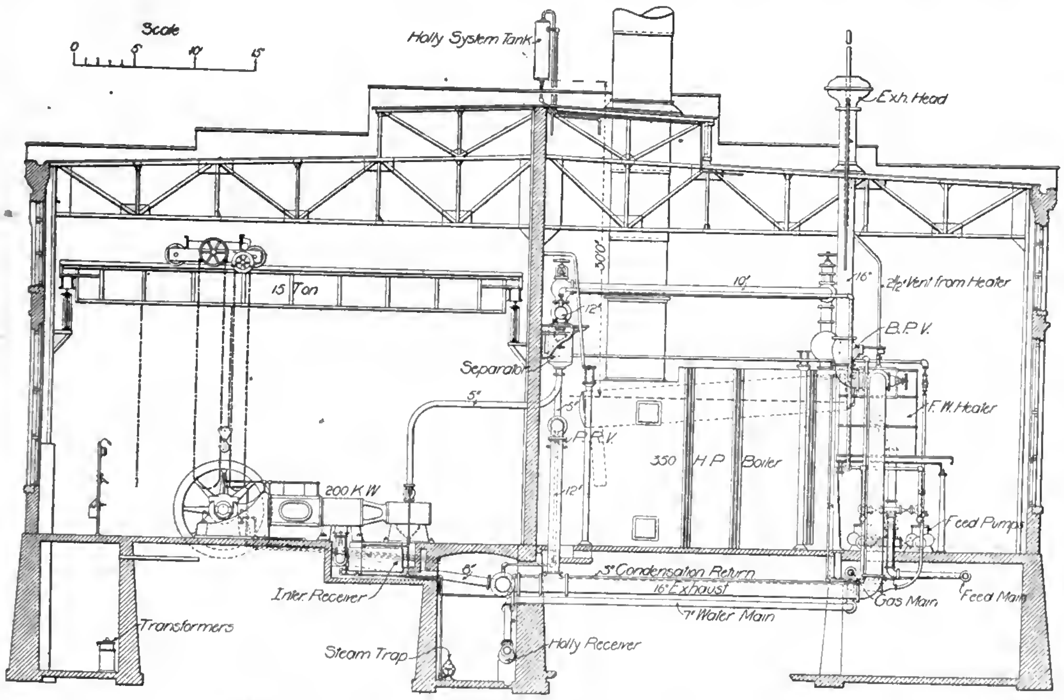
The hot blast is distributed through concrete trunk ducts from 36x40-in. to 20x20 in., running longitudinally under the floor within the rows of crane girder columns which extend approximately one-half the length of the shop building. Midway in its length each duct is connected with its blower by a concrete cross-duct under the side bay floor. These cross ducts are 4½ ft. square. The longitudinal ducts have 15x24-in. outlet connections alongside each crane column which supply the hot air duct risers. Galvanized ducts 20 in. square carry the air from the outlet branches to elbows which discharge horizontally about 10 ft. above the floor level. There are seventeen outlets supplied from each fan on the south side of the building and fourteen from each fan on the north side. The duct velocities are figured high for the cross and trunk ducts, averaging about 2,000 ft. per minute, but are reduced in the branch and outlet connections approximately 1,200 to 1,500 ft. per minute at the outlet elbows.



Plan of the Power Plant at Parsons.

Provision is made for diverting the discharge of the blower at the corner of the building opposite the blacksmith shop into the latter building for heating nights and on holidays when the forges and furnaces are not in operation. As at such times only partial heating is required in any of the buildings, it was figured that the hot blast delivery from this fan could well be diverted from the main shop to the blacksmith shop. For this purpose there is a full-size branch from the delivery duct from this blower to the blacksmith shop, where the underground duct connects with a 40-in. circular galvanized iron duct that rises within the building to a horizontal distributing duct 18 ft. above the floor level, which has five 20-in. horizontal outlets. No other heating arrangement is provided for this shop, as before stated. The hot air from the forges and furnaces is allowed to rise directly into the building without exhaust hoods. Smoke is removed by two 48-in. disc exhaust fans one in each end of the roof monitor, which are direct-driven by 3½ h.p. motors. Each fan is rated at 16,000 cu. ft. of air per minute.

A small amount of heating is also required in an oil-tank pit in the yard, in which fuel oil for the smith shop forges is stored. Owing to the underwriters' requirements, the tanks were located 200 ft. from the nearest building, and depressed below grade in a concrete pit, 14x34½ ft. in interior dimensions and about 8 ft. deep. There are two 6½x27-ft. cylindrical steel tanks, each of 4,000-gal. capacity, for the main storage and two 33-in. x 8½-ft. cylindrical steel pressure tanks, containing 350 gal. each, from which the oil is forced pneumatically to the shop. In order that the oil, which is a cheap grade of heavy fuel oil, may flow freely, the pit and the conduit carrying the piping have a 1¼-in. heating line from the high pressure heating main. Two coil radiators are used, one of 116 lin. ft. of 1¼-in. pipe between the large pair of tanks and the other of 52 lin. ft. between the small pressure tanks. As the pit has a wooden roof with tar and gravel covering about 10 in. above grade, the oil is easily kept at moderately high temperature and its fluidity is maintained in the conduit by the uncovered steam supply line. There is no return line, the condensation being discharged by a Geipel steam trap into a drain. For underground pipe lines, sectional tile conduit 8 in. in diameter was used, which carries a 2-in. oil line and 1¼-in. steam and air lines, the pipes being supported on expansion rollers spaced 11 ft. apart.



Cross Section of the Power House, Showing Pipe Systems.

Power Plant.—The shop group has been centered around the power plant which has sufficient capacity to provide power for the new locomotive shop and also for the car repair shop, with room for increase. The station takes care of the heating and lighting of the buildings, furnishes power for all the machinery driven electrically or pneumatically, and furnishes current for lighting the yard. The location of the power house was determined almost wholly by the center of power consumption, which lies near the center of the main locomotive shop building; the lighting of the yards and buildings in all portions of the property is done by high voltage circuits and thus does not affect the power house location. The site chosen is convenient for obtaining both fuel and water supplies and the piping and wiring to the buildings are carried in subways, so located as not to be affected by future extensions.

The plans of the station were drawn for an 84x215-ft. structure to accommodate a contemplated plant of a capacity represented by a total of 3,000 boiler horse-power, but only a portion of the equipment has yet been installed. There are now five electrical units of a total capacity of 1,000 kw., two air compressors together capable

of compressing 3,000 cu. ft. of free air per minute and four batteries of boilers having a combined rating of 2,000 h.p. The building is laid out with longitudinal boiler and engine rooms, capable of extension on either end, with a longitudinal wall through the center dividing it into boiler and engine rooms of equal width. Both the rooms have their floors 6 in. above the surrounding grade as are those of the other shop buildings, and in both there is a clear head-room under roof trusses of 26½ ft. A basement with 10-ft. head-room has been excavated under both boiler and engine rooms, surrounding the boiler and machinery foundations, in which piping connections and a considerable amount of auxiliary machinery are located. The building has a ferroinclave reinforced concrete roof covered with four plies of tarred felt laid in roofing pitch and covered with gravel. This roof is carried by steel roof trusses on 29½-ft. centers. These trusses on either side of the building have monitors on the ends adjoining the division wall, which is carried up to the monitor roof level. The monitor is 12½ ft. in width on either side and has 30-in. sash on the sides. The floor construction is of concrete with cement mortar finish throughout.

There are four batteries of water-tube boilers, with space left for two more, which are arranged along the inner side of the room facing a 15-ft. firing floor on the outer side, to permit ample lighting on the boiler fronts. Each battery of two boilers is 25 ft. wide. There are 4½-ft. spaces between them and a 3½-ft. space at the rear for steam and blow-off piping connections. The boiler room arrangement and equipment are considerably simplified by the use of natural gas for fuel, but arrangements have been made for handling and storing coal in case the gas becomes exhausted. The structural feature of the building are so arranged that elevated coal bunkers may be built over the firing floor, and space has been left in the roof and basement for installing a coal and ashes conveyor. The lower run of this conveyor would pass close to the outlet doors of the boiler ash pits which open into the basement and would raise the ashes to an elevated pocket, while coal would be raised from a basement receiving hopper to the bunkers. An opening has been left in the outer wall of this basement to permit constructing such a hopper under the coal siding alongside the boiler room, with crusher and auxiliary conveyor for delivering the fuel to the main conveyor. Short steel stacks are all that are needed while gas is used, but a tall brick stack to serve all boilers will be built if coal is used. A 58-in. steel stack is now used for each battery; these are supported on the rear of the boiler fittings and rise to a height of 60½ ft. above the boiler room floor.

Sectional water-tube boilers of the Heine make are employed, each rated at 250 h.p. Each has two 36-in. x 22½-ft. steam drums parallel to the tubes and a heating surface of 140 4-in. tubes, 18½ ft. in length which are expanded into wrought steel water legs which are riveted to the steam drums. Each drum is connected through 10-in. nozzles into a 30-in. steel cross drum 8 ft. long above the boiler front which carries two 6-in. safety valves and the main 10-in. steam nozzle. The boilers are hung free of the settings by link suspensions from two pairs of 15-in. I-beams which span the front and rear of the settings. The settings are 20-in. thick at the sides and 22-in. between boilers. They are carried on concrete foundations having ash-pits at the front which slope toward the special outlet doors through which ashes may be scraped out on the proposed conveyor. At present however, the ash pits and furnaces are closed with a fire-brick floor at the future grate level and in this flooring are nine openings about 5½ ft. in length in which the natural gas burners are inserted. These burners are 5-in. cast-iron pipes of a special form developed by the railroad company for this purpose, which have numerous small holes in the upper side opening into the furnace, with a 5-in. inlet on the lower side connecting through the ash-pit door to the gas valve. There are nine burners to each boiler, supplied through 1½-in. valves and connections from a 6-in. header covering the two boilers of each battery. This header is supplied by 6-in. connections from the gas distributing main on the basement ceiling directly under the boiler front. Provision has been made for adding Greene chain-grate stokers, if it be desired to use coal for fuel.

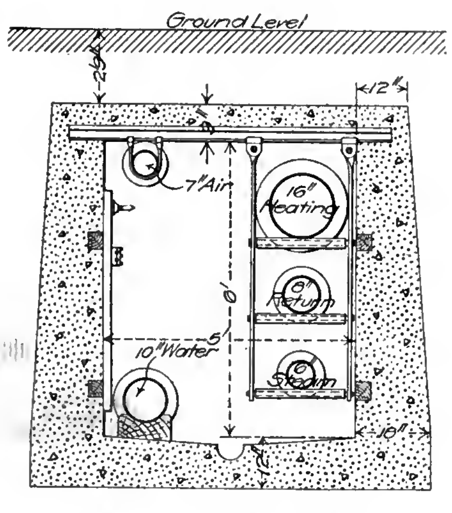
The boiler feed comes from the city works, supplemented by the condensation from the heating systems and the drips from the steam piping. All condensation and hot waste water, including the jacket water from the air compressors, is delivered to a Cochrane open feed-water heater, from which the boiler pumps draw, while make-up is supplied by an 8-in. connection from the 12-in. discharge line of the fire pumps. The boilers can be also fed directly from the mains. The heater is mounted on a steel platform 8 ft. above the firing floor at about the center of the room, and under the two feed pumps are below it. The heater is supplied with steam through an inductive connection from the 16-in. atmospheric relief riser from the engine room exhaust main, which discharges to the heater through an attached oil separator. The heater has a capacity of 2,000 h. p., and is fitted with chemical tanks for treating the water to remove a portion of the scale-forming impurities. The feed pumps are Fairbanks-Morse duplex pumps, each having 12x8x12-in. cylinders. They feed the boilers through a 5-in. main on the ceiling under the firing floor; this has 3-in. branches carried up between each battery and dividing into 2½-in. connections to each boiler. The boiler blow-off system consists of two 1¼-in. connections from the lower edge of the rear water leg of each boiler into a 4-in. blow-off main carried longitudinally through the boiler room in a trench at the rear of the setting. This main is carried out through the northerly wall of the building into one of the yard drains.

The steam piping systems are laid out with longitudinal headers for both high pressure and exhaust, the former in an elevated position on the boiler room side of the division wall and the latter in the basement on the opposite side. That for the high pressure system is a 12-in. header carried on cast-iron brackets 19½ ft. above the boiler room floor, with 10-in. branches to the boilers and eight 5-in. branches to the engine-room. The boiler connections are long-radius horizontal bends with a Davis automatic angle stop and check valve at the boiler nozzle and an angle stop valve at the header. The engine connections are made from the lower side of the header through Hoppes angle receiver-separators immediately below, from which the delivery lines lead down to the engines, compressors and pumps. The drainage of the header is effected directly by these separators, except at the ends, which are drained by two 1¼-in. connections. The condensation is removed from the separators and the header-end connections, and also from the throttle end of all steam connections, by a Holly loop system having a condensation receiving tank in the engine room basement and an elevated discharge chamber, together with the piping to return the condensation automatically to the boilers. The 16-in. exhaust header has eight 8-in. connections from the engines and pumps that pitch sharply downward toward it, and three delivery connections, one of full size which leads across to the feed-water heater and atmospheric relief riser in the boiler room and another connection of similar size at the north end of the power house through an oil separator into the piping tunnel for connection to the heating systems of the various shop buildings, with the exception of the store house, which is supplied by a similar 5-in. connection with oil separator at the southerly end of the power house. Condensation is drained from the receivers of the compound engines by Bundy steam traps which discharge to the sewer. A system of engine drains has also been provided so that the engine and pump cylinders and the receivers of the compound engines may be blown free in starting, the discharge being piped to the sewer. The oil separators in the connections to the low pressure heating mains are Bundy grease extractors from which condensation is drained to the sewer.

Boiler Room, Showing Gas-Fired Furnaces.

There are five tandem-compound four-valve engines direct-connected to 200-kw. generators of 2,000 cu. ft capacity per minute, another compressor of 1,000 cu. ft. capacity, and two large

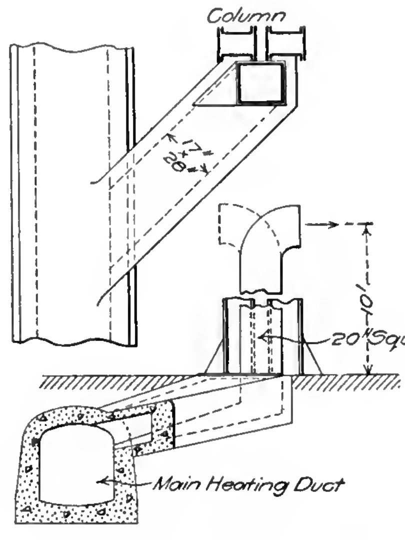
pumps. The engines are the Fitchburg heavy-duty side-crank tandem-compound type, with Tangye frames, and are designed to operate non-condensing with a considerable back pressure. They have governors of the centrifugal shaft type and double eccentrics for independent operation of the admission and exhaust valves. These units all have 14 and 22x21-in. cylinders and, operating at 200 r.p.m., have a rating of 320 h. p. each. The air compressors are the Ingersoll-Rand compound two-stage type designed to deliver compressed air at a pressure of 100 lb. The two units deliver air through a 7-in. line to vertical steel storage and cooling tanks outside the building; these are 54 in. in diameter by 12 ft. high and from them the air distribution system of the shop plant is supplied through a 7-in. connection. The engines and compressors are all lubricated by a continuous gravity oiling system, consisting of an elevated storage tank supplying oil to all bearings and a collecting and filtering system in the basement from which the oil is pumped back to the tank. The two pumps are the Fairbanks-Morse underwriter type of 1,000 gal. capacity each, and draw from the reservoir and city water service as before stated.



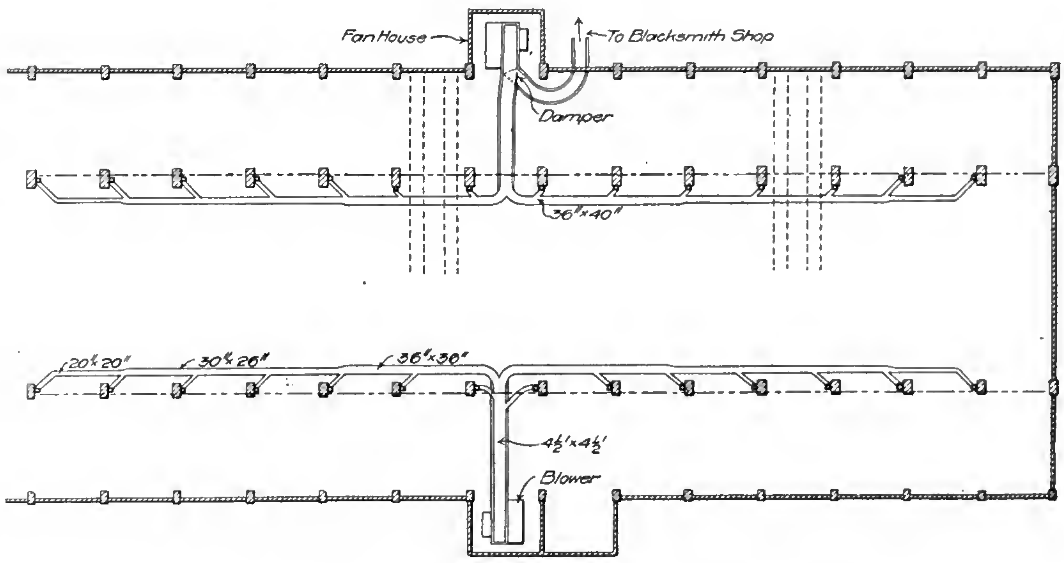
Section of Pipe Tunnel.

As before stated, the station supplies current for lighting both buildings and yards, the distribution system for which covers a considerable area, and for the power service in the buildings. For the former, an alternating current distribution was thought desirable on account of the distances of transmission which are over a mile in either direction. For the power service direct current was adopted to permit the use of variable speed motors for direct-connected machine tool drives. The generating equipment accordingly consists of three direct-current and two alternating-current units of 200 kw. capacity direct connected to the engines. The generators are all Westinghouse engine-type machines; those for the direct-current service are compound-wound multipolar machines delivering 230-volt current, and the alternating-current machines are of the revolving field type wound for two-phase current at 60 cycles and a potential of 2,300 volts. The alternators are arranged for excitation from either bus-bars of the 230-volt direct-current machines or from a 30-kw. motor-generator. No steam-driven excitor was necessary with this arrangement, as it is possible to start up the alternating current service by exciting the alternator field with current from any direct current generator, after which the motor generator set may be started for independent excitation to render the regulation independent of the voltage variations of the direct-current system.

The electrical distribution is controlled by a 18-panel switch-board, containing three generator panels, a total panel and three feeder panels at one end for the direct-current equipment, and two generator panels, an excitor panel, a total panel and four feeder panels at the opposite end for the alternating-current system. The switchboard equipment was supplied by the Westinghouse Electric & Mfg. Co., and contains oil switches for the control of the 2,300-volt alternating current and total recording watt meters for the measurement of the power consumed by either the direct or alternating system. There is also a small two-panel board for the control of the two-series alternating current arc lighting circuits, each operated by constant current transformers. The distribution system embraces nine circuits for direct-current, which are entirely local, and eight circuits for alternating current, four of which are for the new shop group and the others for transmission to other portions of the company's property. Of the direct-current system five feeders are carried to the locomotive shop for the crane motor and machine tool motor circuits, one each to the blacksmith shop and store house, and the remaining three to the old buildings for the operation of motors in the car shop. From the alternating current board, four feeder circuits supply local lighting in the main shop, blacksmith shop and store house, one the constant current transformers, and the remaining three the lighting at the old shops about 1,500 ft. distant. The freight department about 2,200 ft. distant, and the passenger depot about 4,000 ft. distant. The direct-current motor load, consisting of crane motors and machine tool motors in both old and new shops, averages about 400 kw., while the lighting load varies from 250 kw. to the uniform all-night load of about 150 kw.



Outlets of Heating Ducts.



Hot Blast Heating, Northerly Half of Main Building.

The new shops were laid out, and the buildings and their equipment, including the power plant, were designed by Mr. G. R. Henderson, who was consulting engineer to the Missouri, Kansas & Texas Railway. James Stewart & Co., New York, were general contractors for the shops. Mr. A. A. Allen is the vice-president and general manager of the system and Mr. W. O'Herin superintendent of machinery and equipment located at Parsons.

Sludge in Septic Tanks.

Septic tanks were first put in operation in the Lawrence Experiment Station of the Massachusetts Board of Health in 1898 and since that time tanks of this sort have been operated there. In the Board's last annual report there are some figures showing the disappearance of sludge which has been observed in the tanks; while such figures are applicable only to the local sewage they are of considerable interest because made with both concentrated sewage containing large amounts of suspended matter and with the regular station sewage. The two tanks receiving concentrated sewage were operated with storage periods of 18 hours to 15 days in one case and of 5 hours in another, and showed a disappearance of 82 and 75 per cent. of the sludge respectively. In the tanks receiving station sewage from 68 to 89 per cent. of the sludge disappeared. The detailed analytical and measurement results seem to show that more than 80 per cent. of the volatile organic matter deposited in the septic tanks in question is passed into solution or given off as gas. This is a deduction from analytical data, but it is of course difficult to obtain entirely representative samples. At times gas evolution causes sediment to rise and pass from the tanks, so that much matter passes off this way, which causes the figures showing sludge destruction to be greater than is actually the case. This fact has been pointed out in earlier reports of the Board. The analytical results show an apparent decomposition of much mineral matter, but this must be due mainly to the passage of this matter from the tanks without being detected. The time of storage within the limits of the experiments, ranging from 5 to 49 hours, except in the case of the 15-day experiments made with one tank in 1899, and the strength of the sewage seem to have little influence on the percentage of organic matter disappearing or on the number of pounds of dry sludge disappearing per million gallons of sewage. The average station sewage contains about 2,080 lb. of suspended matter per million gallons.

The Water Supply of Goldfield, Nevada.

The Goldfield, Nevada, mining district is in the center of one of the most desert regions in this country, where rainfall and moisture are almost entirely lacking and the aridity is pronounced and oppressive. In the face of the hardships and difficulties of living in a region of this kind, the remarkable richness of the mineral deposits of the district has attracted a large population, the town of Goldfield alone having about 22,000 inhabitants. The permanence of the resources of the district has been so well determined that an immense amount of money has already been expended in providing good transportation facilities, cheap electrical power and an adequate and suitable water supply to the isolated desert region in which the district is situated. The result of the provision of these facilities has been to change the camp of tents and temporary shacks into a city with pavements, electric lights, water works, sewers and other modern improvements. The construction of these improvements has been carried on at very unusual expense owing to the isolation of the district and the cost of transportation and labor.

When the richness of the mineral deposits in Goldfield and vicinity was discovered in 1903 the town was 100 miles from the nearest railroad, and for over a year after the wealth of the region was exploited no railroads were put under construction to reach the district. Since then, however, three standard-gauge lines have been built into Goldfield, providing good transportation facilities. The first of these was the Tonapah & Goldfield R. R., an extension of a branch of the Southern Pacific R. R., 100 miles in length, the branch connecting with the main line of the latter road at Reno, Nev. The second was a branch of the San Pedro, Los Angeles & Salt Lake R. R., 220 miles in length. A third railroad, the Tonopah & Tidewater, is just being completed from Tonopah through Goldfield to a connection with the main line of the Atchison, Topeka & Santa Fe R. R., with a total length of 326 miles. Practically all of this railroad construction was carried on in desert country, where water for all purposes frequently had to be hauled 30 to 50 miles, and, in instances through districts where no work could be done in the summer on account of the terrific heat. Some of the grading required also involved a large amount of work, so the cost of these lines has been excessive.

Electrical power for the Goldfield district, and for several other mining districts in the vicinity, is furnished from the extensive hydro-electric developments of the Nevada-California Power Co. on Bishop Creek in California, 113 miles from Goldfield. This creek is a tributary of the Owens River, from which the new water supply for Los Angeles, Cal., is to be obtained. It has its source in a mountain range which is covered with perennial snow, and its flow is remarkably uniform throughout the year. The power company has two hydro-electric stations, with a combined capacity of 7,500 h.-p., in operation, and is constructing two more stations, which will give an ultimate total capacity of 14,000 h.-p. Much additional power can also be developed as the company controls 3,200 ft. of fall on Bishop Creek, and large storage reservoirs can readily be built on the headwaters of the stream at a reasonable cost. The power generated is transmitted to Goldfield at 60,000 volts over a pole line 113 miles long, and branches from this line are extended to other points. Much of the transmission line was built through the rough mountain country and thence across the desert at a very great expenses. The whole power development project has been more than justified by the demands to be supplied, however, and will keep pace with these demands with difficulty.

Although ample railroad and power facilities were thus constructed at a great outlay, the provision of an adequate supply of satisfactory water remained to be accomplished. Such a supply has now been developed in the mountains, 30 miles from Goldfield, and the pipe line which delivers it to the city was recently placed in operation. Prior to the completion of this pipe line water was obtained from a mine and from various small wells and springs. All of this water was highly impregnated with alkali salts and practically none of it was suitable for domestic consumption. The salts contained in it were also of such nature that the water was highly unsatisfactory for use in boilers, or in the concentrating mills required to work a large portion of the ore which is mined in the district. Furthermore, the supply was entirely inadequate, so no fire protection could be provided and water commanded an apparently unreasonable price.

The chief part of the original supply was obtained from a mining company, which pumped water about 10 miles against a head of 800 ft. from a series of alkali springs, for use in a concentrating mill. These springs produce about 36,000 gal. per day, and the mining company sold the surplus over the requirements of its mill to a local water company at a flat rate of half a cent a gallon. The other springs and wells from which water was obtained were at varying distances from the town, but were all of small capacity. Two small and separate systems of distribution mains had been laid in the central part of the town, and water was retailed at three-quarters of a cent a gallon to consumers connected with these mains. Beyond the limits of the distribution mains water was delivered in barrels on wagons at prices of 1 to 3 cents a gallon, depending on the distance it had to be hauled. Under these conditions it cost $750 a month for enough water to run an 80-h.p. boiler; it also cost 25 cents to water a team of horses, and fire insurance could not be obtained owing to the lack of fire protection. In fact, a disastrous fire occurred, which could not be checked because no water was available. The inauguration of the new water supply has changed all of these conditions, as an ample amount of good spring water from the mountains is now available under a pressure that provides fully for fire protection.

The mountains in which the supply has been developed are 25 to 30 miles from Goldfield, along the western edge of the desert. The development has been made on, or in the vicinity of Mount Magruder, which is covered with snow until late in the summer. The surface of the upper part of this mountain is largely loose, disintegrated granite, with rocks of considerable size, which grade into gravel down on the mountain sides, and finally into the soil of the desert. Practically none of the melting snow ever runs off in streams and very little of it shows on the surface along the sides of the mountain, most of the water flowing away under ground and being dissipated through the dry soil of the desert below. In a few places along the side of the mountain, where the bed rock nearly outcrops at the beginning of the overlying gravel, several small springs appeared, and other conditions indicated the presence of an underground flow. At several of these points horizontal tunnels have been driven back into the side of the hill to intercept the sub-surface flow and to increase the output of the springs.

One of the principal sources of supply that has been developed in this manner is from Cartee Spring, across a canyon from Mount Magruder, at the base of a mountain of similar formation. This spring, which flowed upward of 80,000 gal. a day before it was developed, and had been used for 30 years in irrigating a small ranch, now delivers at least 100,000 gal. a day. The Gusher Spring, another one of considerable flow, is on the side of Mount Magruder, about 5 miles up the valley from the Cartee Spring. Three miles around the mountain from the Gusher Spring are the three State Line Springs, the water from which was used for years in placer mining. Another series of three springs has been developed on the side of Mount Magruder, between the Cartee and the Gusher springs, and

Two Views on Pipe Line during Construction across the Low Intervening Country.

three more exist adjacent to these. The springs which have been developed are perennial and have a normal daily flow of over 1,000,000 gal. Other large springs remain to be utilized, chief among these being the Hyde Spring, which will deliver 200,000 gal. of water in 24 hr., but is lower than the pipe line, so its flow will have to be pumped when required.

The tunnels which have been built into the side of the mountain to develop the underground flow involve no special features. They were usually driven so the bottom of the tunnel was at, or very close to bed rock, and were continued back into the side of the mountain until they intercepted the crevasses or channel through which the underground flow comes down the mountain. The total flow is thus conserved and

Hauling Pipe from the Railroad Station.

the original capacity of the sprıngs increased from 60 to 100 per cent. The tunnels were made about 6 ft. high, 3 ft. wide at the top and 4 ft. wide at the bottom, and have lengths varying from 20 to 160 ft. They were heavily timbered throughout to hold the loose material through which most of them had to be driven.

The various springs that have been thus developed are connected by a line of spirally-riveted steel pipe which is merely a continuation of the pipe line leading to Goldfield. This line starts at the State Line Springs and extends as a 6-in. pipe for three miles to the Gusher Spring, the fall in this distance being 32 ft. From the Gusher Spring to the Cartee Spring, in a distance of 5 miles, the fall is 1,200 ft., so a 5-in. pipe is fully sufficient to carry the flow. The series of three springs which have been developed on the side of Mount Magruder are connectetd to the 5-in. line by a 5-in. pipe.

Three miles toward Goldfield from the Cartee Spring is a summit, called Lida Summit, which is only 27 ft. below that spring, so in order to secure the desired capacity a 9-in. pipe was used for the main line in this distance. From the Lida Summit the country drops away rapidly, the line crossing a valley about 20 miles wide before reaching a second summit, called Malapi Summit, at the edge of Goldfield. The drop in this 20 miles is about 900 ft.; the Malapi Summit is 500 ft. lower than the Lida Summit and 400 ft. above the town. It was originally intended to operate the pipe line by gravity, but a pressure of over 390 lb. per square inch would thus have been brought on the section of the line between the two summits. The decision was made, therefore, to place a pumping station part way up on the rise to the Malapi Summit and operate the section of the line between the Lida Summit and this station by gravity, and thence pump the water against a head of about 150 lb., over the Malapi Summit. This arrangement permitted ordinary 7-in. spirally-riveted pipe to be used between the Lida Summit and the pumping station.

The flow line is all placed at least 18 in. below the surface, which is sufficient depth to protect it from frost in the region traversed. Air valves are provided at all summits and blow-off valves at low points, at intervals of about two miles. Owing to the nature of the country and the absence of rainfall, no waterway crossings had to be built, nor protection against washing provided at any point.

The pumping station contains a single 400,000-gal. Goulds triplex pump, belt-driven by a 50-h.-p. electric motor. A second unit of the same type will be installed when required. Electrical current is obtained from the Nevada-California

Mountains in Which the Supply was Developed; Desert in Foreground.

Power Co. The pump delivers into an 8-in. pipe line 6,000 ft. long, which leads over the Malapi Summit to storage tanks on the side of the latter. Several temporary tanks, with a combined capacity of 400,000 gal., are at present installed, but two new tanks, with a capacity of 200,000 gal. each, will be placed to provide for the variations in domestic consumption. One of the present tanks, with a capacity of 200,000 gal., will be retained for storage for fire purposes. These storage tanks will render available in the town a pressure of 50 to 60 lb. for domestic consumption and of 120 lb. for fire protection.

The distribution mains of the two original water supply companies operating in Goldfield were purchased by the company which made the development of the new supply. One of these systems was made up of spirally-riveted pipe and the other of standard well-casing and machine-banded wooden pipe. As parts of these systems were small pipe, and nothing smaller than 6-in. pipe will be used in the main part of the town for the new system, much of the original work is being replaced. In all new work lap-welded wrought-iron pipe, with Converse joints, is being used. All connections to the distribution mains are metered, water for domestic consumption being sold at ¼ cents a gallon and for commercial purposes at $2.50 to $4.00 per 1,000 gal.

The chief difficulty encountered in the construction was in building the pipe line across the 20 miles of desert between the two summits. All of the pipe for the entire line had to be hauled from the railroads at Goldfield. Water for all purposes frequently had to be hauled 15 miles. The trench for the line was opened up with eight and ten-horse teams on plows, but a hard, cemented conglomerate encountered just under the surface required a large amount of light blasting and greatly increased the cost.

An analysis made of the water from the new supply showed only 21.04 gr. per gallon of solids, with but 0.44 gr. of suspended matter and a trace of organic matter, while nitrates and nitrites were absent. The water, therefore, contains nothing to make it objectionable for domestic use. The percentage of scale-producing salts, the sulphates, which are the only corrosive salts present, and those salts which produce foaming, are all low, so with reasonable care the water can be used for boilers with no deleterious results. Carbonates predominate in the water, but are remarkably low, as compared with other waters in the country surrounding Goldfield. In fact, this analysis showed the water to compare favorably with most domestic supplies, which is a remarkable circumstance in this desert country in which the supply has been developed.

The scheme of securing water for Goldfield from the mountains was devised by Mr. Loren B. Curtis, of Denver, Colo., who, assisted by Mr. Charles G. Patrick, conducted the investigations of the source of the supply, prepared the plans for the work and supervised the construction. The water supply system and distribution mains are owned and operated by the Goldfield Consolidated Water Co., which is controlled by Denver and Goldfield interests.

TWO SCHOLARSHIPS in McGill University, Montreal, will be given by the Canadian Pacific Ry. to those employees or sons of employees who stand highest in entrance examinations next year. There are three students now holding such scholarships.

Methods of Increasing the Capacity of the New York Subway.

When the New York Subway railway was put in service, a good many people thought that the rapid transit problem in Manhattan was solved for at least a decade. Before the first operating year had passed, this belief had vanished. The difficulties of travel on the road during the rush hours proved even greater than on the elevated lines and came somewhat near the disgraceful scenes in evidence about six o'clock any week day afternoon at the Manhattan terminal of the Brooklyn Bridge. Naturally enough the overcrowding was attributed by the public to the lack of enough trains, but the correctness of this opinion seemed questionable after some study, and the fact that the subway was about taxed to its utmost gradually became apparent to those who observed the conditions critically. Pending the construction of more subways, it is necessary to utilize this one to the utmost, and so the Public Service Commission retained Mr. B. J. Arnold to study the conditions and suggest methods of improving the service now rendered by the Interborough Rapid Transit Commission. The full report on this subject is not yet written, but a preliminary report was made last week, from which the following extracts have been made:

It is but fair to say that, taking into consideration the circumstances under which the subway was built and is now being operated, it is one of the best constructed and best operated railways in existence. On the other hand, the service demanded of it is far in excess of that of any other road, and as a consequence conditions are now such that although the time card calls for a headway of 2 min. between trains south of 96th St. during rush hours, in actual operation the trains fall behind this schedule from 12 to 30 sec. under normal conditions during these hours. This results in only about 25 express trains per hour leaving Grand Central Station instead of 30 trains, as called for by the time card.

After studying the causes of delay, Mr. Arnold is convinced that several of them can be promptly removed and the 2-min. headway, as given by the time card, maintained under normal conditions during rush hours. Many of these delays are due entirely to the excessive time taken for loading and unloading trains at the platforms, and are caused largely by the policy of holding the trains at the stations until all the cars are jammed full of passengers, in an attempt to clear the station platforms. This policy should be changed to one of starting the trains within a fixed time after they have stopped in order that the maximum number of cars may be made to pass through the stations after allowing reasonable time for loading. This time of loading and unloading the express trains should be limited to 45 sec., instead of an average of 65 sec. taken at present at Grand Central Station. This can be accomplished provided the proper degree of efficiency is maintained by the platform men and train guards, by putting into effect the following method of operation:

First. In view of the fact that northbound evening express trains leaving Grand Central Station carry approximately 25 per cent. more passengers than are brought into this station from 14th St., a system of loading should be adopted, which will regulate the loading at Brooklyn Bridge and 14th St. in such a way that there will be capacity left in the cars for the increase of load at Grand Central Station, and thus avoid the present excessive crowding.

At present time the cars come into Grand Central Station fully loaded, and the delay at the station platforms is caused largely by passengers getting off slowly from crowded cars and the difficulty of loading so many additional passengers into cars already full. The delay caused by this congested condition of the cars at Grand Central Station soon backs the trains up in the subway as far as 14th St., and as the trains are held at 14th St., they are naturally loaded more fully, and thus the congestion is increased automatically, which can only be remedied by a combination of systematic loading and prompt movement of the trains.

In other words if part of the passengers who are ready to enter the trains at 14th St. are cut off, all trains can be moved on time, and therefore, more trains operated than at present. Thus additional speed and comfort can be obtained for all of the patrons of the subway by a small amount of inconvenience to a few patrons who are slightly delayed in taking the cars at 14th St., and on the principle of the greatest good to the greatest number, this policy should be adopted.

Second. On each express platform there should be stationed a train dispatcher provided with two stop watches, one for the local the other for the express service, with instructions to give the signal for closing the doors not later than 40 sec. after the train has come to a stop, thus allowing 5 sec. to close the doors and start the train within a 45 sec. period. Subsequently indicators visible to the passengers can be installed which will show them the time in seconds remaining before the closing of the doors.

Third. The guards upon the cars should be instructed to open the doors as soon as the train has stopped. There is now at times a noticeable delay in geting these doors opened. The train guard should also be instructed to listen attentively for the closing signal, and at once make every effort to close the doors with the assistance of the platform attendants, and when the doors are once closed they should be kept closed instead of being opened occasionally to let off a delinquent passenger.

Fourth. Train guards should be instructed to keep themselves more alert and to transmit promptly the starting signal. If it is found that the guards cannot be trained to attend to this matter of signaling promptly, it may be necessary to require an electrical system of signaling whereby the motorman will get the signal on the instant the last door is closed.

Fifth. The station attendants should be given positive instructions to act promptly when the signal is given for closing the doors. This can be done by positively regulating the stream of passengers entering the car so that the last passenger in will not obstruct the closing of the door.

In order to secure better service for the patrons of the subway the Interborough officials have pointed out that suitable police regulation on the station platforms should be provided in order to control such individuals as may interfere with the prompt closing of the doors. [The police department has now provided such special officers].

By making other improvements it will be possible to reduce the headway still further, for the present signal system is arranged so that by slightly changing it at the stations trains can be easily operated on a 90-sec. headway, if such a headway were not prohibited by excessive station stops. Mr. Arnold suggests that the Interborough officials be requested to prepare a train schedule on the basis of a 105-sec. headway during rush hours, which is a reduction from the present schedule of 15 sec. This saving in the headway can be secured at once by changing the block signaling system at the express stations. At the present time the station block is not cleared until the leaving train has nearly left the platform. With an eight-car train on the express tracks it requires from 22 to 25 sec. after a train starts to get the signal which allows the following train to proceed. It then requires a certain length of time for the following train to pull into the platform and come to a stop. For example, at Grand Central Station this time amounts to 50 sec. for a north-bound train. If the signal to the following train could be given at or about the time the leaving train starts rather than waiting until the train has cleared the platform, the 15-sec. saving could be effected at express station stops.

Mr. Arnold is studying the necessity of changing the design of the present cars so as to provide one or more openings in the sides, but he cannot reach a fair decision until the effect of the improvements suggested above, or their equivalent, has been shown.

There will always be the problems as to where to draw the line between seating capacity and standing room. At present during rush hours there are practically twice as many people standing as there are seated. If more seats were provided in the present cars, one seat would displace two standing passengers, and either the carrying capacity of the car would be reduced or the standing passengers would be more crowded than at present, which seems practically impossible. As it is impracticable to use wider cars, owing to the lack of clearance in the present subway, the only method of providing more seats is to provide more of the present type and size cars, but with more cross seats, which method would tend to greatly increase the time required for loading and unloading them. As soon, however, as the service of the subway becomes improved either by providing additional seating capacity or by more rapid service, instead of this service creating additional comforts to those who are now riding more people will be attracted by this superior service, and the applicants for seats will outnumber the available seats in practically the same ratio as at present. It is, therefore, evident that a decision must be made, relative to the general nature of the service to be supplied, before the proper type of car can be determined. The desirability of providing a certain number of passengers with a maximum number of seats, and thereby limiting the capacity of the subway to practically the number of seats that can be made to pass any given point within a given time must be compared with the desirability of providing transportation to the greatest number of passengers possible, even though a large majority are compelled to ride for a short time without being provided with seats.

It has been contended not only by those who have suggested certain methods for improving the subway service, but also by the advocates of better service in most of our large cities, that each passenger should be provided with a seat, or at any rate, that whatever improvement is attempted should tend to increase the seating capacity of all cars operated over the seating capacity of those now in use. There is no question as to the righteousness of this contention, but the futility of attempting to furnish such service to all patrons of the road may be judged any evening by the most casual observation of the crowded conditions of the present subway cars. If the policy is adopted of providing seats to the majority of those who ride during rush hours, it will result in a material decrease in the total number of passengers which it is now possible to transport in the subway, and would therefore result in turning away many passengers who now make use of its service.

If the principle of a slight reduction in the seating capacity of the present cars can be adopted, increased carrying capacity can be obtained by eliminating all or a part of the present cross seats. Their elimination makes it practicable to introduce center side doors into the present cars, should this change be found nec-

essary later. In case the traffic cannot be properly handled nor the desired 45-sec. limit for station stops be maintained with the present end door cars, the use of those center doors in connection with the absence of cross seats will make it practicable to load and unload so rapidly that this limit can be maintained.

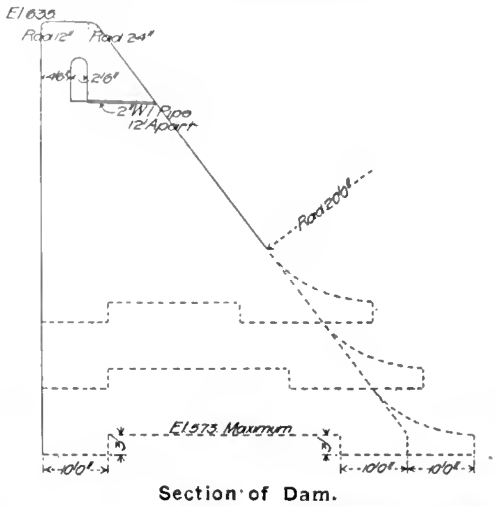
No one having the best interests of the public at heart will deny that if it were possible to provide each passenger with a seat throughout his entire journey that this should be done, but as it is practically impossible during rush hour periods in most transportation systems now existing in the principal cities of this country, the question of just how far this principle can be departed from and still serve the best interests of the public by providing as many seats in the cars as practicable requires most careful consideration.

The hardship imposed upon those who are compelled to stand in the subway cars during the rush hour period is not as great as it at first appears to be, for the reason that, owing to the transfer system between the express and local service, so well worked out in this railway, few passengers are compelled to stand for any great length of time. This is brought about through the fact that the passengers in each car are changed so often, due to transfers at express stations, that many of those who stand at first soon get seats, compelling the newcomers to stand, who for like reason and in turn soon find seats.

In further support of the policy favoring increased standing room in the cars it is but proper to point out that the reason for diminishing the number of seats is for the purpose of providing greater aisle space so that a system of circulation of passengers from the entrances toward the exits of the cars may be more easily maintained, resulting in greater comfort not only to those standing but also to those seated, and at the same time avoiding the conflict of streams of passengers with its resulting discomfort, now so evident at the express stations during the rush hours. As an additional result of maintaining a definite circulation of passengers, greater expedition will be possible in loading and unloading, station waits will be reduced, and the average speed of travel materially increased, so that the discomfort of standing is further lessened by being shortened.

The question then tersely stated is as follows:

Having 60,000 people to carry per hour, shall we, by following one policy, provide seats for 40,000 people with standing room for possible 10,000 more, and turn away 10,000 to other and slower means of transportation, or by adopting, at least until future subways can be built, the other policy whereby increased standing capacity is obtained, provide seats for 20,000 and carry the other 40,000 standing for short intervals of time, and thus furnish transportation for the entire 60,000. Inasmuch as an answer to this question involves a decision based upon public policy rather than upon engineering feasibility, Mr. Arnold feels that the Commission should first pass upon it and instruct him accordingly.



Section of Dam.

A CAR FERRY service across Lake Ontario has been placed in operation between the Genesee River, above Rochester, N. Y., and Coburg, Ont., a distance of 60 miles, by the Grand Trunk and the Buffalo, Rochester & Pittsburg railways. The boat, which is expected to make two round trips in 24 hours, is said to be the largest on Lake Ontario, being 316 ft. long, 57 ft. 4 in. beam and drawing 17 ft. It has a capacity of 26 cars and is expected to develop a considerable coal carrying trade. Though intended primarily for freight, passenger accommodations have been provided on the upper deck.

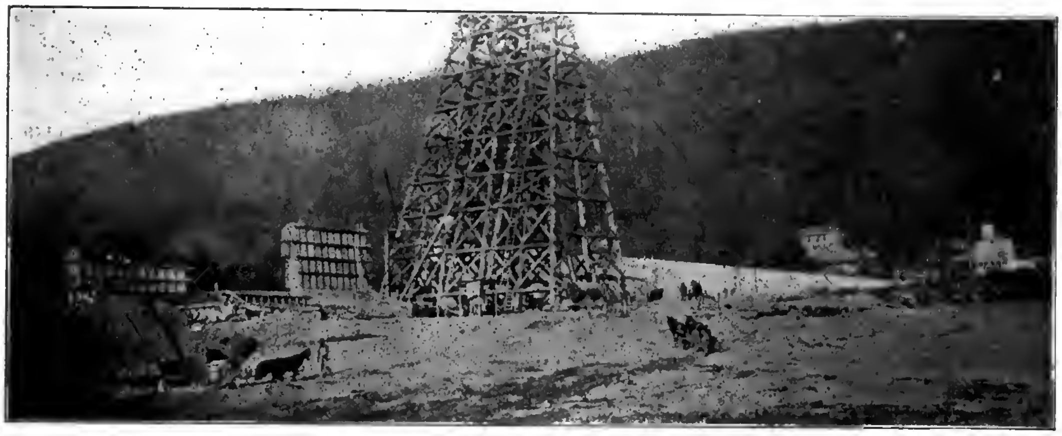
The Chattanooga & Tennessee River Power Company's Plant.

By Howard Egleston, C. E.

During the past ten years the growth of Chattanooga, Tenn., has been very remarkable, and there is every prospect that her future development will be even greater than her past. Blest with cheap coal from nearby fields, her cost of power has been very low; add to this her location, central to immense developments of iron, great forests of hard wood, and many other raw materials, her wonderfully good transportation facilities, and we have the reasons for her being one of the largest manufacturing cities in the South. But in addition to these advantages, nature has furnished another, hitherto not utilized—the Tennessee River as a source of power.

For nearly three-quarters of a century U. S. Army Engineers in charge of the improvement of our inland waterways have studied the improvement of navigation of this river where it breaks through the mountains near Chattanooga. Finally, in 1900, it was practically determined that a dam and lock should be built at Scott Point, 17 miles below Chattanooga, if an appropriation could be obtained from Congress, but some of Chattanooga's wide-awake citizens had been impressed by the success attending the development of water power in other Southern cities, and Messrs. C. E. James and J. C. Guild took the matter up with great energy. By demonstrating the enormous benefit, commercially, that would accrue to Chattanooga, if the power of the river could be converted into electrical energy and brought to that city, they secured the co-operation of Representative John A. Moon, of their district, in obtaining the necessary legislation, and finally in 1904 an act was passed authorizing the Secretary of War to grant permission to the City of Chattanooga to build and construct a lock and dam across the Tennessee River at Scott Point. The act also provided that if the city did not accept this privilege within four months from the date of passage of the act, then the Secretary of War should offer the franchise to Messrs. James and Guild for a period of eight months, and failing to contract with them, to contract with any private corporation, firm or business, for the construction of the lock and dam. The citizens of Chattanooga did not accept the offer, but Messrs. James and Guild organized the Chattanooga & Tennessee River Power Co., with Mr. A. N. Brady in charge of the financial end, Mr. John Bogart becoming consulting engineer for the company.

Scott Point has been selected as being the place



Cableway Tower on East Side of River.

View of Lock Basin, Looking Upstream.

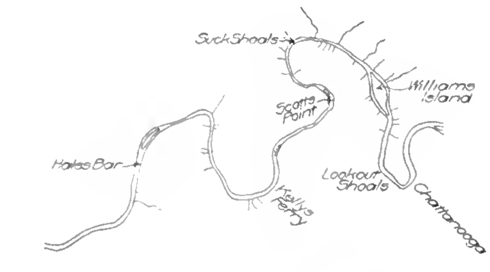
where the greatest improvement to the river could be made at the least cost, but when the plan was changed from simple river improvement to the development of power, it was decided that greater power could be secured, together with an equal or greater improvement to navigation, by constructing the lock and dam further down the river, at Hale's Bar, 33 miles below Chattanooga. Another act of Congress was therefore obtained in January, 1905, authorizing the location of the dam at such other place below Scott Point as the Secretary of War might approve.

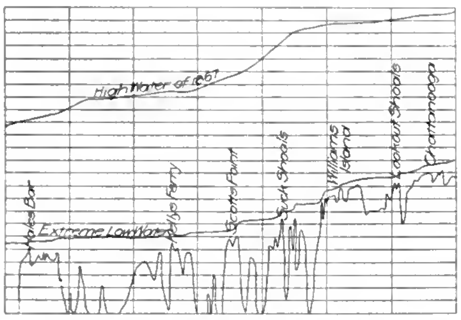
The designs for lock and dam were prepared under Major H. C. Newcomer, Corps of Engineers, U. S. A., by Mr. John M. G. Watt, principal assistant engineer. The power house and all appurtenances for developing the water power were designed by Mr. Bogart.

The lock and dam will be built of Cyclopean concrete, making all walls solid except for a passage through the dam and the necessary culverts for filling and emptying the lock. The total length of lock, dam and embankment between the rock bluff on the west side of the river and the hill where the embankment terminates is 2,300 ft., the dam being 1,200 ft. long, power house 300 ft. and embankment 700 ft. The top of the lock walls will be 52 ft. above present low water, or 58 ft. from foundation to top and 17 ft. above crest of dam. This will allow operating the lock in times of flood of 35 ft., though at that time the river would be 14 ft. above the crest of the dam.

The walls of the lock on the land side will be 30 ft. at bottom and 5 ft. at top, except for the buttresses supporting the gates, where the top will be increased to 25 ft. and the bottom to dam, the difference in height between the upper and lower pools will be over 40 ft. The gates to hold back this great mass of water must be of extraordinary strength; each leaf of the upper gate will be 34 ft. wide by 26 ft. high, weighing about 50 tons, while those of the lower gate will be each 34 ft. wide by 59 ft. high and weigh 130 tons.

Should the gates become damaged at any time the lock can be closed by using five steel trestles at each end. These will be fitted into journals placed in the concrete during the construction





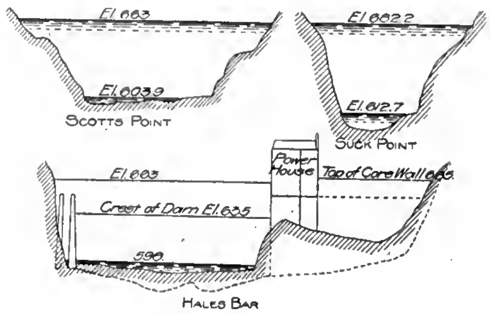
Course and Profile of River.

large quantity of water is flowing, but with a reduced head. Under ordinary conditions of the river the head at the dam will be 36.5 ft.; this may be increased to 39.5 ft. by the use of flashboards.

The generators to be used will be each 4,000 kw. At present it is the intention of the company to install at first only eleven of the fourteen ultimately to be used.

The transmission line is planned to consist of two three-phase lines, both mounted on the same line of poles and carried in as straight a line as possible from the transformer room at the dam to the receiving station in the city, a distance of about ten miles.

The contract for the lock, dam and power house was made with W. J. Oliver in 1905 on a quantity basis, the work to be completed in two years, or in the summer of this year. Apparently a great miscalculation was made, for at this writing, the middle of October, nothing has been done on the dam or power house, and the only evidences of progress are shown in the partly completed core wall for the shore embankment and the coffer dam for the lock, which has been



Sections of River.

Core Wall of Embankment between Bluff and Power Plant.

raised to only 10 ft. above low mark. I do not believe it possible to finish this work under two years, and it is quite possible that a destructive flood may considerably increase this time. To complete the work within two years the working force and plant employed will have to be greatly increased. The General Electric Co. will furnish the electric equipment.

It is the intention of the power company to furnish electric power at not more than $20 per horse-power per year, and they have already contracted for 50,000 h.-p., or practically the entire horse-power now used in the city. This rate will be about one-half of the present cost of power and is sure to cause many industries to locate in this favored city.

33 ft. The river side walls will be 32 ft. wide on bottom and 8 ft. wide on top, widened at the buttress supporting the gate at the upper end to 25 ft. on top and 35 ft. at bottom; and at the lower end to 25 ft. on top and 46 ft. on bottom. In each wall will be built culverts 11 ft. high by 6 ft. wide, running the entire length of lock chamber, and each having ten openings 3 ft. below low water, by means of which the lock chamber will be filled. It will be emptied by two culverts of similar size, having their openings into the lower bay. Stoney sluice gates, operated by electric power, will be used to open and close these culverts.

The gates of the lock will be of the mitering type, horizontally framed, of mild steel, opened and closed by electric motors operating through rack bars. Provision will be made for operating by hand power should electric current fail. In extreme low water, with flash boards on the of the lock. To these trestles will be attached steel beams, against which will rest vertical needles of steel or wood.

Through the whole length of the dam will run a passage 2½ ft. wide by 6½ ft. high, its floor being 12 ft. below crest of dam. From the bottom of this passage will run every 12 ft. a 2-in. wrought iron pipe, extending to the downstream face of the dam, to supply air under the water passing over the dam. The passage will furnish a mode of crossing the river from the power house to the lock and carry the wires for furnishing electric power and light.

The power house will have seven bays, each containing two units. Each unit will consist of a generator and three turbines. This use of three turbines is made necessary by the great variation in the volume of water in the river. In ordinary heights of water only two of the turbines will be used; the third wheel is to be used when a

THE KAISER WILHELM CANAL connecting the Baltic and the North Seas has become too small for the demands of the traffic, and its enlargement and improvement have been proposed. The present profile is 29½ ft. deep at mean water level, 72 ft. wide at the bottom and 220 ft. at the surface. It is proposed to deepen it to 36 ft. and increase the width at the bottom to 144½ ft. and at water level to 334 ft. It is proposed to increase the length of the locks to 1,083 ft. and the width to 147½ ft., with a depth of 45 ft. at mean water level, which is equivalent to 39 ft. at low water. At two points it will be necessary to change the alignment, because the curves are too sharp for large, modern vessels. The present radius is 3,935 ft. and the proposed radius 5,866 ft. Beyond these two instances no change is proposed in the line of the canal. The passing stations are to be increased in number and will be, with the former ones, about 6 miles apart. The cross section of these stations is to be 440 ft. at the bottom and 624 ft. at the water surface. Turning stations will be created at four points by enlarging four of the passing stations, so as to have a length of 3,919 ft. a bottom width of 538 ft. and a surface width of 722 ft.

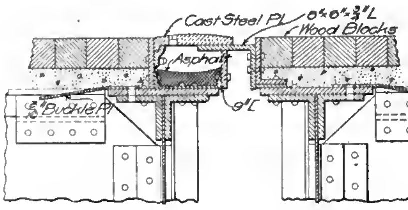
The Queens Approach to the Blackwell's Island Bridge, New York.

The approach to the east or Long Island end of the main spans of the bridge across the East River and Blackwell's Island has provision for two elevated railroad tracks, four other railroad tracks, a carriage way and two sidewalks. It consists chiefly of a steel viaduct with spans of from about 56 to 166 ft. It it 86 ft. wide over all and about 2,663 ft. long from the center of the anchorage pier to the entrance, including about 333 ft. of solid fill between masonry retaining walls at the entrance. The carriage-way and the four surface tracks, rise at a uniform grade of 2.4 per 100 from the surface of the ground at the entrance to a height of about 100 ft. above the ground or 112 ft. above mean low water at the anchor pier. It lies wholly in the borough of Queens and crosses eight streets and boulevards in the suburbs of Ravenswood, Long Island City. Like the main spans of the bridge and the Manhattan approach, described on Nov. 23, it has two decks, the upper one about 63 ft. wide over all, carrying in the center the two elevated railroad tracks and on each side a foot-walk about 14 ft. wide in the clear. The lower deck, about 21 ft. 9 in. below the base of rail of the elevated track has a clearance of about 15 ft. 9 in. under the transverse girders of the upper deck. It is 86 ft. wide over all, corresponding to that of the main spans and differing from the Manhattan approach, which is much wider and is in accordance with the totally different types of construction, being more suitable for the cantilever construction adopted here for the support of the outside tracks which in the Manhattan approach are carried directly by vertical columns under the extremities of the transverse girders.

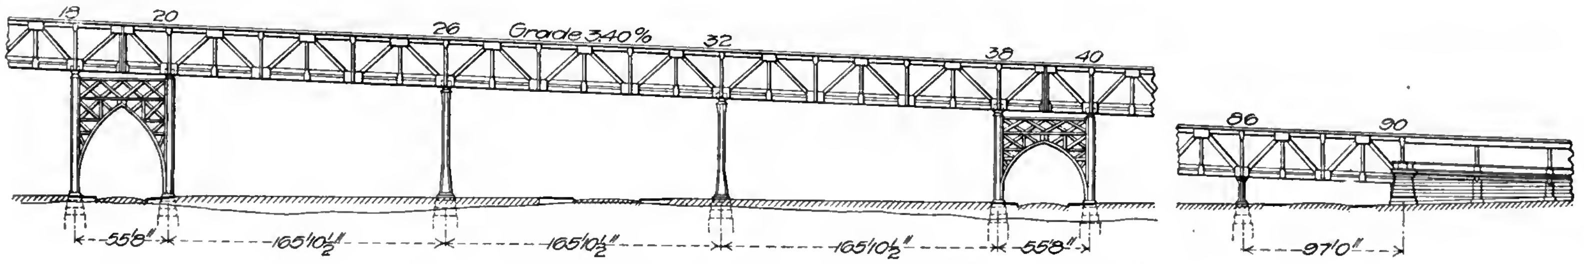
This steel superstructure consists essentially of groups of five spans each, supported on towers 55 ft. 8 in. long and on two transverse bents intermediate between each pair of towers. The lengths of the main spans are proportioned in accordance with their height above the ground, varying from 97 ft. at the lower end to 131 ft. 4 in., 145 ft. 6 in., and 165 ft. 10½ in. at the bridge ends. The minimum clearance of the completed superstructure above the surface of the ground is about 15 ft., and the towers and vertical columns are so located that they clear the intersecting streets, four of which pass through the towers.

Unlike the Manhattan approach this approach has no subway station or depressed tracks, all of the surface tracks leaving the bridge at grade at the Crescent St. entrance, where the only structure of an auxiliary character is the stairway leading to the end of the elevated railroad tracks which may later on be joined to a connecting line in Ravenswood. The embankment approach has a clear width of 86 ft. uniform with that of the lower deck of the steel viaduct and has retaining walls 333 ft. long and 20 ft. in maximum height above the surface of the ground. They are of concrete offset in the rear and battered in front where they are faced with granite down to a few inches below the surface of the ground. They are 3½ ft. wide under the coping and are 10 ft. wide at the base for a height of 20 ft. The filled embankment between them is covered with 6 in. of concrete on which the wood pavements, railroad tracks, and electric conduits are laid and in which there are four lines of electric ducts. The columns for the elevated railroads are carried down 5½ ft. below the surface of the roadway where they are seated on separate offset concrete piers of a maximum height of 16¼ ft. and footings on dense sand. A cast-iron guard encloses the column to a height of about 18 in. above the roadway, and below its top the column is entirely enclosed in a solid mass of concrete.

The elevated railroad structure is substantially the same throughout the length of the approach whether it is supported by the steel viaduct or on the filled embankment. The principal difference is in the feet of the columns, which in one case are seated as already described on masonry piers, and in the other case are the regular vertical posts at the panel posts of the main trusses which carry the lower deck. Accordingly, in the viaduct spans the transverse girders of the elevated structure, about 22 ft. apart, directly support the four lines of track stringers and the four lines of sidewalk stringers, all of which are plate girders, respectively 48 in. and 42 in. deep.



Expansion Joint in Roadway.



Part Elevation of Queens Viaduct of the Blackwell's Island Bridge.

The sidewalks are carried by 7-in. transverse I-beams supported on each side of the bridge by two lines of stringers and by the top cords of the truss. At the end of the steel viaduct there are eight 44-ft. elevated railroad spans supported by the vertical columns. Each of them has eight lines of 48-in. longitudinal plate-girders web-connected to the transverse girders 6 ft. deep that are supported by the vertical columns 60 ft. apart transversely, to which they are connected by vertical web angles and by deep solid-plate kneebrace brackets. There are also two lines of fascia girders 3½ ft. deep riveted directly to the columns and each carrying, together with two adjacent lines of longitudinal girders the transverse sidewalk floor beams on cast-iron filler blocks. The floor panels are X-braced with single 6-in. horizontal lateral angels web-connected to the transverse girders about 2 ft. above their bottom flanges. The sidewalks are made with reinforced concrete floor slabs and have hand rails with cast-iron bolts, cast pipe rails and riveted lattice work webs.

The transverse girders have 7-16-in. web-plates reinforced to 1 3-16-in. thick at the ends and each flange is made with a pair of 8x8x13-16-in. angles and three 18-in. cover plates of different thicknesses and lengths. The columns are vertical and the transverse girders are riveted to them at a slight angle to correspond with the angle of the grade.

The longitudinal girders have their fixed ends field riveted to the webs of the transverse girders and their expansion ends are supported in pockets made with pairs of vertical angles riveted to the webs of the transverse girders and connected at the bottom by a reinforced horizontal shelf angle. The bottom flange of the longitudinal girder slides freely on the shelf angle and the top flange is guided between the vertical pockets by short longitudinal angles riveted to the under side of its top flange and forming transverse bearings.

The four viaduct towers vary in height from about 20 to 80 ft., but all have the same transverse and longitudinal dimensions, namely 55 ft. 8 in. and 60 ft. on centers, and have the same details of bracing modified only by the varying dimensions. The faces are similar in transverse and longitudinal elevations, in each of which the tops of the vertical columns are connected by a horizontal lattice girder and by deep portal struts forming a continuous arch between the columns. The dimensions of the two bents of the same tower vary slightly, but the materials are alike. In successive towers both materials and dimensions vary perceptibly.

In the second tower from the entrance the tallest bent has a height of about 36 feet., and the lattice girders are 7 ft. 9 in. deep on centers, with a rectangular top chord composed of two 12-in. channels and a 34x9-16-in. cover plate. The bottom chord has an H-shape cross section made with two 12-in. channels connected with lattice on their flanges and by an intermediate horizontal diaphragm made with two continuous full-length angles latticed. The web members consist of X-braces each of which has an I-shaped cross section made with two pairs of 3x3½-in. angles back to back latticed. At intersections one member is continuous and the other is cut to clear and spliced with field riveted cover plates on both flanges. The curved portal brace has a rectangular cross section with two 17x⅜-in. web plates, one 25x⅜-in. cover plate, two 8x6x½-in. bottom flange angles turned inward, two 3½x3½x⅜-in. inside and two 4x4x⅝-in. outside top flange angles. The top flanges are connected by the cover plate and the bottom flanges are latticed. The web members connecting the curved portal brace with the columns and with the horizontal girders correspond to those in the latter member and are connected to rectangular extensions projecting from the face of the column.

The column has a cruciform cross-section, closed excepting for narrow lattice spaces in each face, and is also provided with an interior I-shaped diaphragm in a plane parallel to the bridge axis. It is made in the heaviest bent with four 8x6x¾-in. outside and eight 4x3½x⅜-in. inside flange angles, four 8x6x11-16-in. web angles, for the I-shaped diaphragm, two 38x13-16-in., four 7x⅜-in., and one 23x½-in. plates. The foot of the column is connected by ¾-in. bent plates to the 58x1-in.x58-in. base plates seated on a cast-steel pedestal. The bottom chords of the longitudinal and transverse latticed girders are braced at their centre points by I-shape horizontal struts perpendicular to them, each made with two pairs of 6x3½x⅜-in. angles latticed and intersecting in a common point at the center of the tower with two main diagonals of the same panel. At the intersection the longitudinal girder is continuous and

all of the others are cut to clear it and connected together and spliced with large field riveted top and bottom flange cover plates.

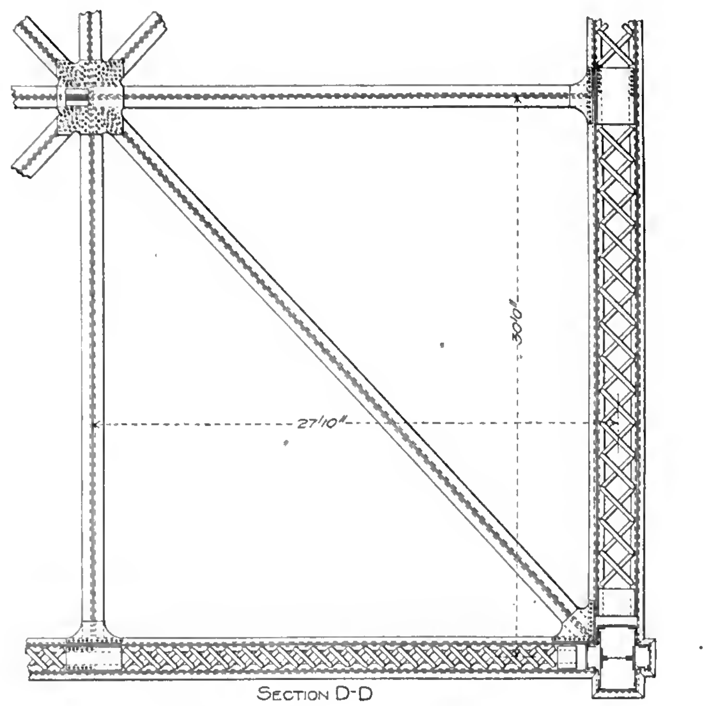
The single transverse bents intermediate between the towers correspond exactly to the bents forming the towers, except that the upper and lower ends of the columns are expanded longitudinally to form wider seats for the trusses and to secure extended bases. The construction is clearly indicated by the side elevation and cross sections of the 30-ft. 6-in. column in bent No. 64, which has a width of 5 ft. at the top and a width of 6 ft. at the bottom. It is made with eight 8x6x¾-in. and eight 4x3½x⅜-in. angles and four 38x⅜-in. and four 7x⅜-in. plates, the 7-in. plates have the small angles forming the wings. The shortest bents have a height of only about 12 ft. and 15 ft. and in them the horizontal girders are omitted, the columns being connected only by the curved portal struts and narrow top struts connected together with vertical and diagonal members so as to practically form spandrel braced arches. The cross sections of the column and portal bracing correspond essentially to those already described.

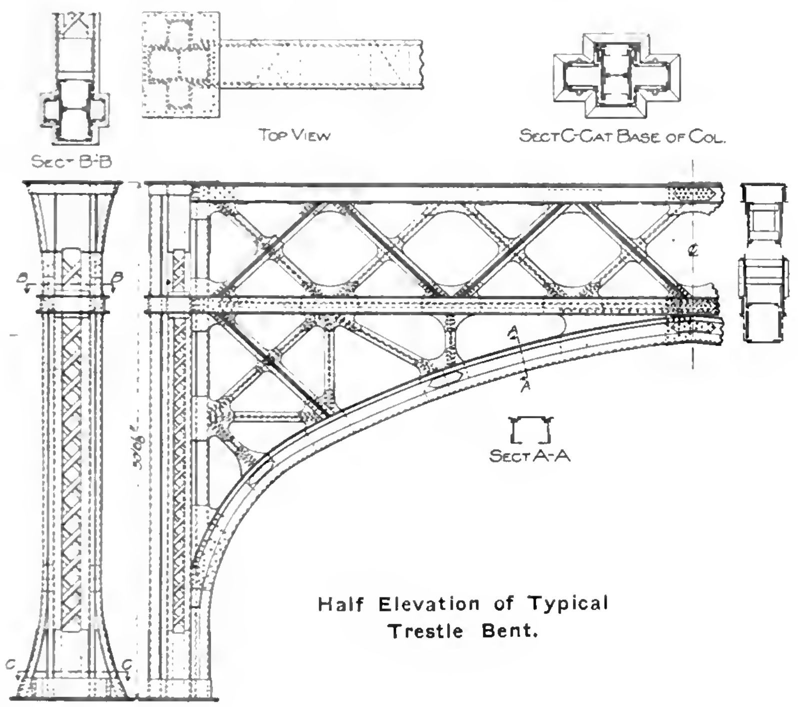
The cast-steel column bases have cruciform plans corresponding to the cross section of the columns and have a uniform height of 8 in. They are of cellular construction with a continuous base plate and vertical webs all 2½ in. thick. Both top and bottom surfaces are planed and the vertical webs are located in the planes of the column webs so as to afford them direct bearing without any horizontal top plates. Each pedestal has four 3-in. holes for vertical anchor bolts in the piers, and after its column is erected on it the pockets between the vertical webs are filled solid with concrete extending up into the base of the column.

The spans connecting the towers and intermediate bents are made with two lines of riveted trusses 25 ft. 6¼ in. deep and 60 feet apart on centers. The three spans in each panel between towers are duplicates except that the two end spans cantilever one panel beyond their supports on the tower to form half of the tower span. Except for the three spans at the shore ends which have two panels each, all spans have three panels, varying with the total length of 131 ft. 4 in., 145 ft. 6 in., and 165 ft. 10½ in. Except for these changes and the corresponding variations in material all spans are essentially duplicate and the details of construction and connections are alike throughout the approach. The spans between the first and second towers from the shore ends are 131 ft. 4 in. long on centers, with 21 ft. 10⅝ in. panel lengths.

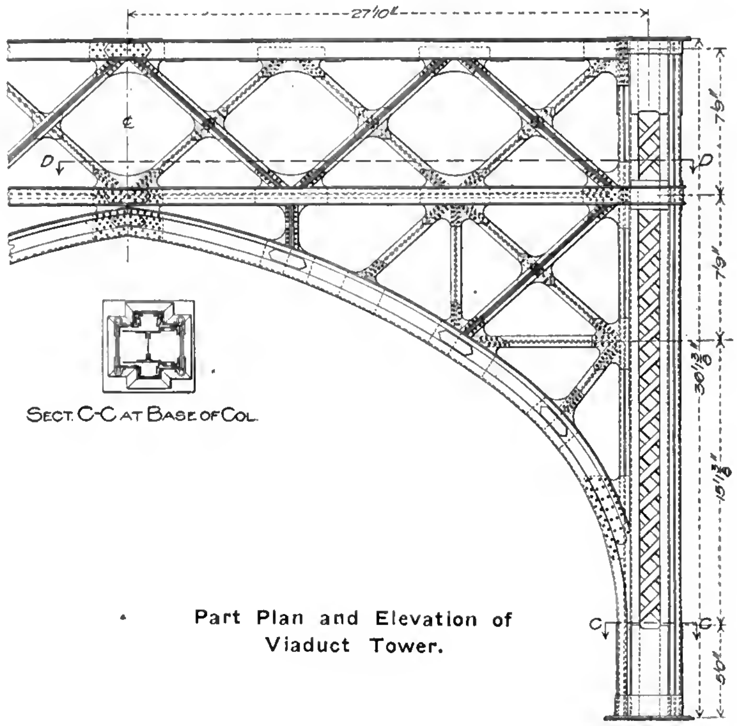
Both top and bottom chords have rectangular cross sections made with a pair of built channels with their flanges turned inward and latticed. The maximum bottom chord section consists of four 6x4x⅝-in. flange angles, two 30x9-16-in., two 28x½-in., and two 22x⅝-in. web plates, giving a net area of 96 7-10 sq. in. The minimum bottom chord is made with four 6x4x7-16-in. flange angles and two 30x⅝-in. web plates, giving a net sectional area of 45.7 sq. in. The top chord is of similar construction materials and dimensions, with a minimum net area of 33 3-10 sq. in.

Both top and bottom chords are apparently continuous through the three spans from center to center of towers, but sliding joints with cover plates bolted on through slotted holes are introduced in the top chords near the intermediate bents to separate the spans and prevent continuous girder action in the trusses. The construction of the diagonal members is similar to that of the chords, being made with rectangular cross sections composed of two built channels with their flanges turned in and latticed, with a maximum cross section composed of four 6x6x½-in. flange angles, two 30x½-in., two 28x9-16-in., and two 18x½-in. web plates. The panels are subdivided by vertical posts having a uniform I-shape cross section made with four 7x3½x½-in. flange angles and a 23½x⅜-in. web plate.





Half Elevation of Typical Trestle Bent.



Part Plan and Elevation of Viaduct Tower.

All members of the trusses are shipped separately, the chords being made in two-panel lengths and having ¾-in. connection plates shop riveted to the backs of their channels at panel points and projecting beyond their inner flanges to serve as connection plates receiving the field riveted connections to the vertical and diagonal members. At the panel points over the intermediate posts supporting the center span, these connection plates serve as field splice plates for lower chords. At all other points top and bottom chords are spliced with six or eight web and flange cover plates field riveted to both members.

The trusses are connected at panel and sub-panel points by the transverse girders in the upper and lower deck which are field-riveted to the vertical members with their flanges flush with those of the chords. At the girder connections the chord webs are connected by the vertical members of the truss which pass through them or by pairs of vertical transverse diaphragms which stiffen them and distribute the load through both of the built channels. In the lower chord these members also provide continuous connections between the main section of the floor beam uniting the trusses and the cantilever extensions on the outside of the trusses. Horizontal connection plates riveted through the lower flanges of top and bottom chords at panel points and to the floor beam flanges provide for the field riveted connnections of the single top and bottom lateral system diagonal angles. The trusses have no transverse vertical diagonals, but are sway-braced by the depths of the connections to the transverse girders and by the portal-like kneebrace brackets under the upper deck.

Over the vertical posts in the towers and transverse bents the trusses have bearings on 9-in. pins engaging half-hole bearings in cast-steel shoes and pedestals. The shoe differs from those ordinarily employed for the bearings of riveted trusses for

girders in that it has, besides the horizontal bearing on the bottom flange of the chord, a pair of vertical web plates connected by an integral transverse diaphragm and engaging and riveted to the webs of the lower chords. Both vertical and horizontal bearing surfaces are faced and the rivet holes are drilled after the shoe is assembled to the lower chord, thus insuring absolute precision in the rivet holes.

The continuous half-hole bearing for the pin is stiffened with longitudinal and transverse webs and has in the center a groove for a collar, which is also grooved into the pin and locks it in position. The pedestal has a similar half-hole pin bearing stiffened with one longitudinal and four inclined transverse webs integral with the wide base plate, 3¼ in. thick, secured to the tower or

The four trolley stringers have pairs of 5x3½x⅜-in. flange angles and single full length 16½x⅜-in. top flange cover plates. The seven intermediate stringers carry the roadway at 3½x3½x½-in. flange angles without cover plates. All the stringers are web-connected to the web of the transverse girder and are seated for convenience in erection on horizontal bracket angle shelves and have the upper corners of their webs cut to clear the top flanges of the transverse girders.

A solid floor of ⅜-in. buckle plates is riveted to the top flanges of all stringers and transverse girders. The cantilever ends of the transverse girders are field riveted to the vertical posts of the trusses and are spliced to the main girders by pairs of angles on the top flange and by an 18x15/16-in. cover plate 7 ft. 9 in. long on the

At these points there are double floorbeams 20½ in. apart on centers with special top flanges connected by a sliding apron plate. A full length trough made with 5x¾-in. plates riveted to the flanges of a horizontal 9-in. channel is riveted to the top flange of the fixed girder, and the space between the channel flanges is filled with asphalt hitched to one end and making a gutter to carry off drainage water from the pavement without danger of leakage to the road below. One edge of the trough has a continuous cast-steel bracket forming a sort of hinge connection for the checkered cast-iron apron plate 12 in. wide and 2 in. thick, with a convex checkered upper surface, which is made in sections about 5 ft. long. The outer edge of this plate is supported by and slides freely on the horizontal flange of a 6x8-in. angle riveted to the transverse movable girder and bearing on the upper edge of one of the trough plates. This arrangement provides for a movement of several inches, causes very little ir-

Cable Conduit Stringer.

vertical post with numerous field rivets around the outer edge. The space around the webs is filled solid with concrete retained by a projecting fillet around the edge of the base plate, which is recessed to lock the concrete in position. At the expansion ends the height of the pedestal is made 7¼ in. less than at the fixed end, and it is seated on a nest of eleven 4-in nickel steel rollers 40 in. long, supported on a cast-steel bed plate 3 in. thick. The rollers are fixed transversely by center guide ribs and their shouldered ends engage the vertical flanges of angles carefully fitted to rebates in the end of the base plate and pedestal, thus excluding dust and rubbish from the rollers.

The transverse girders in the lower deck are each made in three sections, one of them 58 ft. long between the trusses, with a 12-ft. cantilever extension outside the trusses at each end. The 58-ft. section has a 72½x7-16-in. web shop spliced in three lengths and a pair of full length 8x6x⅝-in. angles in each flange. The top flange has a single 24x¾-in. full length cover plate and the bottom flange has a full length 18x⅝-in. and a 34-ft. 18x½-in. cover plate. The girder is divided into 5-ft. panels by vertical web stiffener angles at the connections to eleven lines of stringers, all of which are plate girders with 27x28-in. webs.

bottom flange. Their outer ends are connected by a continuous line of facia stringers made with a 45x⅜-in. web plate and a single 6-in. 15-lb. channel riveted to the outside of each flange.

The stringers for the outside trolley track are of special construction with a 27x⅜-in. web and 5x3½x½-in. flange angle. The top flange is reinforced by a 60½x⅜-in. cover plate, to which is riveted a 6-in. bulb angle reinforced by a 2x2-in. stiffening angle to serve as a guard-rail. The lower corners of the webs are notched to clear the top flange of the cantilever and give a bearing on it for the stringer web and allow the bottom flange to be seated in the usual manner on a bracket angle riveted to the girder web. The end of the lower flange is stiffened by a pair of inclined web stiffener angles and pillar plates.

The electric conduit in the center of the trolley track is made with a pair of built channels 13 in. deep with their flanges turned in and the upper one supporting the Z-bars forming the slot. The curb girder just inside the trusses has a rectangular cross section, made with two 15-in. channels, with both flanges turned in the same direction and connected by an 18x⅜-in. cover plate on top and by lattice bars on the bottom.

Transverse expansion joints are provided in the lower floor on the center lines of the towers.

regularity in the surface of the pavement and can be easily inspected, cleaned or repaired.

The specifications for the sub-structure and super-tructure are very complete and correspond substantially with those already mentioned in the article descriptive of the Manhattan approach. The requirements for the structural steel and for the cement correspond to accepted standards and contain ample provisions for tests and inspections. All parts of the work are proportioned for expansion and contraction due to a change of temperature of 160° Fahr. and all rods and tapes used in laying out these works in the shops are carefully standardized with those used in the location work. Paint is mixed with 500 lb. of red lead to 19 gallons of pure linseed oil. The red lead must contain at least 80 per cent. true red lead and not more than 1/10 of 1 per cent. of metallic lead. It shall pass through No. 19 silk bolting cloth with a residue of only 1 per cent Very complete specifications and descriptions are given for the track construction, electric equipment, rail joints and bondings and the creoresinade wood block pavement.

The principal quantities in the second section include about 17,000 cu. yd. of excavation, 35,000 yd. of fill, 8,400 yd. of concrete, 2,500 yd. of dry rubble retaining walls and coping, 4,900 yd. of

granolithic concrete walks and foundations, 10,500 yd. of pavement, 3,900 lin. ft. of four-way electric conduits, 9,500,000 lb. of structural steel, 280,000 lb. of steel castings and 60,500 lb. of nickel steel castings, 172,000 lb. of steel rails and 173,000 lb. of cast-iron.

The bridge was designed and its construction supervised by the Department of Bridges of New York, Mr. J. W. Stevenson, commissioner; Mr. C. F. Ingersoll, Jr., chief engineer. The contract for about 1,420 ft. of the viaduct nearest the river was awarded to the Buckley Realty Construction Co. and the contract for the remainder was awarded to the Maryland Steel Co., who fabricate the structural steel work at their steel shop and who have sublet the contract for the erection and for the sub-structure work to the Snare & Triest Co., New York.

Ditch Construction on the Seward Peninsula.

The placer mining industry of the Seward Peninsula, Alaska, was developed at a very remarkable rate, the possibility of lucrative mining being established within about a year of the discovery of gold. The great drawback, however, was the absence of water, and though good sense and engineering judgment discouraged the construction of ditches, the rich field awaiting development promised a return on the heavy investment necessary to get water. Construction was first started in the Miocene Ditch, a project about 60 miles long, which carried the water from the head of Nome River across the divide to a point above the benches of the Snake River slope. The constructors had no precedent for such work in this climate, but by sheer grit surmounted all difficulties. The success of the enterprise ushered in an era of construction during which, in 1905, the ditch of the Taylor Creek Ditch Co., of New York, was built. The latter work was described by Mr. James A. Kelly, engineer for the company, before the Pacific Northwest Society of Engineers, in a paper reprinted in the September "Proceedings" of the society, from which these notes have been taken.

The data furnished to Mr. Kelly consisted of a profile of the proposed ground to be traversed, which plainly showed itself to be the work of the barometer and hand level, and a verbal description of the country. The date fixed for embarking upon the expedition was June 4.

Among the materials necessary were one-half mile of 40-in. No. 10 B. W. G. steel riveted pipe, 400,000 ft. of No. 1 clear fir lumber, surfaced four sides, and some few miles of burlap 12 ft. wide; plows, scrapers and graders; sixty-five horses, twenty-two wagons, material for a suspension bridge and tons upon tons of provisions for the laborers and feed for the horses; 50 tons of coal; tents to house three hundred men, office tents and stable tents, the latter accommodating twenty horses each.

The pipe was nested, one section 5 ft. long, full riveted, enclosing four other sections nested inside and bound with clamps of strap iron after the fashion of sheet steel. Hay was hydraulically compressed. Sustenance for the men selected from the class of provisions generally conceded to be the most filling and nourishing for their weight. The material and supplies were sent by tramp steamship to Teller, at the mouth of Grantley Harbor, the main part of the expedition sailing to Nome with the horses, wagons and some few implements for the construction. The trip to Nome and unloading of boats occupied about 15 days. Then followed a wait of about two weeks to allow the horses to recover from the effects of the sea voyage and get acclimated; also to allow spring freshets in the rivers time to subside.

During the first week in July the expedition started out overland for the Kugorock River, a distance of about 150 miles. It tallied-up ten wagon outfits, each comprising six horses and two wagons and about twenty men, including drivers. From ten to twelve miles per day was the average haul, and that with only about 3,000 lb. load for six big horses and two wagons. Extra feed and provisions for horses and men were brought up by boats from Teller through Grantley Harbor and Great Salt Lake to Mary's Igloo, a distance of 65 miles, and from here on up the Kutsitrin River in horse boats to Lane's Landing, fifteen miles. This place was about half way between Nome and the destination and was generally used as a supply station for the surrounding country. The horse boats were usually about 20 ft. long, built scow fashion, but with a great deal of dish, and flexible enough to be twisted without breaking. They were pulled up stream by one horse.

The Peninsula is practically barren of timber, except for a few small clumps of cottonwoods and dwarf firs in river bottoms, and is for the most part covered with tundra. There were no roads in the country, and had there been, contrary to what is usual, the beaten track would be the thing to shun, it being always one continuous mudhole. On the 18th of July the expedition started down the slope into the Taylor Creek valley, and at noon camped at a point about the center of the proposed ditch line.

Transportation of the main part of the material was effected as follows: One supply station was established on the beach at Teller, and another one, to be used as a base, established on a navigable slough or arm of Great Salt Lake and named Kugorock. Here the party built a large warehouse and stable 60x80 ft., with a strip off each side used for stables for horses and the center for perishable supplies. A light draught stern-wheel gasoline boat provided with several scows was placed on the run between these two supply stations, traversing Grantley Harbor and Great Salt Lake and the aforementioned slough, a distance of 60 miles. From here on material was transported by wagon outfits up the bed of Mary's River to the summit, down Coarse Gold Creek to the Kugorock, and up the Kugorock to Taylor Creek, a distance of 45 miles, and distributed as required. The wagons were the common type of farm wagon, with perhaps all vulnerable parts a little stronger than is usual. One ditch company used an ordinary wagon with extra tires of steel 10 to 12 in. wide, shackled on over the felloes of the wheels, these tires sometimes preventing the wheels from sinking in the mud, but making matters much worse when they did. Another outfit would have nothing but narrow felloes and tires, with spokes widening toward the hubs so that if the wheels did sink more readily they would the more easily be pulled out. Wherever possible wagon trains took to the beds of streams, which, though full of boulders, at least had the virtue of being solid.

The methods of making the surveys were simple, being first the setting of stakes 1½ ft. above the proposed sub-grade of the ditch, the fall of which was only about 4 ft. per mile, owing to the necessity for developing head in as short a distance as possible and the danger from erosion in glacial ground consequent to high velocities. Following the level party, a hand level party reset the lower stakes to obtain some respectable appearance of curvature and allow for slope, at the same time setting upper slope stakes to conform. Slope was usually 2 to 1. The stake material was all of selected fir, 5 ft. long, 1½ in. wide, ¾ in. thick, surfaced four sides, and shipped in bundles of fifty each. On the ground the bundle was sawed in two and the stakes sharpened.

The ditch was to be some twenty odd miles long and designed to carry about 90 cu. ft. per second. It was broken in the middle by a crossing of Taylor Creek, in the form of an inverted syphon carried on a suspension bridge. Spillways were to be placed every mile or so of its length to regulate the flow of the water in the ditch, which would vary considerably owing to the surface drainage. Alternating with these spillways every mile were waste gates, permitting the water to be shut off entirely from the portion of the ditch beyond and allowing the section of the ditch thus isolated to be thoroughly emptied for repairs.

The working season being a short three months, dirt was flying before the first 600 ft. of stakes were set. The stakes being set, tundra was immediately plowed up between the lower slope stakes and up to a point directly over the bottom of the ditch on the up-hill side. This sod or tundra was dragged off by laborers with hooks made from miners' driving picks with the ends bent over, and if the sod was of any value at all as bank it was placed as such, otherwise tundra and light material was dragged down the slope to clear the bank. The ground thus exposed was allowed to thaw. In the glacial ground it thawed and sunk readily to a point below the sub-grade, then burlap was placed in the bottom of the ditch to prevent erosion and thawing, and covered with silt up to grade, the sod left on the upper side gradually dropping as the ground sloughed out from under, forming a protection for the upper bank against further thawing. In cases where the ground thawed unevenly an ordinary device similar to an old-fashioned snow plow, V-shaped, steel shod and well loaded with sand bags, was held against the upper bank and dragged along with horses, pushing the mud against the lower bank and evening up the bottom of the ditch. For ordinary dirt excavation, long-handled shovels and a type of horse scrapers generally known as "slushers" were used, six teams with scrapers comprising an outfit, with one driver, two loaders and two dumpers working in a circle crosswise of the ditch and dumping on the bank. When the ditch was roughly excavated by this means, it was trimmed up and sloped by laborers with shovels and mattocks.

The rock encountered footed about 20,000 cu. yd., and was for the most part perpendicular cliffs of mica schist, interspersed with stringers of quartzite, very soft and almost capable of being moved with mattock and shovels, but not quite, and Mr. Kelley states that after an experience of ten years and the personal use of hundreds of tons of high explosives, this rock is the worst to move he ever encountered, some innocent little shots tearing whole slabs of the cliff away below grade, while other big ones seemed to find their way into crevices and not accomplish anything. In places where no rim was left for the lower side of the ditch, sod walls built with all the care usually given masonry were placed.

Short pieces of flume were used across gaps, with aprons well sodded in, and sometimes burlap or canvas was used to make the joint tight. The foundation pits for the flume trestles were cut in the ground, mud blocks of cedar set and sills set on top, and as far as possible covered up with sod to prevent further thawing of the ground. These were left to stand a while and assume any position or elevation they chose, and trestles and flumes built on top. On the whole line there was about a half mile of flume.

It was intended to construct the dam of concrete, but legal obstacles prevented securing a favorable site and the dam was built of sand bags, sod and boulders.

The inverted syphon was constructed from the 40-in. pipe afore-mentioned, having a maximum pressure at the lowest point of 50 lbs. per square inch, and the pipe was supplied at each hump in the grade with automatic air valves, six in all, and in the center of the suspension bridge with a blow-off. The suspension bridge carrying the syphon had a clear span of 100 ft., and consisted of two 1¾-in. plow steel cables, 4 ft. 4 in. apart, one on each side of the pipe, from which yokes were suspended every 5 ft. apart. The main cables had a dip of 12 ft. at the center of the span, and were carried back 37½ ft. beyond the towers to anchors buried in the frozen ground. The yokes which were suspended between the hangers and carried the pipe were of fir, 6x16 in. x 5 ft. 4 in. Foot boards of 3x12-in. stuff were laid on the yokes on both sides of the pipe and guys of ¾-in. rope were run to shore in four directions from the center, and anchored with dead men frozen in. The towers were built of timber 19 ft. 6 in. high.

The anchorage pits for the main cables were cut into the ice about 15 ft. by means of steam thawers. Dimensions at the bottom were 8x17 ft. Here a mattress was placed consisting of 12x12-in. plank 17 ft. long, and on top of this cedar planks, 3x12 in. x 8 ft., placed crosswise. The main cables were secured to these by means of a number of loops from the flexible small cable and water and mud poured in until the pit was filled up and the holes allowed to freeze again before the false work for the bridge was removed.

By the term "glacial ground" in this article is meant ground with a covering of moss or tundra a foot or two thick, with a stratum or deposit of mud and black peat from 2 in. to 1 ft. thick, and below this from 10 to 40 ft. of ice holding in suspension perhaps 10 to 20 per cent. of silt. Under normal conditions the peat or mud thaws in the summer time a foot or so, but in some places not at all. It was observed by the pioneers, however, that there was less liability to encounter ice on the south slopes, hence frequent crossings from one side of the valley to the other were resorted to.

STEEL CROSS-TIES of trough section placed 6 ft. on centers have been used on about 75 per cent. of the city lines of the Montreal Street Ry. Under each line of rails there is a concrete beam, while between the beams there is the usual concrete foundation for the pavement.

Fire Protection System of the American Dock Stores.

By Frank Sutton, Consulting Engineer, New York.

It has only been during the past few years that the question of some adequate means of fire protection has been adopted. While it is true that the sprinkler head has been used for some time, it has been confined almost entirely to manufacturing establishments, and even then to a limited extent, the owners of buildings having depended largely upon the fire departments of the towns in which they were located. Of late years the importance of some adequate and reliable means of extinguishing fires has been realized, and to-day a large number of manufacturing concerns are endeavoring to provide complete systems of fire protection.

The credit of bringing this branch of engineering up to its present state of perfection is without doubt due to the New England manufacturers, who long ago realized that it was to their advantage to provide some suitable form of protection, and their example has been steadily followed, until at the present time the sprinkler and fire protection business has grown to a very large extent, although, strange to say, this particular line is confined to a small number of concerns who make a specialty of this class of work. This is without doubt due to the fact that the underwriters have been very stringent in their requirements as to the design of the sprinkler head, which is the important factor in an up-to-date fire protection equipment. Then, again, the question of patents has entered largely into the design of heads, and at the present time it is a difficult matter to design a new head which will not infringe on some article already being manufactured. Even up to this time designing engineers have paid much too little attention to this question, the work having been left almost entirely to the sprinkler concerns to design the systems which are installed.

Another important feature in connection with this class of work is not only the advantages gained by protecting the property against loss by fire, but also the large reduction in the rate of insurance, varying from 30 to 50 per cent. reduction for a sprinkler equipment. The writer has known of cases where in a first-class equipment the insurance is carried for from 5 to 8 cents per hundred, which is extremely low. These low rates are confined mostly to the mutual companies, which are in the majority of cases more stringent in their requirements and will only assure what might be termed preferred risks, such as factories of certain construction and manufacturing certain lines of goods, and in some cases docks and warehouses, and will only accept risks that are protected with sprinkler equipments.

Sprinkler systems may be divided into two classes, wet pipe systems and dry pipe systems, the wet pipe system being used and being required for all purposes where the lines are not exposed to freezing. It is only in cases where the pipe is exposed to low temperatures that the dry pipe system is installed.

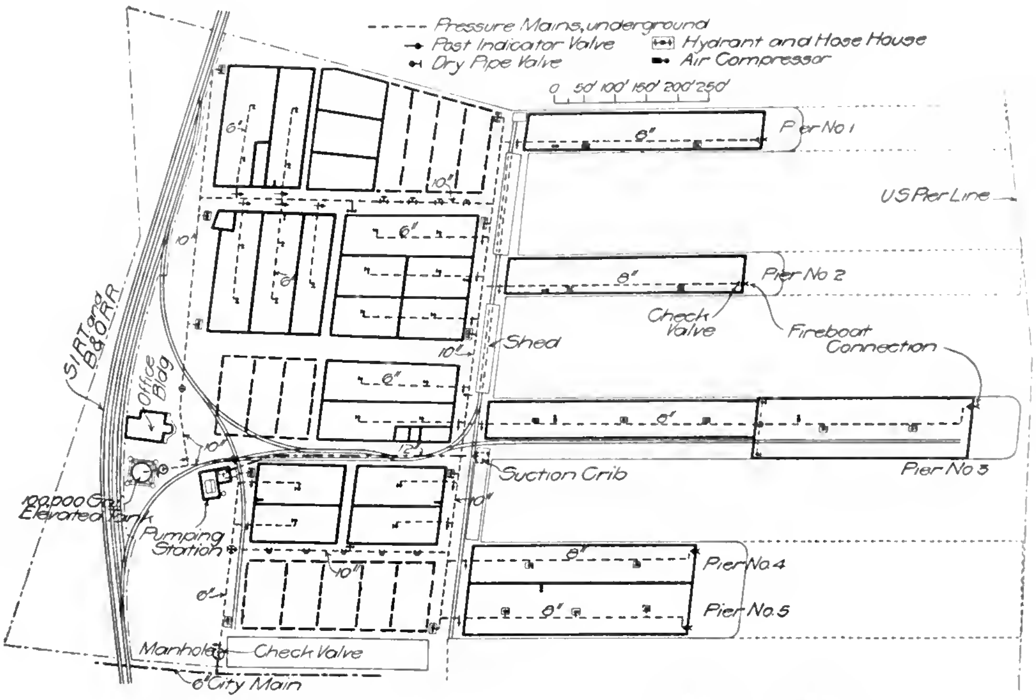
The principal differences between these two systems is that in the wet system the piping up to the sprinkler head is full of water. The dry system is supplied with air in that part of the piping which is exposed to freezing temperature. This is accomplished by keeping a pressure of air in the lines a little above that of the pressure in the water pipes and interposed by a specially constructed dry valve which operates when a head discharges, thereby relieving the air pressure and allowing water to flow through the lines. The illustration shows a dry valve which is used by one of the sprinkler concerns. These valves are all constructed on similar lines and are fully protected by patents.

To install a first-class fire protection system there should be at least two sources of supply and preferably three; that is, three distinct sources from which water may be drawn. One source is the sprinkler tank, located at some distance above the highest sprinkler head, and another source is the supply of water furnished by some public water works, either getting direct pressure into the system or operating through a fire pump. Other sources may be either a lake or a river, or artesian wells or springs, depending upon the location of the building. It is also sometimes customary to build a large reservoir, underground or outside, holding anywhere from 100,000 to 500,000 gallons, that may be drawn upon as required.

The insurance people, especially the mutual companies, insist on two sources, namely, a sprinkler tank and a fire pump if the street pressure is not great enough to carry the water to the highest sprinkler head. Where a steam fire pump is installed it is obligatory on the part of the assured, especially in mutual risks, that the boiler plant be kept under 50 lb. of steam at all times, so as to assure ample protection in case of fire. The electric fire pump is used to a considerable extent, but is not considered by the underwriters so good as a steam pump, on account of the danger of the pump motor being put out of commission either by water or by the breaking of electric wires.

The wet pipe system is by far the simpler of the two systems to install, as no complicated dry valves, air compressors or the like are required. The two systems, however, operate practically the same; that is, whether a dry pipe or a wet pipe system is installed the underwriters will require the same sources of supply and the equipment installed in the same manner, as far as the spacing of sprinkler heads is concerned, and the sizes of pipe used in connection with the installation of the system.

The following description of the fire protection system installed in the extensive docks and warehouses of the American Dock & Trust Co., at Tompkinsville, Staten Island, on lower New York Bay, gives an idea of a thoroughly up-to-date dry pipe system. In buildings of this class it would have been impracticable to install a wet pipe system, on account of the danger of freezing the lines, as neither the piers nor the warehouses have any heat whatsoever, and, in fact, the underwriters particularly stipulate that no heat shall



Warehouses and Docks of the American Dock Stores, Staten Island, N. Y.

be installed in any public warehouse. It became, therefore, necessary to install a dry pipe system throughout.

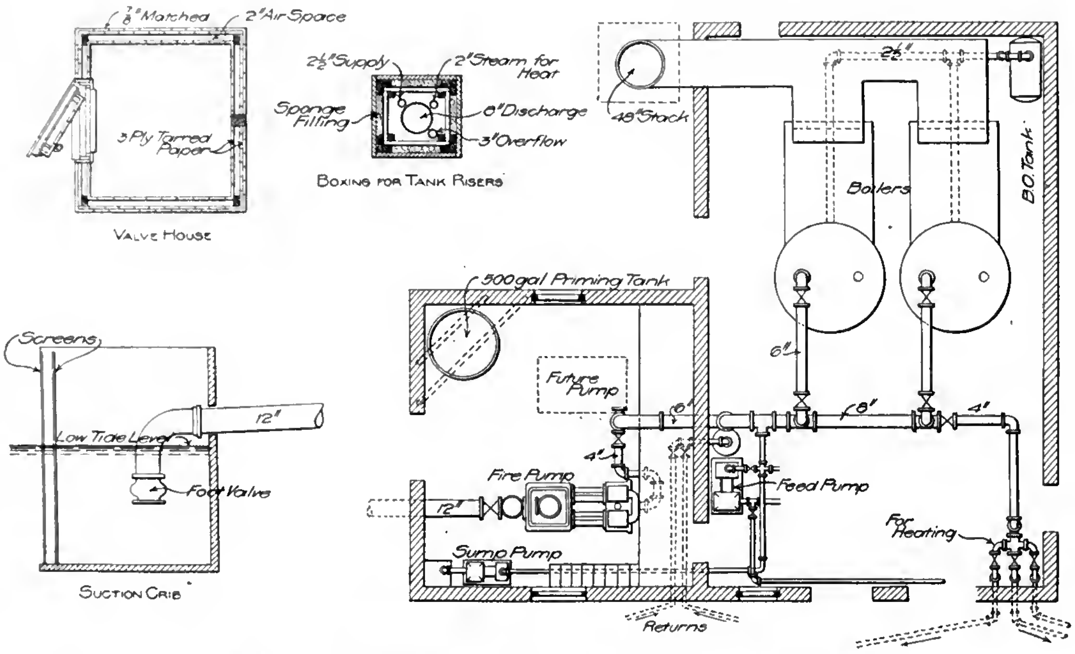
This particular system has three sources of supply, namely, a 100,000 gal. sprinkler tank erected on a 100-ft. tower, a supply from the Staten Island Water Co., running full 6 in. into the property, and a 12 in. suction line, running from the Lower Bay to the fire pump. It can be seen that from these three sources the property in question is assured without doubt of always obtaining at least one source of supply in case the other two are for any reason out of commission in time of fire.

A specially constructed brick and concrete pumping station has been located at the back part of the property on a line of the Baltimore & Ohio R. R., as shown on the plan. The boiler and pump rooms are divided by a brick partition, and a fire pump has been placed at a level about 6 ft. below the grade to assure a good suction from the Bay at low tide. The plant consists of two 150-h.-p. Fitzgibbon boilers, designed for a working steam pressure of 125 lb., which, however, is only used in cases of emergency, where the pump is required to work at its maximum duty. There has been installed one 1,000-gal. Worthington standard duplex fire underwriters' pump, having a 12-in. suction and an 8-in. discharge. The pump is also fitted with four independent 2½-in. nozzles, with gate valves for drawing four streams from the pump house in case of necessity. The boiler plant is fed by a duplex pump and also an injector to assure the boiler being supplied at all times. Ordinarily anthracite coal is used for running the fires, but a supply of cannel coal is always kept on hand, so that in case of emergency a high steam pressure can be developed within a very short space of time.

This line feeds the hydrant system and also the sprinkler system. The underground system is connected with a 10-in. drop riser, running from the sprinkler tank into it, and a 6-in. service pipe, running from the mains of the Staten Island Water Co. The discharge from the fire pump also empties into this line. Standard two-way underwriters' hydrants have been placed at intervals of about 200 ft., and at each hydrant is a complete hose house, equipped with standard underwriters' cotton hose, lanterns, wrenches, nozzles and other appurtenances required by the underwriters.

freezing. The sprinkler system itself is kept at an air pressure of about 45 lb. in this particular case and is supplied from a system of air lines, which start from the boiler house and are connected to a New York Air Brake Co.'s duplex, locomotive type air compressor, steam driven. The air compressor is automatically operated by a governor placed on the steam inlet to the compressor and set at 45 lb., which starts the pumps when the pressure falls below this amount.

In case a sprinkler head is set off it can be readily seen that the pressure in the line is immediately relieved, and the water forces its way



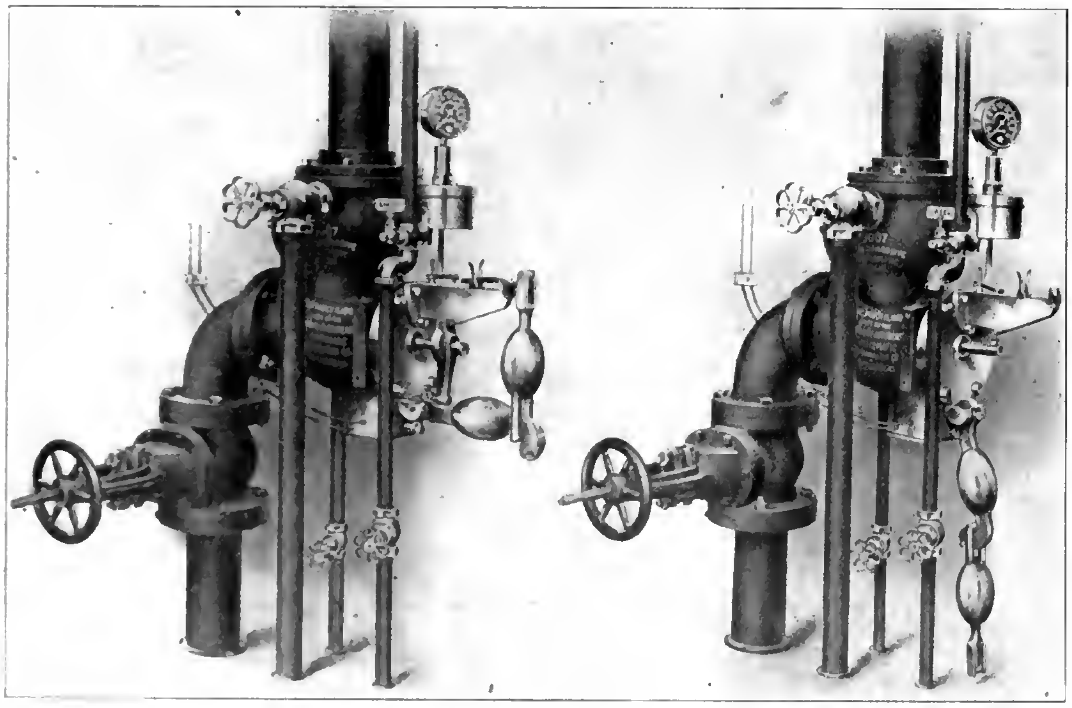
Details of Pumping Station for the Fire Protection System.

through the system and discharges at the head.

In addition to the dry sprinklers there has been installed a water curtain wall around the sides and fronts of all piers. This curtain wall consists of open sprinkler heads, set at a distance of about 8 ft. apart and divided into sections of about ten heads each, each section being operated by an independent valve, located in the valve house on the piers. This curtain wall is for use principally in case a steamer or lighter should take fire while tied up at the pier, so as to protect the pier against damage by fire.

In connection with this equipment a complete electric signaling system has been installed, with an annunciator placed in the pump room and connected with each valve house, so that in case a sprinkler head is set off the signal will be given in the pump room, locating the exact section of the discharged head. In addition to this system of electric signals, a water-motor gong is placed outside each building, which gives a further indication of the discharged head in that section.

The property is patrolled night and day by a force of skilled men, who take hourly readings of all instruments and conditions of valves and other apparatus in connection with the plant.



Closed and Open Positions of the Dry-Pipe Valve.

Around the suction line where it enters the water a large yellow pine crib has been erected, with two iron screens placed on one side. The crib was necessary, on account of the large amount of seaweed and other material which would get into the suction if the line was dropped directly into the water. A 12-in. foot-valve has been placed on the end of the suction to keep the suction line always full of water and to safeguard against having the pump start on a practically empty line.

A complete system of cast iron high-pressure service mains, ranging from 10 to 6 in. in diameter, has been laid through all streets and alleys.

The warehouses and piers are equipped with a complete system of dry sprinklers, there being at the present time about 7,000 heads installed. Each warehouse and pier is separately controlled from the underground system by a post indicator valve located outside the building. The main continues from the post valve under the floor of the building and connects inside the building in a valve house, with an automatic dry valve. This is the point where the air pressure on the sprinkler system starts, the valve acting as an interceptor between the water and the air. These houses are kept heated in the cold weather by lard oil lanterns to prevent the water from

The system as installed has been made as complete as possible, and no expense has been spared to bring it up to a thoroughly up-to-date condition. It was only after several disastrous fires at the American Dock Stores, which did considerable damage to the buildings, that it was decided to install some system of fire protection. The entire sprinkler and hydrant system, as well as the steam plant, was designed by the writer, and installed by the Manufacturers' Automatic Sprinkler Co., of New York.

Reforesting Mineral Lands in Michigan is being taken up by the Cleveland-Cliffs Iron Co., which proposes to plant 14,000 acres.

Secrecy in the Arts.

Extracts from a paper by James Douglas, LL.D., presented at the Toronto meeting of the American Institute of Mining Engineers.

The title which we have assumed claims for the sphere of our activities the whole American continent, regardless of such trifling details as boundary-lines. The fact that we meet to communicate each other's experience, to discuss our difficulties, and to seek each other's aid in solving the intricate problems that so often present themselves in the course of our professional life, is an acknowledgment of our individual helplessness; and therefore an argument for united effort. But no effort can be of any value if there is an underlying suspicion of reserve and lack of candor in our treatment of the technical questions which it is our province at these meetings to discuss.

Yet there are limits to the extent to which we may go as officials of public companies. We know that even as professional men it is not always easy to reconcile principles with practice, and on this subject of sincerity and transparent diffusion of our experience there is some slight difference of opinion and difficulty of application. The most of us are paid officials of corporations whose *raison d'être* is to make money, and whose executive officers sometimes, not without some reason, consider their trade secrets as part of their capital. Some companies confide these secrets to the honor of their technical workers under as strict rules as those imposed on their cashier in the distribution of their money. Unless, therefore, our employers permit, we as employees are under pledge of secrecy.

If the question were left to us alone, it would be easy of solution. Our reliance on one another, as workmen in such distinct branches of engineering as civil, mechanical, electrical, and mining, is so close that we must co-operate in every large enterprise we undertake. We cannot succeed singly, for few of us claim to be so encyclopædic in our knowledge or universal in our experience as to make it safe to rely on our own acquaintance with the practical details of every one of these important departments. Every industrial advance brings us closer together and makes it more impossible to act independently.

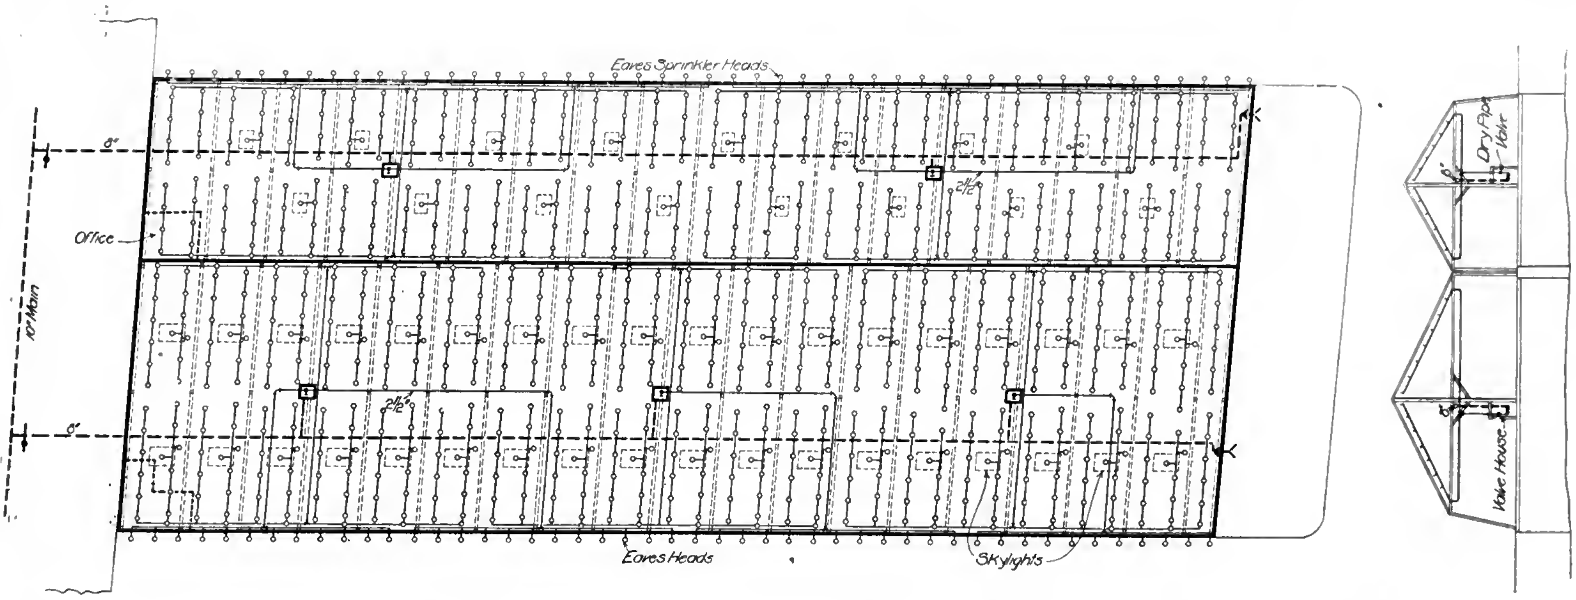
I think, moreover, that many of us are also convinced that open-mindedness to the suggestions of others is a useful quality to carry into our work, even after we and our scientific staff, in our joint wisdom, have co-operated in formulating and laying out our plans. Every draftsman in our offices, every master mechanic in our shops, every foreman in our mines, is an expert in his particular line, and may be supposed to be familiar with minutiæ which have escaped our observation, or, to put it frankly, may know more than we do ourselves on some of the innumerable details which make up the sum total of the questions on which we have ultimately to pass.

I recently went into our purchasing department and found every desk empty, and all the clerks assembled in the manager's room. He had found it conducive to the most efficient conduct of his office to assemble all his staff once a week for free discussion as to the most economical distribution of work. The result was that instead of late hours and overtime the necessary day's work was obtained very easily within office hours; for suggestions from the men actually engaged were found to be worth more than those from the men merely superintending.

How far and how completely should even corporations and industrial concerns permit and encourage the interchange of information? I am inclined to think that few limits should be set; for every limitation means the concealment of some fact or some principle which only if revealed can be developed to its full significance and utility. As a rule this can be best done by the action of many minds and many hands. Till developed it does not yield its full advantage to even the original discoverer, for he alone, unaided, in the solitude of his laboratory or behind the bars of his factory, without the practical assistance of his fellow-workers, rarely brings his original germinal idea into efficient, practical utility.

Were we free to appeal to purely altruistic motives, it would therefore be superfluous to argue in favor of complete knowledge- and experience-sharing, but profit-sharing is after all the impelling motive of industrial advance to-day, as it has been in all ages, and to reconcile the admitted evils of secrecy with the admitted advantages of publicity, the patent laws have been framed. They have always given the patentee the right to use either in his person or through his agent his invention or discovery for a limited number of years, provided he describes it so fully that it can be practiced by one skilled in the art. The publicity and knowledge conveyed by the specification stimulates the inventive faculties of others, and patented and unpatented improvements, along the line of the original invention, demonstrate both the value of publicity and the cupidity of men, even of the technico-scientific class.

It is foreign to my purpose to discuss the patent laws, except casually as they bear upon the subject of secrecy in the arts. One's thoughts pass with pleasure from the contemplation of money-making inventors and investigators to such prophets and apostles of science as Sir Michael Faraday. Sir Michael's profound and original investigations into electricity and magnetism gave the world the dynamo. Though he did not work out the mechanical details of a practical generator, he undoubtedly invented appliances which might have been used for making a strong basis-claim for a patent. But nothing could have been more repulsive to his spirit or foreign to his high aim in life than gauging his time and talents by a mere money standard. He lived contentedly on the small salary he received from the Royal Institution, preparing his lectures to children with as much care as he bestowed on those delivered before the Institution which made him famous; and turning his great learning and power of investigation to the nation's good in return for very scanty remuneration, for he deliberately decided to devote his life to scientific research for truth's sake, rather than to use his vast attainments in the service of Mammon. At the commencement of his career, Faraday added to his salary from the Royal Institution by what he called commercial work. At first, his average earnings from this source were £240 per year. By 1831 they reached £1,090. By 1838 they had shrunk to nothing; for in the meantime his great discovery of magneto-electricity was made, and his thoughts were so intently directed to his experimental work that no time could be spared for money-making.



Typical Lay-out of Mains, Valve Houses and Sprinkler Heads on Piers 4 and 5, American Dock Stores.

But to descend to a lower plane. If it is the fact that technical science has progressed of late with unwonted speed through the co-operation of many workers, and that this co-operation has been made possible by the publication and exchange of ideas and experiences in the technical and scientific journals, would not our progress be even more rapid and thorough if all barriers of secrecy were broken down, and every encouragement were given to our techincal workers to describe in print and by conference, their notions and their actual experiments? This is the attitude of some, I may almost say of most, of our large concerns, but unfortunately it is not that of all. It is impossible to compare, as to efficiency and profit, works the gates of which are fast shut, and in which obscurity and secrecy are imposed and practiced, with those to which free admission is granted and in which freedom of information is encouraged. But the following reflections force themselves upon us in this connection.

We know that very few technical papers issue from certain establishments; that on their officials silence is imposed; and that to these works inquisitive visitors are politely but peremptorily

refused admission. There are not many such, but they are and have been very successful. But suppose that in imitation of their practice and regulations all were tempted to adopt it, so that the same policy became universal; what a sudden paralysis of industry would follow! Our secretaries would find it difficult to fill even their shrunken volumes of transactions with papers worth printing; our students would have to content themselves with the antiquated learning which their professors could supply; for there would be no more summer classes for practical work in mines, smelters and electrical factories, and the professors themselves would have to learn from old books. Every manufacturer and smelter would be obliged to bribe his neighbor's workmen and tempt away his neighbor's superintendents for information. As a result, before long, the very works which now find it so profitable, or think they do, to tap their friends' stock of knowledge and experience, and give nothing in return, would be driven in upon their own resources, and would undoubtedly then find them not so complete as they imagine. Of course, I am supposing an impossibility, because the spirit of intellectual freedom in our professions is too strong and too widespread to submit to such a tyranny, and because, before such darkness of ignorance had settled down on our great industries, the most pronounced advocates of secrecy would feel and acknowledge the ultimate consequences of concealment, and would become reformers.

This is a temper of mind foreign to a new country like ours, whose special industries have not been established long enough to wear grooves of rigid practice and sink into ruts of self-satisfied indifference. About the best correction we can apply to the growth of dry-rot is the banishment of secrecy. A curious instance of its blighting influence is seen in some of the older, not the newer, industries of the old world. The iron- and steel-works of Europe have not kept pace with ours in size and production, but the iron-masters of Great Britain and Germany, in coke-making and in blast-furnace economies and in steel-making processes, have been our teachers. Nor have they been shy of communicating their improvements, or, through jealousy of our success, slow in adopting ours. No nobler monument of international comity in thought and experience exists than the seventy volumes of the "Proceedings of the Iron and Steel Institute." And with few exceptions the iron- and steel-works of England, Scotland, Germany and France are open to any accredited worker in the same domain.

Yet before England was conspicuous as a maker of iron, she was famous the world over for her copper and tin production. But, between self-conceit and the inbred habits of trade-secrecy, her copper-smelting industry has fallen from its high estate. And it is not accidental, but linked as closely as any effect with its cause, that this decline is in great part the result of habits of secrecy which grew with the growth of age. At Swansea, every gate of the smelting-works is guarded, and as a result it has been as difficult for thought to escape out as for suggestions to find their way in. Swansea should still enjoy the leadership which her skilled labor, splendid coal and commanding maritime situation put within her reach; but she has preferred to gloat over her secrets behind closed doors rather than go out into the world in search of new business as well as technical methods, while also inviting the world to enter and exchange ideas with her. What is the consequence? New Zealand copper comes here to be refined, notwithstanding the first practical application of electrolysis to metals was made by Elkinton in England, and the Vivians adopted the Manhès method before Farrell introduced it into this country.

There are, however, of course, exceptions in England to this too prevalent habit of secrecy. To the works of the Rio Tinto at Port Talbot or of the Cape Copper Co. at Briton Ferry in South Wales, where metallurgical novelties have been tried, introductions are not refused. But the alliance of decay and suspicion in the instance I have given can hardly be accidental; and we may be sure that what is baneful in its effects in Europe is not likely to be beneficial here; for while the Atlantic separates continents it does not delimit the operation of laws.

In political life, vitality is maintained only when every man takes his full share as a debater in the discussion of political questions, and as a voter in the determination of state affairs. So in scientific and technical matters, the banishment of deceit, mystery and jealousy, and the freest admission of daylight by means of the unreserved diffusion of information through the press and personal intercourse, will instill into the whole body of workers a feeling of healthy rivalry, which, while stimulating their mental activity, will correspondingly benefit the financial interests of their employers.

I have supposed an extreme case—that the example set by our few secretive establishments were followed by all. Let me imagine a more probable issue, such as, I believe, will result from the fellowship of knowledge and experience which Mr. Carnegie, in presenting to our national engineering societies their new home, urges them to cultivate—namely, that all our technical manufacturers will learn how they gain, and not lose, by encouraging their staff-officers to study their neighbors' methods, and by throwing open their own establishments, in turn to the freest criticism of their competitors in trade. What will result? Nothing but advantage, I believe, to all whose wisdom and means have enabled them to provide themselves with the raw material of manufacture on advantageous terms, and to locate their works or factories at localities favorable for economical operation. Loss only to those who, in any case, ought to go out of business, because they have failed to secure the conditions essential to success! And, above all, benefit to the public, which, after all, is the finality we should always keep in view.

How, now, can these two cardinal conditions —financial success and public approval—be best attained? Unquestionably, by mutual help and the most unreserved publicity. In any branch of industry, no intelligent worker claims that he and his staff have attained either the utmost economy in operation or the most thorough acquaintance with all the reactions which may enter into the processes which he practices. Each knows that hundreds of other intelligent and well-informed men are eagerly at work on the solution of the same problem. Some may be a little cleverer than others, and some may have made a little more progress in certain lines than their co-workers. But this discrepancy will not necessarily continue; for the clever fellow is picked up by rival works, the secret so carefully guarded leaks out, and the disturbed average of paid ability and of stock of knowledge is restored. But if the companies and their staff are unwilling unreservedly to pool their knowledge and experience, the advantage of making into one great stock such accumulated experience and knowledge of these hundreds of workers is forfeited. With certain reservations, and by special permission, many of our larger establishments, in all or in certain departments, are freely open to each other's technical officers; but instead of being admitted upon sufferance, they should be invited in, with full liberty to study processes and test machinery; for assuredly the host would benefit as much as the guests by the discussion which would follow such unreserved exchange of ideas and comparisons of appliances and methods.

I have referred to certain limitations to publicity. One, undoubtedly, is costs. Under our present economic system, no manufacturer or miner or metallurgist cares to give away his costs, and that for very obvious reasons. What they are may be inferred, but professional courtesy forbids direct inquiry into that delicate subject. This restriction, however, need not interfere with unstinted technical freedom of intercourse.

There is, moreover, an additional judicious limitation to publicity. Most of our largest concerns are incorporated and financed as joint-stock organizations, in which thousands of technically ignorant and helpless shareholders are interested. Unquestionably, indiscriminate admission to works and mines must be refused, for, unfortunately, there would be visitors who, if admitted, after the visit would tell remarkable stories, from actual observation, with the view to affect the value of stocks. But such restrictions do not affect the main proposition that mercantile concerns of every class, depending for success on technical knowledge and skill, would gain by the removal of restraint on the thought and action of their technical staff.

I am not blind to the fact that the same object is sought to be attained by the consolidation of many works under one organization, or by the encouragement of friendly financial co-operation among even competing companies; but this tendency to consolidation has not yet succeeded in obliterating competition, and will not as long as there are active, intelligent men among us, who prefer to rule rather than to be ruled, and to manage their own business rather than have it managed for them.

On the benefits or disadvantages of the present movement towards consolidation of works and the combination of capital in large industrial undertakings, there is, and will be, of course, considerable diversity of opinion. That competition is wasteful and is encumbered with other evils few will deny; that it has a keenly stimulating effect all will admit. Yet it remains to be determined whether a board of absentee managers and paid officials will be a compensating substitute for the ambitions, personal pride and tireless energy and skill of the individuals who have built up great works which they may have seen, perhaps reluctantly, absorbed into a combination. There are, apart from the political and sociological aspects of the present consolidation tendency, technical and economical conditions which force themselves upon the consideration of those of us under whose management works have grown from small to large dimensions. The difficulty of maintaining a high standard of quality as the demand is made for enormously increased production is urgently presenting itself both to the management and to the public. And it is doubtful whether, after expansion has reached the point where administration charges become light, there is actual economy in unlimited expansion; and whether the most skillful and closely managed corporate organization can replace the personal supervision of a single mind. But what immediately concerns us in the present discussion is the dangerous temptation to adopt secretive methods by very large corporations.

The larger the combination grows the more sensitive will the management be lest business and trade secrets which they possess, or think they possess, be revealed by subordinate officers. The imposition, therefore, of strict rules of silence on all except those in supreme command is likely to result. If the absorption of any one class of our national resources should pass under

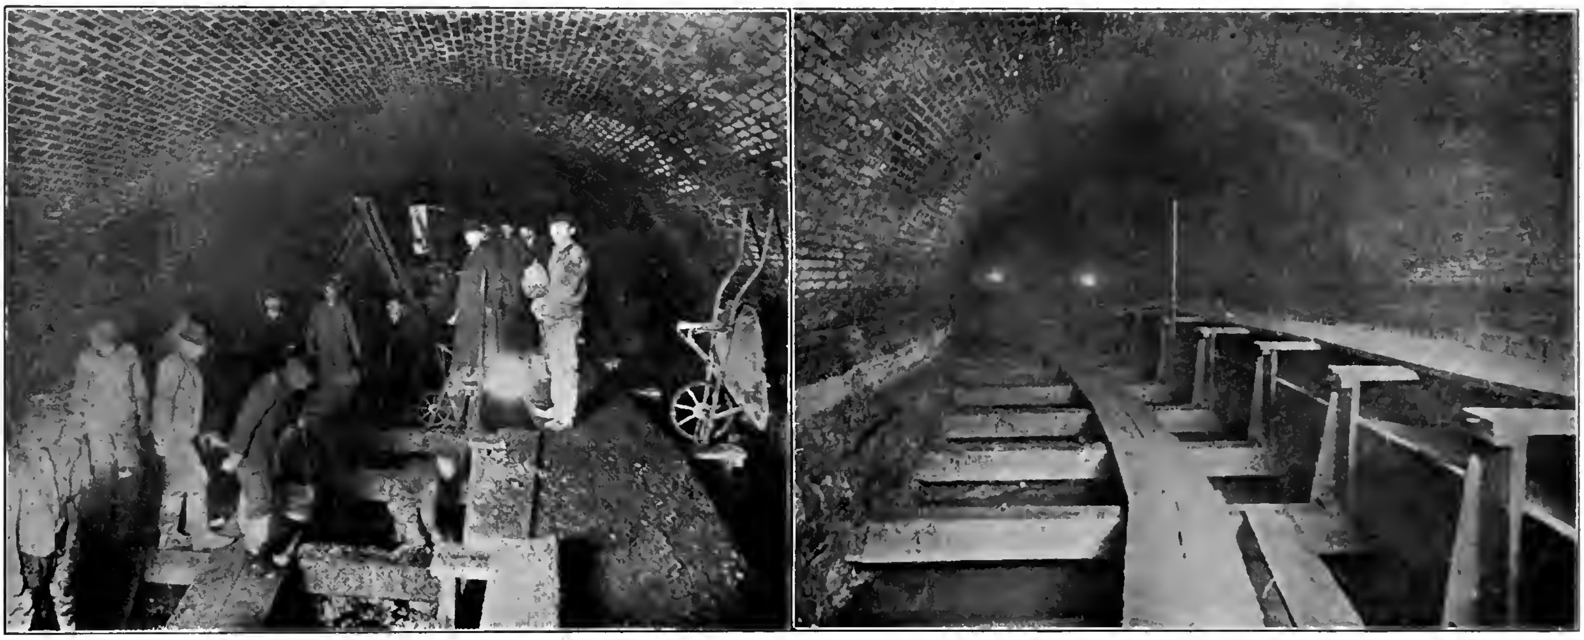
the control of any one organization, the technical knowledge necessary to the development of that particular resource would be of interest to that organization alone, and the risks of publicity, and therefore the evils of secrecy, would become a merely academic question. This dangerous point, under our present industrial system, will probably not be reached; for state socialism, to which concentration steadily approaches, would be the inevitable alternative and would be adopted before the other alternative had been attained. But it must be to the management of those enormous consolidations a grave consideration how they can give such latitude to the members of their staff as will produce that healthy self-reliance which comes from freedom of speech and freedom of opinion, without endangering the tremendous financial interests for which they are responsible. Whatever individual difference of opinion on this subject there may be among the managers of the great industrial establishments, there is not any difference of opinion in the country at large; and public opinion has to be consulted. Therefore, would it not be safer and better for the interests of the shareholders to adopt the policy of freedom which I have outlined, and thus placate the public? For the growing public anxiety, amounting to animosity and suspicion, against our big corporations would be allayed if it were apparent that the technical officials of the small concern had at least the right of knowing what the big concern was doing, and the big official did not arrogate to himself the possession of exclusive knowledge and exclusive skill. From the point of view of public policy, the question is one well worthy of consideration; for it is coming about that not only railroads, as public highways, but all large corporations utilizing the country's natural products and converting them into necessary objects of trade, will pass under closer legislative scrutiny and public criticism in the future than they have in the past—a necessary limitation, which will become more exacting the larger the corporations grow—if the tendency to growth continues.

While unquestionably dangers can be foreseen as arising out of these great industrial aggregations—not only of capital but of industrial energy—dangers technical, social and political—there are also great possibilities of good. One of the benefits may justly be claimed to reside in the large funds that are thus rendered available for technical research, from which the public derives benefit indirectly, even if the results are not published. But if we could banish secrecy; if every industrial establishment of any magnitude, which is in its own interest carrying on technical research, should encourage its technical staff to confer freely with the members of every other technical staff, would not the sciences and arts progress far more rapidly than if one huge organization controlled a given industry? All our principal metallurgical and chemical concerns have laboratories, and carry on investigations and make experiments, generally on a large working scale; and surely the advancement of technological science can be better attained in a number of such laboratories than if there were fewer or in only one. There is keener competition of wits when many brains are working independently. The friction of honest rivalry is a force not to be despised. The stimulus of ambition is sure to be stronger in smaller than in large consolidated workshops. The air in such laboratories is freer and purer than when men are working in the stifling atmosphere of secrecy. I believe that such a consolidation of mind and high impulses would carry us further and faster along the road of human progress than all the money that all the trusts could appropriate for the advancement of technical knowledge.

Buttressed Masonry Dams continue to be constructed from time to time, chiefly as extensions of old structures, and it is considered likely by a number of engineers that the type will find more application as a result of the present rapid increase in favor of the buttressed concrete retaining wall. For this reason mention may be made of a detailed analysis of such dams presented earlier in the year to the Institution of Civil Engineers of Ireland by Mr. M. T. Ormsby, and recently printed in Vol. 33 of its "Transactions." The final results of the study give the leading dimensions of such structures up to 40 ft. in height, in which there is no tension in the concrete, and the resultant force makes an angle of 35 deg. with the vertical. With the dimensions he gives, the maximum pressure at the toe of the buttress works out to 6.29 tons per square foot in the higher dams, corresponding with a maximum vertical pressure of rather less than 4½ tons per square foot. The saving of masonry, as compared with a solid trapezoidal dam, varies from about 40 per cent. with a 10-ft. dam and masonry of 1.8 specific gravity to about 28 per cent. with a 40-ft. dam having masonry of 2.2 specific gravity. Experiments on models of such dams are also described.

The Reconstruction of Large Sewers in St. Louis, Mo.

The sewerage system of St. Louis is built on the combined plan, the domestic sewage and storm-water run-off being carried to the Mississippi River by the same sewers. Some of the latter were constructed 30 to 40 years ago before the districts which they serve were built up to any extent, and, in cases, where the immediate districts gave no evidence of being developed fully at any future time. Several sections of the city which were almost open country when the main outlet sewers serving them were built, are now congested business or residence districts. As the old sewers were apparently not designed for such conditions, their capacities are consequently now insufficient in many cases. This inadequate capacity of some of the main sewers, and the structural failure of others, has necessitated a large amount of reconstruction on several of the main outlet sewers.



Runways for Handling Excavation and Materials, and Temporary Flume in Reconstructing a St. Louis Sewer.

The Rocky Branch outlet sewer is one of those having an inadequate capacity to carry the storm water reaching it. This sewer serves an area of about 3,500 acres in the closely built-up residence portion of this city where practically all of the streets are paved. The lateral sewers in the area are also largely on comparatively steep grades, the whole combination of conditions tending to bring the storm water to the main outlet very quickly. The latter has a total length of 8,700 ft., the first 2,500 ft. of which from the river is across the low swampy river bottom, the ground rising gradually from this low land to the district served by the outlet sewer.

The outlet sewer for over half a mile from the river has a semi-circular arch, with a clear span of 18 ft., which is carried by haunch walls with vertical faces. The arch consists of four to five rings of brick laid in cement mortar; the haunch walls have cut stone facing backed with rubble masonry.

In constructing the bottom of the sewer, at least, no uniform grade appears to have been followed, as numerous breaks in grade occur in it at uncalled for points. These breaks were introduced at some places, moreover, without similar changes in the grade of the arch. The bottom of the sewer was never lined, nor the natural surface properly leveled. A part of the sewer is on rock and the remainder on soils of different capacities for carrying loads. Where rock foundation occurs the bottom of the sewer

was in many places left as the rock was blasted out, with the result that depressions 2 to 7 ft. below grade frequently exist. In soft foundations the haunch walls of the arch were built on heavy logs laid transversely with the sewer. These logs are 18 to 24 in. wide, 8 to 14 in. thick and 18 to 19 ft. long. They are still in a good state of preservation, although the sewer was built in 1870 and the velocity of the sewage over them has been high at various points.

This sewer had become so badly overtaxed that some means of relief for it became an immediate necessity. It is built in a city street for 3,500 ft. back from the river and is of such size that in this distance no room exists in the street for a relief sewer. Furthermore, the soil and other conditions in adjoining parallel streets made the construction of a relief sewer in the latter impracticable. The grade of the bottom of the existing sewer is accordingly being straightened, and the bottom lowered to some extent and lined with an inverted brick arch, with the belief that the carrying capacity of the sewer will be increased in this manner sufficiently to provide for the removal of the flow reaching the sewer. This straightening of the bottom grades required the excavation of 2 to 7 ft. of materials, varying from quicksand to rock and included the logs, where they occurred. The arch ring was also underpinned down to the new bottom level and a new invert placed. Where the sewer was built on rock, this rock was blasted out at the sides, during the original construction, only enough to carry the arch ring, so the excavation made to straighten the bottom grade had to be carried wide enough to provide room for a new haunch walls for the arch.

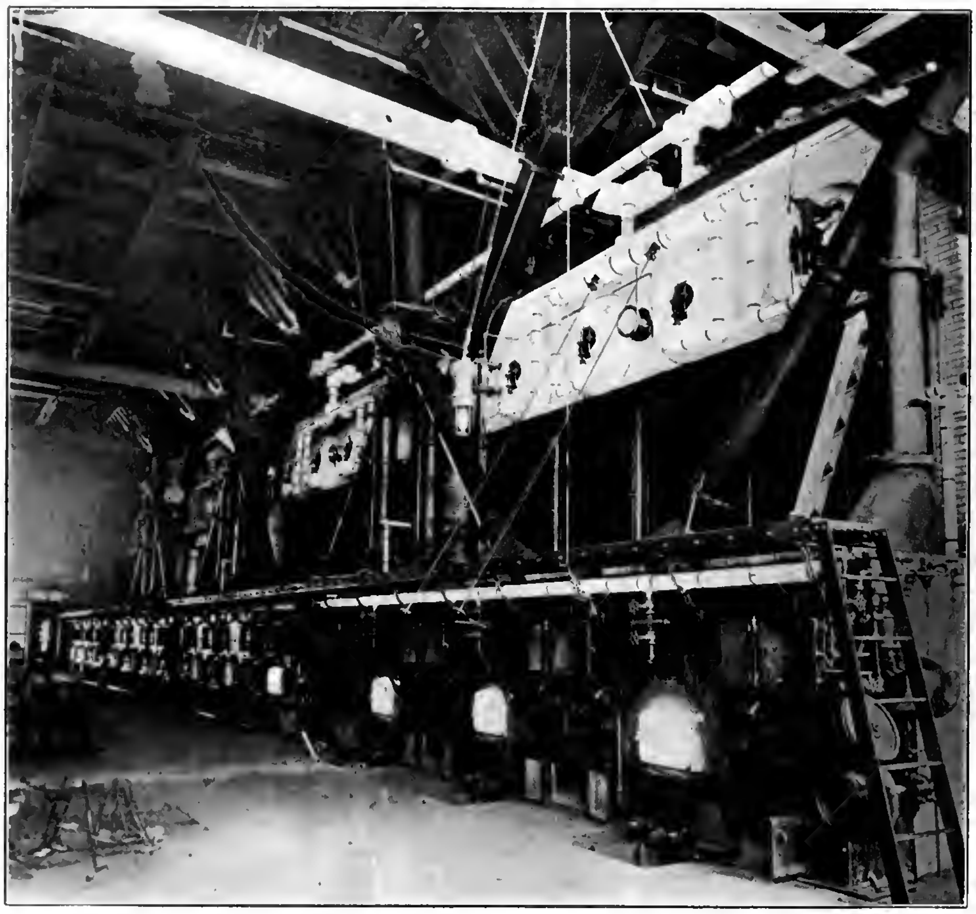
The work of lowering and straightening the bottom of the sewer was started at the river and carried back for 3,500 ft. to high ground at a point where the sewer leaves the street and passes under private property. From this point a new sewer will be built to relieve the existing one, as conditions are such as to permit the construction of this relief sewer.

During the reconstruction, the dry weather flow reaching the outlet sewer was carried at all times in a wooden flume which was supported. with its bottom on an average of about 6 ft. above the bottom of the sewer, by 12x12-in. transverse timbers having their ends set in the old masonry. This flume had sufficient capacity to carry some storm water in addition to the dry weather flow, but during heavy rains the water filled the lower part of the sewer and covered the work in progress. Much pumping was thus necessitated, and as ground water was encountered in several places while the reconstruction was in progress, the pumps were kept almost continually in service.

For some distance from the river the bottom was largely alluvial deposits, the haunch walls of the sewer as originally built being carried in most of this distance by the heavy transverse timbers. In the reconstruction work, where these timbers occurred the haunch walls were taken out in short sections and the timbers removed. While the excavation necessary to lower or to straighten the grade of the bottom was being made and the brick invert laid, and until masonry underpinning had been carried up to the haunches of the arch from the invert, the arch was carried on shoring on jackscrews. All of this shoring and reconstruction work was handled with much difficulty, some of it being particularly hazardous. Quicksand was encountered for a length of 500 ft. in making the excavation for the new bottom, but the latter was put in as planned in this section, without losing any of the sewer. The work was handled in short sections after the quicksand was encountered, from 4 to 6 ft. being opened at a time. As soon as the timbers were removed and the excavation made, the bottom was sealed with concrete in sacks. Considerable sheeting and much intricate shoring had to be done in all of this work to restrain the quicksand and to support the sewer arch until the concrete seal could be placed.

Rock was encountered in the bottom after the higher ground was reached, and its surface rose faster than the grade of the sewer, so that the lower part of the latter is in excavation in rock at the upper end of the reconstruction work. The sequence of operations after the rock was encountered was generally the same as that followed in the reconstruction in soft ground, except no concrete seal had to be placed in the bottom. The rock was blastetd out as required, small shots being used to avoid injury to the existing masonry and to prevent the disturbance of the shoring supporting the portions of the arch from openings to the point where work was in progress in the same manner. The concrete was mixed by hand in the sewer.

The reconstruction of the Mill Creek outlet sewer has also recently been completed in a manner similar to that followed in the work just described. This sewer provides a drainage outlet for 6,000 acres of congested city districts. It has a brick arch, with a clear span of 18 ft., carried by cut-stone haunch walls, the latter being originally built on heavy transverse timbers in the same way as in the Rocky Branch sewer. These old timbers used for the footing and invert began to give way, so a new invert had to be built. The capacity of the sewer being somewhat overtaxed, the new invert was placed 2 ft. below the original bottom formed by the timbers, and was laid at a more uniform grade than the one on which the former had been built.



Boiler Room of the Main Power Station at New Orleans.

which the haunch walls were temporarily removed. Where the rock came up on the sides to any extent only enough of it was blasted out to secure a bond for the concrete wall used to underpin the existing wall. The underpinning in all cases was done with concrete, the inside face of the new wall being built out a few inches farther than the inside face of the existing masonry to insure the stability of the latter.

The blast holes required in excavating the rock were made by Ingersoll Sergeant air drills, supplied with power from a central plant erected by the contractor. This plant contained an Ingersoll-Sergeant compressor belt-driven by a 150-h. p. electric motor, and an alternating current generator furnishing power for lights in the sewer.

Several steam pumps were installed to keep the water level lowered while work was in progress and to pump out the sewer after a heavy rain. These pumps were supplied with steam from the boiler of a derrick outfit which was used in lowering materials into and hoisting them out of the sewer. The excavated materials were hauled to openings in the arch of the sewer on a plank runway laid on the timbers carrying the flume, and the supplies were hauled from these

The haunch walls of this sewer are of first-class cut-stone masonry and the soil through which it is built is for the most part fairly good, so the reconstruction could be carried forward in longer sections than was possible on the Rocky Branch sewer, 32 ft. of the bottom generally being opened up at a time. The timbers being in a good state of preservation, they were chopped off close to the sides of the haunch walls and the part between the walls removed; the excavation for the new invert was then made and the invert built. The latter is of concrete, with a lining of vitrified paving brick, the ends of the old timbers being covered by the concrete.

The dry weather flow in this work was also carried by a flume supported by transverse timbers carried at the ends by the old masonry of the sewer. Since the amount of ground water encountered was much less and the soil conditions considerably better than in the Rocky Branch reconstruction, work was handled with less difficulty.

Mr. H. F. Fardwell is sewer commissioner and Mr. J. A. Hooke is assistant sewer commissioner of St. Louis. The reconstruction of the Rocky Branch sewer was carried on by the Cooney Construction Co. of St. Louis.

The Market Street Station of the New Orleans Railway & Light Company.

One of the advantages of the concentration of public-service undertakings in a city under the control of one organization is the practicability of concentrating the power plants to whatever degree is desirable. This is well shown by the improvements carried out in New Orleans under the direction of Sanderson & Porter, the New York consulting engineers, by the New Orleans Railway & Light Co. When this corporation took over various independent railway, gas and electric properties of that city a few years ago it was at once seen that some of the smaller and less economical power stations could be abandoned to advantage and two of the plants greatly enlarged. A single central station was not desirable, because its construction would have made it necessary to abandon two modern generating stations and because in some areas the distribution of the railway load made it more economical to generate direct current near the points of heavy consumption than to produce alternating current in one central station, with high-tension transmission and conversion to direct current in sub-stations located at the points of consumption. The less likelihood of complete shutdowns in cases of station troubles was another consideration.

The system as reconstructed comprises one direct-current commercial lighting station and one direct-current railway station in the congested districts, and one large alternating-current station to feed the balance of the territory and the outlying districts. This station also contains 6,000 kw. of direct-current generators for feeding the railway lines in its vicinity. The three stations have an aggregate capacity of 25,000 kw. Sub-stations have been built preparatory to abandoning the small generating plants, over 100 miles of underground conduits have been constructed and a complete new street lighting system, with 3,000 series alternating arc lamps, has been installed. As the load increases and the system is extended additional sub-stations are to be built, and the capacity of the main or alternating-current power station is to be increased up to 50,000 kw. It is not necessary that new generating stations be built until this capacity is reached.

A 2,300-volt and 6,600-volt 60-cycle alternating current and 250-volt and 600-volt direct current are now generated. By means of static transformers between the two alternating-current voltages and motor-generator sets between the alternating and direct current systems the generators in any station may be used to supply current for the commercial or arc lighting or railway services.

The magnitude of the initial and ultimate investment involved for apparatus and the importance of handling the varied services in the most reliable and economical manner were governing factors in settling upon the frequency and voltage characteristics of the generating and distributing systems. The far-reaching importance of correctly establishing these essentials was early recognized, and the decision to adopt a frequency of 60 cycles for the alternating service was finally made as a result of careful deliberation and study of all possible methods. This frequency has been made standard for alternating power required for lighting and railway service. The decision against 25-cycle frequency was based upon the much greater cost of such installation, which would have involved heavy expense for frequency changing apparatus for the large amount of the service requiring 60 cycles and the unsuitability of 25 cycles for the operation of incandescent and arc lamps.

By using only one alternating-current generating frequency the load factor on the station and on the generating units was much improved, with resulting large savings in the cost of generated power, and the idle investment in reserve apparatus was minimized. The large sub-station energy loss which would have resulted from the use of such frequency changes as would have been necessary had 25-cycle generation been adopted was saved by the adoption of a uniform 60-cycle frequency.

It is believed that the higher frequency standard more nearly satisfies all of the present and future requirements and that it will show a decidedly higher all-round efficiency, everything considered, than 25 cycles or a combination of 25-cycle and 60-cycle generation. Furthermore, increase in business is largely dependent upon adopting a system which will involve the least first cost of installation to the consumer. The lesser cost of 60-cycle motors constitutes an important factor, viewed from the standpoint of the operating company.

Sixty-six hundred volts was adopted as being a thoroughly standardized commercial voltage, for which motor generator sets of 50 kw. and upward could be readily wound, so eliminating sub-station transformers. The transmission distances, being relatively short, did not call for a higher voltage than 6,600, which would permit sending the maxi-

mum desired amount of energy through any individual feeder with small energy loss. The frequent flooding of the underground conduits by heavy rains, which for short periods may overtax the capacity of the drainage system, rendered expedient the adoption of a moderate voltage, involving no particular difficulties for insulation under these conditions.

The recent work has involved the construction of practically an entirely new station at Market and South Peters Sts., on the Mississippi River, about two miles upstream from the business center of the city. The station now contains 17,800 kw., and provisions have been made for an ultimate capacity of 50,000 kw. In the "Street Railway Journal" of Sept. 18, 1904, a description of the then existing plant stated that it contained two 2,250-kw. Westinghouse and one 1,500-kw. General Electric railway generating units driven by Allis-Chalmers vertical compound engines, contained in a new building and supplied with steam from boilers in an adjacent old station. The building now forms a portion of the generating room of the new station.

The building is a brick, steel and concrete structure. The portion built measures 181 x 212 ft. and is 122 ft. high. When extended 92 ft., as planned, it will be 273 ft. long. It is supported on approximately 4,000 round piles driven on about 3-ft. centers. The piles are 50 ft. long, and some were set 30 ft. below the surface or were driven to a total penetration of 80 ft. In excavating for foundations and trenches for pipes the surrounding earth was assumed to be of liquid weighing 120 lb. per cubic foot. Excavations were protected by 6-in. grooved piling 30 to 50 ft. in length, with splines measuring 2 x 4 in., to insure alignment and tight joints. Where possible excavating was done by means of an orange-peel digger, and the earth was removed by a tramway. The piles were capped with a reinforced concrete bed approximately 6 ft. thick.

The average load over the entire foundation is something less than 2,000 lb. per square foot, but at points the load concentrated is very much above this figure. At such points twisted steel rods varying in number with the loads were used to reinforce the concrete.

Plans provide for the ultimate installation of four 72-in. pipes to serve as condenser intake and discharge pipes. All four pipes have been extended through the levee, three have been installed under the boiler room and one intake and one discharge pipe have been placed under the railway tracks between the boiler room and the levee. The pipes are made in 30-ft. lengths of ½-in. riveted steel by James McNeil & Bro. Co. and were covered with a protective coating from the American Asphaltum & Rubber Co.

Special provisions have been made for removing sand and silt from the pipes. Water jets supplied with water from a fire pump have been installed at 10-ft. intervals in the bottom of the pipes, and by a system of valves the intake and discharge pipes may be connected at the station end with a propeller type of circulating pump, so located in the connection that a flow of 8 to 10 ft. per second can be produced through the pipes. The pump is driven by a 700-h.-p. 550-volt motor. When the pipes are to be cleaned the jets are first operated to loosen the deposit, and this is then washed out by the flow from the pump. The pipes terminate at the river end in concrete wells, that for the intakes being provided with three sizes of screens.

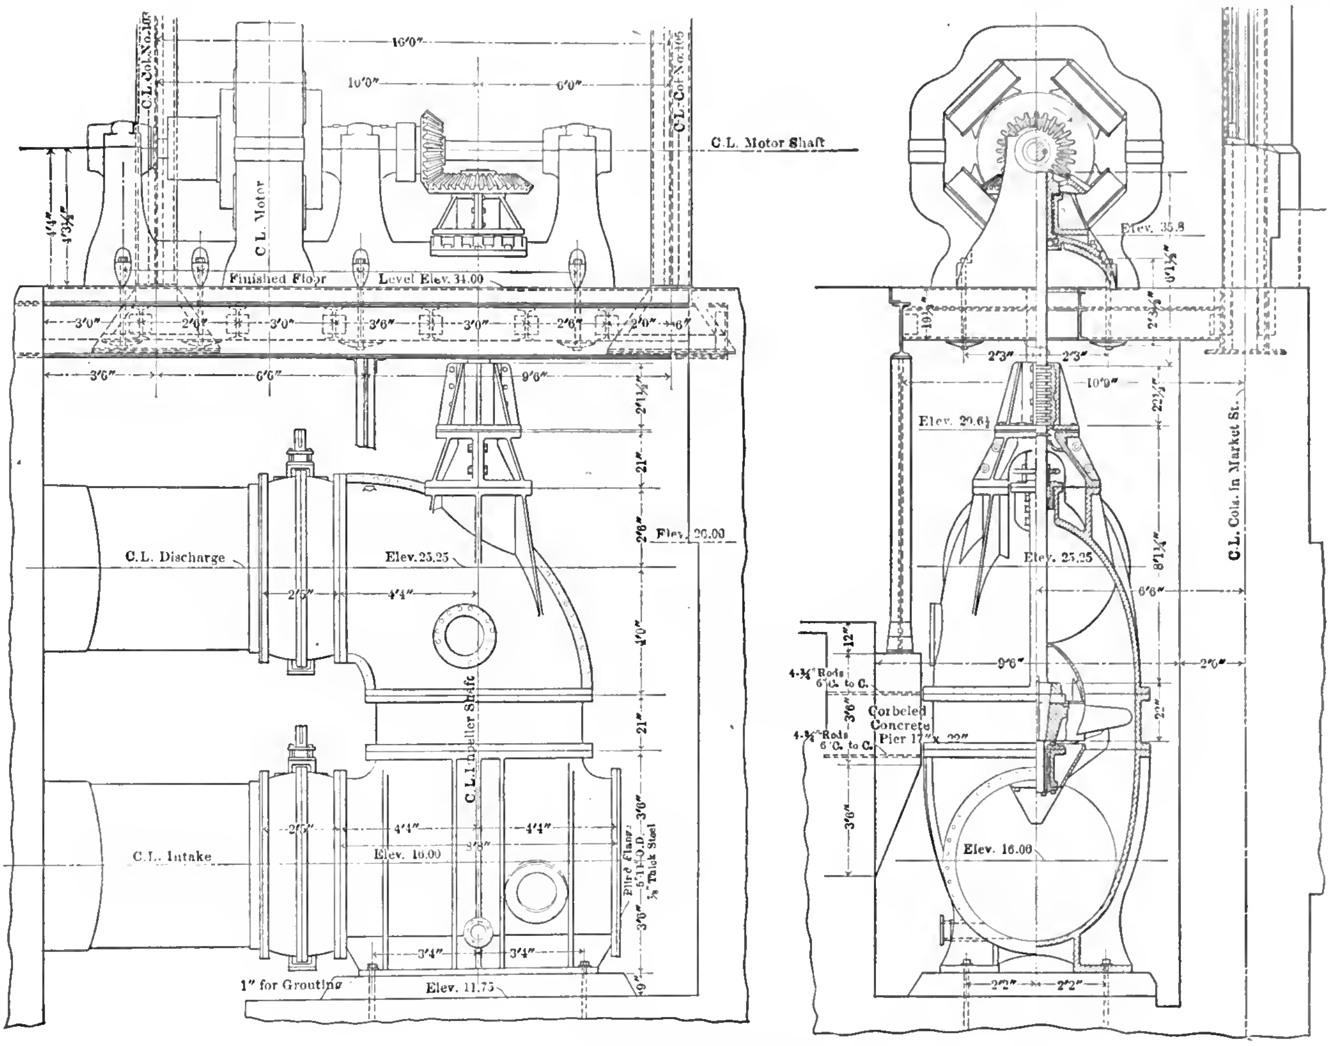
The building has a steel framework, with brick walls. The roof is of Ludowici and book tile, with a composition top. Bunkers and floors are of reinforced concrete. With regard to steel and roof construction, the building may be said to consist of three parts, the generator room, the double-deck boiler room and an intermediate section occupied by switchboard apparatus, shop and offices and toilet rooms. The adoption of this arrangement permitted the successful execution of the new construction without interference with the operation of units which had to be kept in service. Ample ventilation, important in Southern power plants, is provided by monitors and pivoted windows.

The two steel stacks erected are 15 ft. in diameter and extend 273 ft. above the street level. Both are brick lined to the roof line. Plans provide for the later erection of two additional similar stacks when building is extended.

The present building provides for sixteen 900-h.-p. boilers. Twelve such Babcock & Wilcox water tube units are now installed. They are located on two decks in double rows facing each other and parallel to the generator room wall. They are of forged steel header type, constructed for 200 lb. pressure and are fitted with Babcock & Wilcox bent tube superheaters for 150° superheat. Behind them are Sturtevant economizers, there being one economizer with 4,900 sq. ft. of heating surface to each two boilers. The scrapers of the econmizers are driven by induction motors.

The boiler plant is equipped with thirty-six 300-h.-p. Murphy smokeless furnaces and stokers, set three in a battery under each boiler. Coal is fed to the furnaces through down spouts extending from the overhead bunkers. Provision has been made to later install scales in each down spout. Ashes from the furnaces fall direct into a hopper underneath, while the fine ashes drawn over the bridge wall and the soot accumulation are carried into this hopper by a motor-driven screw conveyor.

Boiler feed water is obtained from two 750-ft. wells, one 6 and one 8 in. in diameter, having



Impeller Pump for Flushing Condenser Mains, New Orleans Power Station.

a combined capacity of over 1,800 gal. per minute. Water is raised with air furnished by two Ingersoll-Sergeant compressors in the boiler room basement. The water is discharged either into tanks in the basement of the boiler room or into a 60,000-gal. stand-pipe near the building. The boilers are fed by a 1,000-gal. De Laval steam turbine-driven centrifugal pump and three Epping Carpenter pumps, with 16 x 10 x 16-in. cylinders. Connections are arranged so that the water may be forced either through the economizers or direct into the boilers.

A switch extending along the east end of the station contains a 100-ton track scale, and all cars are weighed before and after being unloaded. The cars are run on a sheltered track under the ash bunker at the end of the boiler house and unloaded into a hopper beneath the track. After passing through a crusher provided with an adjustable positive feed the coal is carried by a bucket elevator to the top of the boiler house structure, where it is discharged on a belt conveyor and distributed to any predetermined part of the coal bunkers by an automatic unloader. A 35-h.-p. 550-volt direct-current motor drives the crusher and both belt and bucket conveyor.

The initial coal-handling plant has a capacity of 100 tons per hour, and the plans provide for a duplicate equipment of equal capacity. The initial coal bunkers hold 2,000 tons, and those of the ultimate building will store about 5,000 tons. Additional storage capacity is provided in a vacant lot near the station, coal being conveyed to and from this storage space in electric cars. Dock privileges have been obtained from the city and a portion of the plant for unloading river coal from boats has been erected. This has a rated capacity of 200 tons per hour.

Small side dump cars operating on tracks in the basement underneath the ash hoppers convey the contents of these hoppers to the east end of the building, where the ashes are dumpd into an automatic skip. This skip bucket of 60 cu. ft. capacity hoists the ashes to the top of the boiler room and dumps them into a bunker built over the coal switch. Ashes are discharged by gravity from bunker direct into steam or electric cars and conveyed to the suburbs to be used in track construction or filling.

All high pressure piping is of standard lap weld mild steel, with fittings and valve bodies of cast steel. The high-pressure steam valves are especially designed for use with superheated steam at 200 lb. pressure and have extra long necks at the stuffing boxes. Chapman valves were mainly used, the large ones motor-driven.

The boilers on the upper deck feed through lines passing down behind them into headers running the full length of the boiler room in the rear of those boilers on the lower deck. These headers also receive the steam of the lower deck boilers. Crossover pipes running just underneath the second floor connect the header most distant from the generator room with that one nearest to it, which may be regarded as the main steam header. Steam mains to both reciprocating engines and turbines pass through the boiler room wall and underneath the generator room floor to their respective units.

Connections from the headers behind the boilers drop through the floor to mains supplying the auxiliary apparatus. Extensions continue through the basement wall to serve the engines driving the condenser pumps and other auxiliaries.

In the new portion of the generator room there are installed three 1,500-kw. three-phase 60-cycle 2,300-volt Curtis turbines. A 3,000-kw. and a 500-kw. 6,600-volt turbine of the same make are also provided in the initial building, the former now being in operation and the latter under construction.

One common oiling system, with one accumulator, serves the step bearings of the three smaller turbines. A separate oiling system, with an accumulator, is provided for the two larger turbines. The oil pumps and other auxiliary apparatus, except exciters, are located in the basement.

Three motor-generator sets now operating on other service, each consisting of 500-kw. 2,300-volt synchronous motors and 600-volt direct-current generators are to be installed on the main floor alongside the exciters under the bus structures and will permit transferring 1,500-kw. capacity from either alternating-current or direct-current portion of the station.

Past difficulties in the operation of surface condensers using the silt and clay bearing water of the lower Mississippi River led to the general adoption of Dean and Allis jet condensers on the engines and Alberger jet condensers on three of the turbines. One 1,500-kw. turbine was provided with an experimental, specially designed Alberger surface condenser. The jet condensers of the 1,500-kw. turbines are connected to 12-in. centrifugal pumps and of the 3,000-kw. condenser to a 16-in. pump. All the circulating pumps are driven by single-cylinder Buckeye engines. The turbine condensers are each served by Alberger dry vacuum pumps, which may be run separately or on a common vacuum system.

The exciter equipment already installed consists of an 80-kw. induction motor-driven unit and a 75-kw. unit, driven by a two-stage horizontal Curtis turbine. The exciters are connected to a double bus system, and voltage regulation is effected by a Tirrill regulator built for four exciters. Plans provide for two additional 150-kw. exciter sets, which will be installed near those already in operation on the main floor underneath the switch structure.

The switchboard proper is located on an overhanging balcony at the same height as the second floor of that section of the building between the boiler and generator room. From his position on the balcony the operator has a general view of the entire operating floor. Behind the switchboard are the generator switch and bus structures. On the floor above are similar structures for feeder busses and switches, and there is also located on such floor 2,300-volt regulators for the commercial feeder circuits. On the fourth or top floor is an arc light sub-station. All main and high-tension switches are of the oil break type controlled from the main switchboard by pilot switches. Both generator and feeder busbars are in duplicate and all may be sectionalized.

The floors on which the switch-control apparatus is located are constructed with a view of facilitating repairs should it ever become necessary to get at the cable or conduits. The I-beams support a 6-in. solid concrete floor. On this is a 11-in. loose filling, in which the conduits are laid, this being covered with a 4-in. concrete floor.

The bus and cell structures are built in groups, with the main and auxiliary bus structures flanking a common passageway on the second floor, and the feeder bus structures similarly arranged on the third floor. The structures are of concrete, with the exception that the tops and bottoms of the generator and sectionalizing switch compartments are of Alberene stone. The structures are reinforced by iron rods running through the barriers from top to bottom. The generator leads are carried down under the generator room floor from the generator terminals to junction boxes and then up the building columns in brass conduit direct to the generator switches of the main generator and auxiliary busses. A group switch connects the 2,300-volt main generator bus to a main feeder bus on the floor above, and a similar switch connects the generator auxiliary bus with an emergency feeder bus. The 6,600-volt generator and auxiliary busses are permanently connected to extensions of these busses in structures on the floor above and from which the feeders are taken off. The 6,600-volt and the 2,300-volt bus systems are connected by two 1,500-kw. oil-insulated water-cooled three-phase transformers, located in the basement.

The generator control panels are located at the west end of the initial switchboard, the plans providing for the installation of 6,600-volt feeder panels west of them, so that they will be centrally located with respect to the ultimate switchboard. To the east of the generator panels are exciter and house service panels and space for three synchronous motors and three railway generator panels.

The space east of the switchboard and bus structures is devoted to offices, a machine shop, toilet and wash rooms, which contain needle baths and porcelain finish wash troughs, supplied with hot and cold water, and are furnished with expanded metal lockers. Separate toilet and wash rooms are provided for the colored firemen.

General lighting of the generator room is effected by arc lamps supported on wall brackets. The boiler room and switchboard structure are lighted with incandescent lamps.

Collecting Paper from a Street Rubbish Can in Denver,

A Storage House for Records, documents and valuable papers is being planned by the Pennsylvania Lines West of Pittsburg, according to a recent report. At the present time a great many valuable papers are stored in the offices of the various divisions in buildings which are often far from fireproof. In order to remove the danger of loss by fire, it is proposed to erect a large fireproof building in Pittsburg where the records from all parts of the system west of that point could be filed and cared for.

Street Cleaning in Denver, Col.

Street-cleaning operations in Denver have been developed along lines somewhat different from those followed in most cities in this country. The streets in the central portion of the city are paved with asphalt, over twenty-five miles of this pavement having been laid. The remainder of the total thirty-five miles of paved streets are paved with sandstone block, and, in addition, nearly twelve miles have been macadamized. A considerable mileage of the balance of the streets are surfaced with gravel, and are provided with curb and gutters. All of these improved streets are cleaned regularly, at intervals depending entirely on the density of the traffic tributary to them.

A large percentage of the street traffic in Denver, and particularly of the horse-drawn vehicles, is over the asphalt streets. Consequently, a major portion of the activities of the street-cleaning department of the city is devoted to these streets. Rotary sweeping machines, each mounted on a four-wheel truck drawn by a team of horses, are used to collect in furrows the principal part of the detrius on the asphalt. These machines are followed by automatic pick-up machines, also mounted on a four-wheel truck drawn by a pair of horses, which collect practically all of the material placed in the furrows by the sweepers. When the weather is propitious, the street over which the pick-up machines has just passed is thoroughly washed with sanitary flush-tank wagons, built especially for this purpose. These flushing wagons are followed closely, in turn, by men with brooms, who sweep into the storm water sewers such water, refuse and fine particles of material as remain. All of this work is done during the day, the heavily-traveled streets being cleaned first. After the sweepers have passed, block men with brooms and two-wheel push carts continue the removal of refuse the balance of the day.

The operation of the rotary sweeping machines during the day, without delivering a continuous cloud of dust to interfere with traffic on the streets, or with pedestrians, is rendered possible by several changes which have been made in the construction of these machines. The most important of these changes, so far as avoiding an obnoxious cloud of dust is concerned, has been the extension of the tight wooden deck over the machines so two heavy canvas hoods can be placed around the machine, instead of a single hood, as is usual. The two hoods are arranged so an air space of about 5 in. is provided between them. This enclosed air space quite effectually intercepts all of the dust that passes under, or through the inner hood, with the result that the sweepers thus equipped are regularly operated in the daytime, without complaint from the merchants and residents along the streets, or from pedestrians. This ability to do all of the sweeping in daylight has greatly increased the efficiency of the street cleaning forces, and reduced the cost of the work, as compared with the efficiency and cost when the work was done at night.

The refuse collected by the block men with brooms and push carts is placed in 3-yd. boxes, placed at convenient intervals in the alleys. The alleys in the business district are also cleaned daily and the refuse placed in these boxes, which are emptied into wagons each day.

A sanitary rubbish can of special design, which has been used for about two years in the business district, has proved particularly effectual in obtaining the assistance of pedestrians to keep paper, fruit skins and similar litter off the streets. Prior to the use of these special cans ordinary round garbage cans were placed at the street corners and other points, as the receptacles for this litter. The records of the street-cleaning department show that these original cans enabled much of the refuse and litter formerly cast into the streets to be collected. Soon after the installation of the new cans the amount of material thus collected was doubled and is now more than three times what it was with the old cans. This condition can probably be attributed, more than anything else, to the attractive appearance of the new cans, which are at the same time built to be specially adapted for service.

The body of each can is 36 in. high and 19 in. square, with a frame of light steel angles and sides of sheet iron, the bottom being open. A leg, consisting of a short piece of steel angle, is placed under each of the four corners; these legs are adjustable in height so the can may be set in an upright position on a slanting sidewalk. The cans are designed to be attached to an angle-iron post set in the sidewalk. Some of the cans which have been installed were built with a vertical depression in the middle of one side, in order that the can might be attached to the angle-iron post in a minimum space. Some few of the cans are also attached to trolley wire posts of the street railway.

The top of the can is an inverted hopper, with a wide-mouth opening, and is not hinged to the body. A groove along one side of it fits over a projection on the inside of the body in such a manner that when a hasp on the oppostte side of the top is attached to a fastening on the outside of the can by a padlock, the top cannot be removed. The wide opening in the top, together with the trim form and the fact that each can is painted a silver gray, with nothing but the words "Rubbish and Paper" on them, appear to be the chief features which attract attention to the object of the can.

A burlap sack, which just fits the interior of the can, suspended from a row of hooks around the sides of the top of the body. The top edge of this sack is provided with eyelets which fit over the hooks. The latter are placed directly under the removable top, so the the sack cannot be taken out as long as the top is in place. The bottom of the sack is perforated to permit the escape of moisture, and as the can is built without a bottom, a free circulation occurs through the contents, keeping them as nearly dry as possible.

The removal of the filled sacks, without causing any dust and without losing any of the contents, is readily accomplished by a simple arrangement. A rope is threaded through the eyelets in the sack so the top of the latter can be drawn together and tied before it is pulled out of the can. An empty sack is then placed in the can and the filled one loaded on a wagon which makes regular collections. In all, 276 of these cans have been installed, and when making a collection three times a week the large rack wagon, shown in the accompanying illustration, is completely filled at each collection under normal conditions. The average load at each of these collections is about 2,400 lb.

The macadam streets in the residence districts of the city are swept regularly and the gutters of the surfaced streets are cleaned by a combined sweeper and sprinkler. The paved alleys in these districts are cleaned three times each week.

The equipment of the street cleaning department is housed in sheds adjacent to the business district. A shop in which all of the equipment is kept in repair is maintained in connection with these sheds. The rotary sweeping machines were built, and the pick-up machines were rebuilt in the shop, according to plans of the department.

The department has 90 men in its employ, regularly maintaining four sweeping outfits, which each include a rotary sweeper and a pick-up machine, with five men and a foreman to each outfit; another man and team are also added to the outfits at work on asphalt streets when flushing is done. Forty-five block men, with brooms and push carts are kept at work, the territory covered by each man depending on the traffic. The expenses of the department for the year of 1906 were $81,482.55, of which over $6,000 was for the establishment of the new plant and $8,454 for new equipment.

The department is under the supervision of Mr. Samuel L. Phillips, commissioner of highways, of Denver, to whom this journel is indebted for the information from which the foregoing notes have been prepared.

Book Notes.

About seven years ago Mr. Thomas Aitken, surveyor to the County Council of Fife, wrote a book on "Road Making and Maintenance," which is one of the best practical manuals on work of this sort in Great Britain. Since it appeared there has been a considerable change in many branches of road work. The automobile has demonstrated its devastating powers on roadways, new types of wood pavement have been introduced, tarring has pushed its way to the forefront, and the author himself has taken a prominent part in the widespread movement to prevent dust. A new edition of the book has accordingly been prepared to agree with the changed conditions. It has the same practical character as the first edition and will be found of much interest to American engineers who wish to secure information concerning the many British novelties in methods and plans which are attracting attention there but seem to be strangely belated in appearing on this side of the Atlantic. (London, Charles Griffin & Co., Ltd., 21s.).

One of the most perfect books typographically that has appeared in this country is the translation by Brother Arnold, principal of La Salle Institute, Troy, of the "Letters of Petrus Peregrinus on the Magnet." The author, a friend of Roger Bacon, was a highly educated French military engineer, who wrote his famous letters in 1269, thus making the first important contribution to magnetic philosophy, the next being the "De Magnete" of Gilbert in 1600. There are a dozen or so ancient manuscript copies of this letter in European libraries, and a copy of the first printed edition, that of 1558, is in the Wheeler Collection of the library of the American Institute of Electrical Engineers. This translation has been made with a scholarly accuracy and literary grace that are charming, and a similar satisfactory introduction concerning the author and his letter has been written by Brother Potamian, of Manhattan College. The great importance of this letter and the exceptional character of its translation and introductory notice led the publishers to give the book a form that was similarly perfect. A large amount of study and experiment was put on the task, and it is believed that nothing has yet been done in this country which is any better, the result being a unique volume of interest equally to those who wish to know about the very beginnings of electrical knowledge, and to bibliophiles. (New York, McGraw Publishing Co., $1.50.)

The first volume of Dr. S. Dunkerley's "Hydraulics" is somewhat disappointing, because it is by no means as good a work on the subject as the author is able to write, and, moreover, it contains typographical and other inaccuracies that are annoying. The first chapter is a discussion of the flow of a perfect fluid through orifices, jets and notches, and the second discusses fluid friction, practical formulas for the flow of

water, steam gauging and allied subjects. The chapter has a short article on water meters in which American meters receive very snippy notice, which is rather surprising in view of the favor with which they are regarded in Europe. The third chapter is a description of hydraulic pressure machines; the elevators of the Eiffel tower are given among the examples of such machines, but the latest patterns of apparatus designed by the same builders, the Otis Co., are overlooked. This is a pity, for elevator machines of the hydraulic type have revolutionized the possibilities of office-building construction and their details are of unusual interest. In the chapter on reciprocating pumps, which comes next, the main interest will probably be found in the discussion of the theory of air chambers, although there is a long description of the Gutermuth spring valve for water chambers, a German novelty. The fifth chapter is on turbines, and the sixth is on centrifugal pumps; in each the theoretical principles are first outlined and then apparatus is described, special attention being drawn to compound turbines and pumps built under the direction of Prof. Osborne Reynolds some twenty years ago. The seventh and final chapter is a review of that scientist's researches in viscous flow and the theory of lubrication. It must not be inferred from what has been stated that the book is not a useful one, for it is one of the best resumés of British research in hydraulics that has yet appeared. Its defects, outside of the poor proof-reading, lie in the references to machinery that can hardly be considered typical of the state of engineering at present. (New York, Longmans, Green & Co., $3.00.)

Letters to the Editor.

Metric Curves.

Sir: Enclosed find a few rules for reducing English curve values to metric. These were deduced for the purpose of platting metric curves, and are not applicable to field work as the values given are not exact. They vary on the same principle that the radius of a 2° curve is not exactly one-half that of a 1° curve, nevertheless they are sufficiently accurate for most purposes of platting, and may interest some of your readers. A table giving the radii, arcs and tangent distances in English values is required for their use.

The basis of the metric curve is: A twenty-meter chord subtends one degree of central angle.

To find the radius: From an English table find the radius of a curve of one-half the degree of the required metric curve, and point off one place; this is the radius of the required metric curve. Required to find the radius of a 5° metric curve: $5° \div 2 = 2° 30'$. R. $2° 30' = 2292.01$. 229.20 is approximately the radius of a 5° metric curve.

To find the S. T. From an English table find the S. T. for the given central angle, but for a curve of one-half the given degree, and point off one place.

To find the arc or length of curve: From an English table find the arc for the given central angle, but for a curve of one-half the given degree, and point off one place.

The above values may be reduced for English to metric, by multiplying the English value by .2, or dividing by 5.

Yours respectfully,

Geo. E. Winton.

Merced, Cal., Nov. 17.

[This relation is pointed out as follows by Professor C. F. Allen in his "Field and Office Tables": "The radius, the chord, length, offset, or other linear dimensions on the metric curve will be 0.2 that of U. S. curves of double the degree or nearly 0.1 those of U. S. curves of the same degree." Professor Allen here takes the degree of curve in the metric system as the deflection angle for a chord of 20 meters, whereas in the above letter it is taken as the angle subtended at the center by a chord of 20 meters. The two formulas, therefore, give similar results.—Editor.]

Heating and Ventilation.

Sir: Your editorial of Oct. 26 and the letter of Mr. Walter B. Snow of Oct. 31 I consider very much to the point, and feel that you and he have done one phase of mechanical engineering a service by calling attention to a situation that requires improvement. It is a fact that most heating and ventilating work of the present day, though not by any means all, is done on rule of thumb methods but little removed from the ordinary work of the skilled mechanic, and such mistakes as develop are either left in or corrected after the installation has been completed. This has permitted men who are little more than steam fitters to pose as mechanical engineers engaged in heating and ventilating as a branch of mechanical engineering, much to the detriment of the work done and to the standing of the profession, the purchaser or owner paying for the mistakes. There are many prominent exceptions to this, as in every line, and those engaged in this work can no doubt name colleagues who have become scientific engineers without ever having seen a college, but such men rose only through natural ability and effort impossible for the average. This situation has arisen largely through the absence of scientific data, but largely also through the ignorance of the existence of such data as there is, on the part of those engaged in the work.

It is the function of the schools of mechanical engineering primarily to teach students what there is known on any particular appropriate subject so far as possible and to extend the knowledge of that subject by research work. Heating and ventilation as a profession is not at this time recognized in any school of good standing in this country and it is an open question whether the time has not come to so consider it. That it is a branch of work capable of scientific treatment and of importance to the general public health admits of no question. It is, however, only one branch of that most broad and scientific department of engineering commonly known as "mechanical engineering," and as such, and by reason of its importance, should receive some treatment in a course of mechanical engineering. It is an error to assume that any such course, however thorough it maybe in its fundamental training on heat, applied thermodynamics, mathematics, physics and chemistry and steam machinery as taught in the laboratory, drafting-room and class, which contains no treatment of the methods of applying this knowledge to the problems of heating and ventilation or the analysis of these problems into the fundamental elements, is a sufficient preparation for its practice. The analysis of practical heating and ventilating problems in as great a variety as possible into their elements, all of which elements are contained and covered in any good course of mechanical engineering, is just as much necessary as the proper teaching of these basic subjects. Any course of instruction laid out with the idea of teaching the practice of heating and ventilation in the shortest time and of teaching nothing else would be entirely too narrow to be dignified by the name of a profession or to be of much use to the engineer who must keep up to date and lead in the solution of new problems.

It would seem that the best preparation for the practice of heating and ventilation would be a course in mechanical engineering to which was added, or which included, an examination of heating and ventilation problems and their analysis into the elements that are included in every course in mechanical engineering. Thus would be laid down a scientific basis as broad and many-sided as anyone could desire. There would be lacking, however, in the man thus prepared the ability to approach in a practical way a heating and ventilation proposition; he would not have much knowledge of costs of materials, labor or fixed charges or how to use them; he would not have much knowledge of the necessity for the exercise of ingenuity in locating his pipes and conduits, his heating surface, his returns, fans, fittings and regulators to those spaces left by the architects for the purpose, nor would he be able to surpervise the installation of a system because he would not know good work from bad. Such practical knowledge as this, however, cannot be taught entirely in the schools. It must be learned in the doing, and with the sort of preparation laid down above should be quickly learned. After the completion of an ordinary four-year course in mechanical engineering, a simple way of acquiring much that is practical and special in heating and ventilation would be the pursuit of a fifth year combining the present methods of instruction with practice of some of the art schools. In the fifth year the student can listen to lectures by prominent specialists on various phases of the subject, for, say, half his time or full time on alternate weeks and spend the rest of his time in the business office estimating and analyzing costs, in the drafting-room making layouts, and in the field assisting in the supervision of installations; he would at the end of that time be very much farther along toward becoming a useful heating and ventilating engineer than if he had spent two years at the practical work alone or a similar time additional in the college.

Mechanical engineering has split up into many specialties besides heating and ventilation, such as the powering of ships, mechanical refrigeration and ice-making, the management of factories, the design, construction and operation of power plants, and special machinery for elevating and conveying, pumping, air compression, crushing and grinding, the manufacture of cement and plaster, brick, textile and paper, the construction and use of machine tools and hosts of others, all demanding recognition. In the present four-year course we find it difficult to teach properly even those things that may be considered most broadly fundamental and necessary to all branches of mechanical engineering. How then are the schools going to face the problem of teaching these specialties as they should be taught? The method that will probably be the most feasible is the fifth year, not devoted entirely to the school, but spent partly in the school and partly in the field after the four years' work, in which special application can be effectively made without narrowness.

Yours very truly,

Charles E. Lucke.

Columbia Univ., Nov. 29.

The Iron Ore Production in the United States during the fiscal year 1906 is stated by the U. S. Geological Survey to have been 47,750,000 gross tons, valued at $100,597,000. This is an increase of about 12¼ per cent. in tonnage and nearly 34 per cent. in value over the production for 1905. Minnesota furnished ore valued at nearly $52,000,000 in 1906 and Michigan produced an output valued at $31,000,000. Alabama ranked third with an output valued at a little over $5,000,000. The larger part of the ore was mined directly by companies using it in their own furnaces.

THE ENGINEERING RECORD
PUBLISHED WEEKLY BY THE
McGraw Publishing Company
James H. McGraw, Pres.; Curtis E. Whittlesey, Sec. and Treas.
MAIN OFFICES:
239 WEST 39TH STREET, NEW YORK.
BRANCH OFFICES:
CHICAGO: Old Colony Building.
PHILADELPHIA: Real Estate Trust Building.
CLEVELAND: Schofield Building.
SAN FRANCISCO: Atlas Building.
LONDON OFFICE: Hastings House, Norfolk St., Strand.

SUBSCRIPTION RATES.
United States, Cuba and Mexico..........$3.00 a year
Canada ....$4.50 a year
Foreign subscription..........$6.00 a year
25 shillings. 25 marks. 31 francs.
Foreign subscriptions may be sent to our London office.

NOTICE TO ADVERTISERS.
Changes in advertisements intended for a particular issue should reach the office of THE ENGINEERING RECORD on Friday of the previous week. New advertisements can be received up to noon of Wednesday of the week of issue.

NOTICE TO SUBSCRIBERS.
REMITTANCES.—Remittances should be made by check, New York draft, or money order, in favor of THE ENGINEERING RECORD.
CHANGE OF ADDRESS.—The old address should be given as well as the new, and notice should be received a week in advance of the desired change.
BACK COPIES.—No copies of issues prior to July, 1906, are kept on sale, except in bound volumes.
DATE ON WRAPPER indicates the month at the end of which subscription expires. The sending of remittances for renewal prior to that date will be much appreciated by the publishers.
CLUB RATE.—In acknowledgment of assistance rendered by subscribers in the securing of new orders, a club rate of $2.50 per annum is quoted. This rate applies to subscriptions in clubs of two or more, at least half of the names in the club to be those of new subscribers.

Entered at the New York Post-Office as Second Class mail matter.

Of this issue of THE ENGINEERING RECORD 15,000 copies are printed. Total circulation for 1907 to date 733,000 copies, an average of 14,660 copies per week.

TABLE OF LEADING ARTICLES.

Publicity.

John D. Archbold, vice-president of the Standard Oil Co., makes the following unexpected acknowledgment in the "Saturday Evening Post" of Dec. 7: "I say with the utmost frankness that I believe the policy of silence which the company maintained for so many years, amid the misrepresentations which assailed it, is a mistaken policy, which, if earlier abandoned, would have saved the company from the injurious effects of much of that misrepresentation." The publicity policy of the great corporation has been for so long one of absolute silence concerning everything except its products, that this announcement by Mr. Archbold is very significant of the present influence of journalism. Some great railway companies long ago recognized that secrecy concerning everything in which the public was concerned had a bad effect on their place in public opinion. Some of the most gifted men in the journalistic field have undertaken this kind of publicity work, one of them even joining the staff of the Standard Oil Co. some months ago. It is safe to say, however, that this step, so far as the Standard Oil Co. is concerned, was taken too late; the public has been led to believe altogether too much evil of this great corporation to look upon its tardy recognition of publicity as anything but a desire to fight back as well as it can against its avowed enemies, who have long shown themselves to be masters of the resources of paper and pen.

It was natural enough for the great commanders of commerce and manufacturing, who were engaged in building up enormous business enterprises, to feel that the public had no right to information concerning their undertakings so long as they kept within the law, and that information concerning the products was all that there was any reason for giving out. Unquestionably this feeling has gradually changed, and it is now seen to be good policy to allow for two characteristics of the average man. The first is his legitimate inquisitiveness concerning the manner in which a product that he uses is made, and the second is a determination to buy that product just as low as anybody else. When a man delves into the secrets of nature in an intelligent manner he is considered a scientist, although very likely his researches may be of no immediate value. On the other hand, when he endeavors with equal intelligence to ascertain how a product is manufactured, so that he may judge for himself what improvements can be made in it without increasing its cost above what he wishes, he is, or was, regarded as altogether too inquisitive. Now these two manifestations of curiosity are really the same, and it is the recognition of this fact that has led to the increasing appreciation of what legitimate publicity means. The fact that the Standard Oil Co. has at last abandoned in a measure its policy of stony silence for that of reasonable publicity is one of those indications of the great business shrewdness that is expected in the management of that corporation.

Another aspect of this matter was referred to in this journal last week in the extracts from the address by Dr. James Douglas at the Toronto meeting of the American Institute of Mining Engineers. Dr. Douglas discussed the extent to which secrecy in the arts was desirable. His arguments for and against such secrecy were well stated, and the address as a whole is one of those contributions to engineering literature that deserve study by every engineer. A little reflection will show, however, that the views of secrecy outlined in the address of Dr. Douglas do not differ from those of publicity outlined by Mr. Archbold. Both agree that secrecy does not pay in these days in most enterprises. The reason for this is obvious. There are some special processes which can occasionally be maintained as trade secrets, and occasionally some one is able to devise a machine which it is advisable to operate in a secret manner. As a rule, however, secrecy is a cloak for ignorance. There are too many thoroughly competent men ready to undertake almost every kind of work to make the average secret, either of process or of organization, of much use. There are three things that count in large affairs. One of them, the most important, is an organization of competent men thoroughly inspired by esprit de corps. The second thing is sound financial management, and the third thing is control of the resources from which raw materials are obtained. At the present date patents are largely things to fight over, secret processes are things to worry over, and an inefficient staff of men is a thing to weep over. Given a good staff, a good supply of raw materials and a financial management that is neither reckless nor timid, and the success of any business is pretty well assured. It is safe to say that one of the first things a corporation of this nature will take in hand is its arrangements for securing legitimate publicity. The art of doing this is still in its infancy. There seems to be a feeling that by spending a little money in the advertising pages of various publications it is possible to control the reading pages, although this is not the case with any reliable journal. The way to secure publicity is that outlined by Dr. Douglas, to give out information which is likely to interest the people who subscribe to the various papers or join the important engineering societies. Just as soon as a corporation understands that there are two kinds of publicity, one entirely appropriate to advertising pages and trade catalogues, and the other appropriate to reading pages, and that the two are as far apart as the North and South poles, it has attained knowledge that, rightly applied, will enable it to gain satisfactory publicity in a manner and to an extent possible in no other way.

Tests of Full-Size Reinforced Concrete Compression Members.

Compressive tests of concrete cubes from twelve inches downward are much like those of steel eye-bars, so many in number as to leave little to be desired. The same is true concerning the tensile tests of cement and mortar briquettes, and it is even more true concerning the tensile tests of steel. In spite of this abundance of experimental investigations of the two materials of the concrete-steel combination there is a dearth of empirical data relating to the reinforced concrete compression member, although the engineering laboratory of the University of Illinois and the testing bureau at the Watertown Arsenal have made experiments valuable in their way, but not yet conclusive concerning some important features of reinforced concrete column design. The tests of banded columns have disclosed information of much importance and have aided greatly in giving the banded concrete column sufficient standing to secure its adoption in many buildings, but a little reflection makes it apparent that some of the most valuable information which can be established by experimental investigation cannot be obtained from columns of that type.

The longitudinal steel in banded columns is of very small sectional area and usually in such shape as to offer no sensible resistance to direct compression in itself, even when such angles are employed as have occasionally been used in this particular class of column tests. The natural and inevitable consequence is, first, a certain heterogeneous action of the two materials, in consequence of which the steel bars or rods tend to buckle under even a small compressive loading and hence to split the concrete surrounding them. This tendency is, of course, opposed and controlled by the steel banding, provided it is heavy enough. Some experiments seem to show that the banding does not in general come into positive effective action until the concrete has been loaded beyond any intensity of working stress which has yet been prescribed for the concrete; in other words, the lateral expansion of the concrete under the maximum working loads of engineering structures is not enough to

develop any material amount of support from the banding steel. Or, to put it in another way, the ordinary round rod steel banding does not act quickly enough to meet the requirements of usual loading on the concrete, although it gives material support to the latter under loads imposed by the testing machine far beyond the maximum working stress in any structure. While, therefore, the tests of full-size banded columns produce results which fully illuminate the conditions attending the action of a wire-wound concrete core, they have not thrown much light upon the ultimate resistance of a combination column in which the steel is so distributed as to form a full load-carrying steel column, while at the same time it envelops and supports as an effective banding the concrete within it.

This latter type of column, used successfully in the building in which this journal is published, is a true concrete-steel column in the full sense of the expression. The combined action of the two materials is radically different from that of any series of concrete-steel columns yet tested. The load acts directly upon both steel and concrete from the initial loading to the full working stress. The steel performs its function promptly and without waiting for the development of lateral strains in the concrete. While the lacing bars may, and undoubtedly will, yield to some extent to the flexure induced by the lateral enlargement of the concrete, it must be remembered that when properly designed the flexure of the lacing bars will afford considerable lateral support to the concrete and, within the working stresses permitted in that material, it may be even quite as much as or more than that offered by wire banding. If it be further remembered that a large part of the mass of the concrete at the four corners of a column is embraced throughout its entire length by the steel angles, and thus held far more effectively in this respect than by any possible wire banding, it is clear that the enclosed concrete must be substantially supported. At the same time the crucial test, of course, lies in the actual loading to failure of full-size members.

There are other features of these combinations of different materials the influence of which can only be satisfactorily determined by experimental investigation. It is ordinarily assumed that in all types of columns the intensities of stress are directly proportional to the compressive strains produced, and as a general law that is certainly true, but the effect upon the stresses in the concrete due to the partial prevention of the lateral strains by enclosure has not yet been demonstrated. It is quite supposable that in the combination of a steel column enclosing concrete the effective support of the latter by the steel surrounding it may throw upon the concrete sensibly more stress than would be the case with unrestricted lateral movement. Under such conditions the steel would carry with increasing loads a less proportion of the total and the concrete more. A careful set of measurements of the shortening of a test column under loads gradually advancing to that producing failure would yield sufficient information to settle this and other similar questions regarding the interaction of the two elements. There can be little or no question about the wisdom and safety of the present allowed stresses by the Bureau of Buildings of New York in columns of this type, especially as there are numerous tests of 1:2:4 concrete, showing that even in ordinary cubes a working stress for the purpose indicated of 750 lbs. per square inch may carry with it at the age of six months a safety factor between 5 and 6. It is much to be desired that in the mass of material testing now being planned ample provision may be made for full experimental investigation of this type of column which has so much to commend it from every point of view.

Vocational Schools.

The discussion which has been carried on in the columns of this journal recently is one that stimulates thought on educational topics. No country has a more active interest in education than our own and nowhere have experiments in education been tried on a more lavish scale. Some of them have been highly successful, others have not. In the early days of the country the situation was a very simple one. There were at the bottom the common schools, covering a range roughly equivalent to the first ten years of the present graded schools. Beyond these were a limited number of schools preparatory to the existing colleges and doing something less than the present classical high school. If these were not accessible the student was likely to prepare for college in his pastor's study. Then came the college, with a rigid course devoid of ornamentation but crudely effective. For professional study there was the divinity school, law and medicine being commonly studied in the office of the practitioner. It is only within the present generation that technological training has became reasonably accessible to those who are not desirous of the old classical training, now very much out of vogue.

The present technological school is the outcome of a demand for practical studies which could be applied to the occupations of every day life. It was roundly abused in its beginning, more for social than for strictly educational reasons. It was looked upon as the resort of young men of small means and mediocre attainments who desired with a strictly commercial instinct to turn studies into dollars in the minimum possible time. At present that stigma has worn off, for the point of view has changed and the growth of industry has opened careers which demand for preparation something more than the old education had to give. And by reason of the same sort of demand, there have sprung up a host of what one may call rudimentary technical schools, and institutions even more strictly vocational, such as correspondence schools and trade schools, teaching for better or worse practical things which can be turned into the coin of the republic. Besides these there are the so-called business colleges, which exist simply on account of the incapacity of the public school to come down out of the moonshine long enough to teach common things thoroughly.

Now the vocational school, by whatever name you choose to call it, exists in honorable recognition of the fact that the grand army of the world's workers must have privates and non-commissioned officers as well as staff and line. One may try to conceal their function behind fine spun theories regarding the superlative cultural value of handicraft, but the fabric is transparent. The students of the vocational school, whether it be a manual training, a trade, or a business school, are there because they lack the time, taste or capacity for pursuing the so-called "higher" education. Many of them are the better for their choice, and all are going honorably forward to find their places in the ranks. Some will win their commissions in due season, others will stay privates and corporals. It is sheer snobbery to look down upon the vocational schools, but it is equally culpable stupidity to suppose that they exist for psychological rather than utilitarian reasons. There are doubtless some boys whose intellects can be stimulated only through their hands, but these cases are essentially unfortunates like those deficient in sight or hearing to whom the ordinary channels of communication are unhappily closed.

The "manual training" high school occupies a somewhat anomalous position at the head of the list. At present it turns out neither engineers nor finished craftsmen, but gives a good sound training so far as it goes. There is a pretty general feeling among engineers and manufacturers who have considered the subject that if the manual training school could go about two years further it would prove invaluable in the training of young men fit to be foremen and superintendents, the sergeants and lieutenants, so to speak, of industry, not out of line for promotion. A very few schools which actually give just about this training can show a remarkably successful list of graduates. It would be an admirable thing if the manual training schools could generally be expanded into this particular sphere of usefulness.

The trade schools have not been so successful as one could wish, mainly on account of unreasoning prejudice on the part of organized labor. The Y. M. C. A. industrial courses and the correspondence schools, by dodging around this obstacle, have, on the other hand, made substantial progress. The trade schools certainly have the possibility of very great usefulness, since the lack of trained workmen is being very severely felt in American industry. They ought to be actively encouraged and made an efficient part of the educational organization. If they were vigorously pushed the prejudice which now handicaps them would soon disappear and one would not be under the necessity of hunting up foreign-trained workmen in many branches of industry. At present all that is done in the way of training for trades is a mere drop in the bucket. Not every man can be made into a good workman, but every man ought to have the chance. With all the millions that are being spent for the cause of education in the United States it is a shame that more and better trade schools are not in operation. They are far more necessary to the national future than are the scores of petty colleges that provide sham B.A. and B.S. degrees in scores of self-satisfied communities. The country could well exchange a job lot of shabby "universities" for as many thoroughly good vocational schools. Education as at present organized is unhappily more extensive than intensive. This is not altogether the fault of the educators, but rather of the community that too frequently wants its culture like its parlor —plenty of veneer and varnish, and never mind about the joints. It is perhaps only a transitory foible of a rapidly growing coutnry,. but it is serious in that it leaves to the future the task of patching things up as best it can. It is time to drop makeshifts and to begin accumulating for the next generation a heritage of honest work in culture as in industry. It is a national boast to give every man a fair chance . Is it not time to make that boast good by giving every man an opportunity to learn how to win an honest livlihood?

Common Sense about Smoke Abatement.

The Chamber of Commerce of Syracuse, N. Y., is to be congratulated on having published the best report on smoke abatement that has yet appeared. It combines scientific accuracy with an appreciation of what is practicable, and is neither disfigured by questionable theory nor marred by the wordiness which disfigures so much that has been written on this important subject. Moreover, from cover to cover the report is characterized by a sanity of view that is gratifying. While it has been prepared for the use of Syracuse citizens, the work has been so thoroughly well done that its advice is applicable in most of our cities. If it is studied carefully and its conservative recommendations are followed, the manufacturers whose plants are now emitting dense smoke and the people who are subjected to inconvenience by such smoke will alike be bene-

fited. It is not surprising that the report is such a good one for the Chamber of Commerce appointed a committee to carry on the investigation which was fully able to execute its task in a proper manner. Four of the members were men everywhere recognized as authorities in industrial engineering affairs, while the others were equally competent to give advice on other features of the smoke problem. Plenty of time was taken by the committee to become acquainted with the conditions in various cities and to study the operation of devices for preventing smoke. Correspondence was conducted with cities having smoke-prevention ordinances and every attempt was made to find out what had been accomplished in this country and abroad. The report is consequently one of those documents which will become a standard authority, and it is to be hoped that the Syracuse Chamber of Commerce has printed an edition sufficiently large to enable engineers and municipal officers in other cities to obtain copies.

It is gratifying to notice that the committee has resolutely refused to lend itself to the position taken by some sanitarians that all smoke is injurious to public health. Very likely it is when present in large quantities, but there is a great difference between the atmosphere of the mill district of Pittsburg and the atmosphere of Syracuse. In Syracuse the problem of smoke abatement is essentially one of aesthetic and economical conditions rather than one of hygiene. This is generally the case elsewhere and the sooner the fact is recognized the sooner will we have good progress in smoke prevention. If an ordinance is passed by a city which makes absolute prevention of smoke necessary at all times, the way is open for endless graft. Such a condition is not practicable nor is it necessary. There are a number of appliances on the market which will prevent smoke entirely under most conditions, when properly applied and managed, and the worst condition they will permit is a gray haze at the time fresh coal is charged on the fires. When the smoke given off by all plants is reduced to this extent, about all that is really necessary has been accomplished.

A great trouble with attempts made in the past to abate smoke has been due to the endeavor to place the matter in the hands of the police, or to take some equally drastic action. This is unfortunate. The history of smoke abatement demonstrates beyond any question that success can only be attained when the manufacturers whose plants belch forth black clouds and the owners of small boiler plants which are offenders in the same way, are brought to an appreciation of the importance to themselves of stopping such practices. Men told peremptorily to stop the nuisance their premises are causing, under penalty of heavy fine, are not approached in a tactful manner. Up to date no attempt to introduce such a policy in an American city has been successful, and most such attempts have been flat failures. On the other hand, marked success has been the result of harmonious action on the part of manufacturers and others to remedy this trouble. This has been shown particularly in the case of Cleveland, where great improvements are being made and arrests and fines are rarely necessary. Of course there will be cases in all cities where the law must be invoked to stop the nuisance. This is to be expected, but it is highly desirable that the number of such cases be restricted entirely to those parties who by nature are reluctant to do anything which is desirable for the public welfare.

It is really surprising that so little has been accomplished in the way of a general education of the people concerning the causes of smoke. The essential facts are readily understood. They do not require a technical education nor a deep knowledge of the secrets of science. The report issued by the Chamber of Commerce of Syracuse states both the principles of combustion and the causes of smoke in six pages of ordinary octavo size. A study of these pages is a matter of half an hour or so, and once the information they give is learned thoroughly the reader is in a position to talk intelligently on the subject of smoke abatement. He is also in a position to avoid accepting the preposterous claims occasionally made for patented devices to bring about smokeless combustion. Probably one reason that so many people are reluctant to try to prevent smoke is the fear that they will fall into the hands of some salesman whose apparatus is made to sell and not to work. Such people will find in this report a fair statement of what can and cannot be accomplished by different types of apparatus. The committee states emphatically that there is no one apparatus which will accomplish everything to be desired in every place, and it gives a warning that the selection of the apparatus for smoke prevention is something which should be entrusted if practicable to an independent specialist. There are a great many people owning small plants who will be reluctant to engage a specialist for the small installation necessary for their works, and for such people this report will be a boon. It is an excellent example of the good work that can be done by such a body as the Syracuse Chamber of Commerce, when it sets about it in the right way and takes plenty of time to do the work thoroughly and impartially.

Notes and Comments.

The Credit Man in business organizations has become a particularly important man these days, and because of the talk going on about over-expansion of business there is danger that, by over-conservative judgment, he may cause his associates to lose some good things. A pretty careful study of reports received by this journal during November, coming from all parts of the country, indicates that there is a very large amount of work fairly certain to be undertaken during the coming year. There is likely, however, to be some change in its character as compared with that undertaken at the beginning of this year. The anti-railway laws in the South have shut down railway improvements there, but more municipal work seems likely to be undertaken. A good many manufacturing companies which have recently reported improvements to be undertaken by them have apparently determined to confine this work more to equipment and reconstruction than to new buildings. The work that will be done will be carried out for responsible people of ample resources, who will take advantage of every flurry that lowers prices to secure whatever they need at favorable rates. The flighty promotor will not have much support and he will not be in evidence. Under such conditions, the credit man who is too conservative hurts his associates and his community. There is a large amount of engineering work greatly needed, there is plenty of money for it, and the only obstacle is the tendency to be too suspicious. It has been stated before in this journal, and this statement has found general approval, that it is highly desirable for the sound business men of every community to get together in an association for mutual help. It has been pointed out that such an association can be of great aid financially in a community where the banks are not rendering the service they should. An equally valuable help can be afforded by maintaining a central credit bureau. This has been done for years by merchants in New England cities; in the largest cities bitter commercial rivals exchange information concerning the financial standing of applicants for credit. A good deal depends now on giving all credit that is reasonable for engineering and industrial enterprises, and for this reason a closer association and supervision of the work of the credit man seems desirable.

The London Water Supply is the subject of an unusually interesting report made public last month by the Water Board of the metropolis. Some years ago, when the existing works were under private ownership and the London County Council thought it would be a good thing to build a great system drawing a supply from Wales, there was a lack of harmony concerning the course most desirable to pursue. Since then the works have passed under the control of a single commission, which has been studying carefully the needs of the future and the means of meeting them. The report states the results of this study. Primarily it is based on the utilization of the Thames by storage and filtration until the cost of works for the purpose becomes greater than the cost of works to bring water from Wales. This decision is a gratifying recognition of the resources of sanitary engineering. It was not so long ago that the idea of utilizing river water, even when filtered, would have been regarded with grave doubt, but we now know that storage and filtration will furnish a good supply from the Thames unless it should be polluted far more than is now the case. Such an increase in pollution is extremely unlikely. The amount of water used daily in the district is now about 225,000,000 imp. gal., of which nearly 129,000,000 gal. are from the Thames and the remainder are from other sources which cannot yield more than 120,000,000 imp. gal. when fully developed. The average daily flow of the Thames over Teddington Weir in the driest year is 900,000,000 imp. gal., so that a large amount of water can be diverted from it. A study of the probable growth of the population to be served and its consumption of water indicates that in 1916 the storage should be 37 gal. for each gallon of average daily supply, in 1926 it should be 72 gal., in 1941 it should be 91 gal., and about 1960 it should be 120 gal. With such an amount of storage 450,000,000 imp. gal. can be utilized from the river at a lower total expense than water will cost from other sources. The Thames is capable of furnishing a larger quantity than that, but the expense of the additional storage renders any further development of the works undesirable. The population served at that date is estimated at the enormous total of 16,286,000 people, who must be furnished 35 imp. gal. per capita daily, 1.5 gal. more than the present consumption. The astounding thing about the project to the American engineer is the belief of the Water Board that all these great works can be built out of its revenues. Evidently the American plan of paying for such things with the proceeds of bonds and thus charging their expense to the taxpayers instead of the consumers is not regarded with favor. Another feature of the report is the admirable foresight shown in the recommendation to acquire a tract in Wales large enough to meet the requirements for the additional water in the last four decades of this century. The principality does not look with favor on the appropriation of its water, and it will be far less expensive and troublesome to acquire the needed territory now than fifty years hence. The investment will not be entirely without returns, moreover, for by forestry and the lease of the land for grazing and agriculture interest charges on the investment can probably be considerably reduced. It must be gratifying to the people of the British metropolis to have such a satisfactory forecast of future possibilities as the Water Board and its engineer, Mr. Bryan, present in this comprehensive and convincing report.

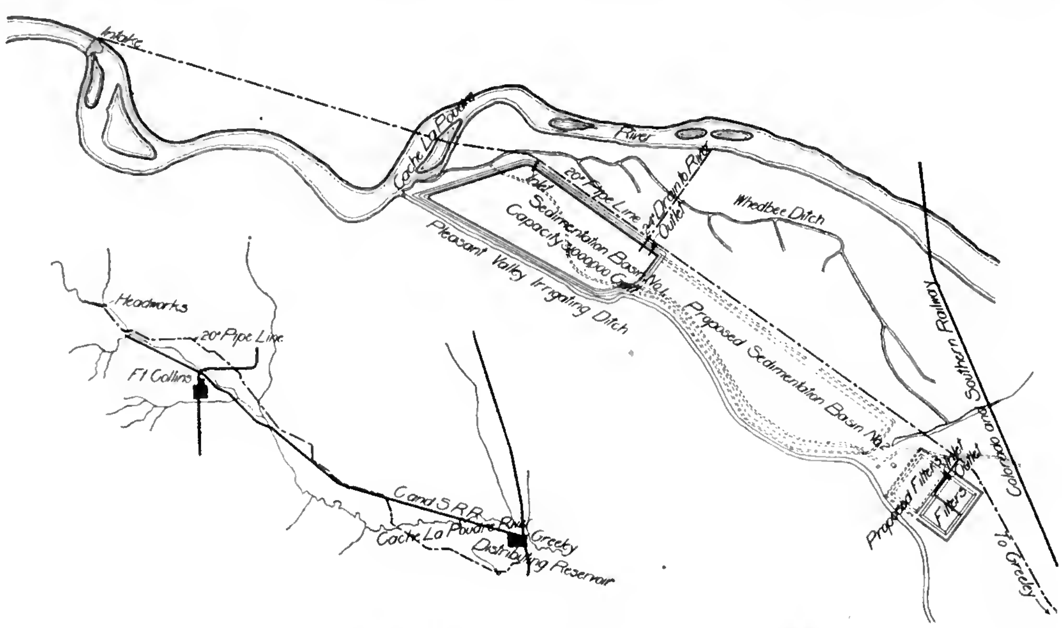
A GRAVITY WATER SUPPLY SYSTEM AT GREELEY, COLO.

A municipal gravity water-supply system, which embraces various special features of arrangement and design has recently been placed in service at Greeley, Colorado. Greeley is a city of about 7,500 inhabitants, 52 miles north of Denver on the eastern slope of the Rocky Mountains, and is surrounded by an extremely productive agricultural region, although the mean average rainfall in this locality is only a little more than 14 in. a year. The great productivity of the surrounding country is due to the fact that, almost without exception, the land is under irrigation. Water for irrigation is diverted from streams which have their source in springs, or in the almost perennial snow fields in the mountains, the foothills of the latter being about 30 miles west of Greeley. The largest of these streams is the Cache La Poudre River, the principal tributary of the South Platte River, the normal and minimum flows of the former being, in fact, greater than those of the main stream. The waters of the Cache La Poudre River, and of its tributaries, with the exception of a part of the extreme flood flows, are entirely appropriated for irrigation ditches which have their headworks above Greeley. Consequently, the only flow in the river at the latter during dry seasons is the seepage water which finds its way back into the stream from the irrigated lands.

Until the new gravity system was placed in operation, the water supply for general consumption in Greeley was derived from an infiltration well built in the gravel bed of the river a short distance above the business section. The distribution mains were operated under direct pressure from pumps in a station on the river bank adjacent to the galleries, a 14,000-gal. tank on the hill above the city maintaining the pressure during maximum consumption. The supply thus obtained and delivered was not only exceptionally poor in quality, but was also quite limited in quantity during certain seasons. The water which seeps back into the river from the irrigated lands is very highly impregnated with alkali salts of various kinds, a hardness of 1,800 parts per 1,000,000 being common to it. These salts impart a decidedly objectionable taste to the water and actually render it harmful. At the same time, the greatest defect of the water for domestic purposes is the extreme hardness. The water in the river at Greeley is also very deleterious to boilers, and was entirely unsuited for other commercial uses. The infiltration well was practically ineffectual in reducing the extreme hardness, although the turbidity which occurs in the river water under certain conditions was removed by it.

Notwithstanding this extremely unsatisfactory water supply, the local geographic and hydraulic conditions rendered the provision of an adequate quantity of good water an undertaking of exceptional magnitude for the comparatively small community to be served. Ground water from deep drilled, or bored wells in the vicinity is generally good, but the quantity to be obtained in this manner is limited. No possibility, therefore, of obtaining an adequate supply from wells existed. As the Cache La Poudre River and its tributaries are the only permanent streams within a reasonable distance of Greeley, it was evident that the only available supply of surface water to be obtained was from this river. The land is irrigated on both sides of the river above Greeley to the foothills of the mountains, so in order to secure a supply free from seepage from these irrigated lands the water had to be taken from the river in the foothills, at least 36 miles from Greeley.

While the location of the only satisfactory source of supply was thus determined within relatively narrow limits, other conditions of an exceedingly serious nature had to be met. Since the difference in the value of water rights in the eastern and western sections of this country, or more properly between the humid and arid regions, is so great, and because of the almost sacred character attached to such rights in a section in which irrigation is well advanced, the conditions which were presented will be treated in considerable detail. The appropriations of the entire flow of the river, up to and including part of the storm-water run-off, have become, under decrees of the courts in the order of their application to actual use, vested rights of great commercial value, due to the intense agricultural development of the river valley. These rights are, consequently, guarded with the utmost jealousy by the individual farmers who own them, and any infraction of them, or interference with their rank and precedure in priority is subject to opposition and protest of formidable character. From these conditions, the acquirement of a diversion from the intake of the ditch to a point some 3,000 ft. upstream in order to locate advantageously an intake for a pipe line leading to Greeley. Furthermore, the quantity of water decreed for irrigation purposes had to be transferred to a right for domestic and sanitary uses. The legal processes of both such transfers frequently meet with strenuous opposition from other water-right owners. The mere diversion of a quantity of water from one to another point of the river may adversely affect the established rights in the intervening section. Besides, the use of water for domestic purposes is essentially more imperative in its demands than for irrigation purposes. It also covers the full year, while water decreed for irrigation purposes may be limited in right to the irrigation season, extending from April 15 to November 15. These transfers were nevertheless made by the court, so the appropriation granted to the ditch placed fourth in the order of priority, and permits the diversion of the water at the desired point. Less than 50 cu. ft. per second have been decreed to other ditches ahead of this one and as the flow of the



Map of Pipe Line and Arrangement of Headworks.

legal right to an adequate water supply at all seasons of the year and at all stages of the river, formed for Greeley, as it must do for all other towns and cities in an arid region where a great irrigation development exists, a most serious problem. In this instance, however, the requisite rights were obtained at a nominal cost and without conflicting with other appropriators.

In the purchase of a site on the river at the edge of the foothills, a portion of the land acquired conveyed with it the title to an irrigation ditch built from the Cache La Poudre River in 1862, which makes it one of the earliest ditches constructed in the valley. This ditch had been used continuously for irrigation purposes from the time it was built practically to the time it was purchased by the city, and it had a carrying capacity of about 7.5 cu. ft. per second. The ditch did not, however, possess a legal existence, so far as the records of appropriations decreed by the courts showed, although it had a right to a supply of water from the stream, because the formality of presenting a claim, or statement of its standing and of having the appropriation of its right decreed by the courts had been neglected. The state laws of Colorado contemplate the correction of such omissions, however, on due notice to all parties concerned in the water appropriations. Accordingly, when the claim was properly presented the decree for the ditch was entered as August, 1862, with an appropriation of 7½ cu. ft. per second. It was then necessary to transfer the point of river is rarely, if ever, less than that quantity, a supply is assured at all times. The quality of the supply is also excellent. The normal total hardness of the water is only 40 parts per million, as compared with the 1,800 parts per million in the original supply of the city; the normal bacterial content is remarkably low, and during almost the entire year turbidity and color are absent. The value of a supply of this character to a community in the semi-arid region in which it has been obtained is scarcely appreciated in sections of the country where water is plentiful and quality of the supply is the chief consideration.

A 20-in. wood-stave pipe line, 36 miles long, has been built to deliver the water to Greeley from an intake in the river near the head-works of the old irrigation ditch. In connection with this pipe line, a 31,000,000-gal. storage and sedimentation basin and two 1.25-acre slow-sand filtration basins have been built a short distance downstream from the intake. A 5,000,000-gal. receiving and distributing reservoir has also been built on a hill, two miles from the city. Sites have also been reserved for a second sedimentation basin of over twice the capacity as the existing one for doubling the filtering area and for a second receiving and distributing reservoir. Provisions for connections for these proposed additions have been made along with the present work, to facilitate future construction.

The ultimate capacity of the pipe line of the new system is 5,000,000 gal. per day, while the

The 31,000,000-Gallon Sedimentation Basin.

normal average daily consumption in Greeley is now about 1,250,000 gal. In the design it was planned to provide for a population of 15,000, with a per capita consumption of 300 gal. This allowance is not unusual in cities and towns in the arid or semi-arid regions where lawns, trees and all vegetation is wholly dependent on irrigation. The construction of the new system along these lines and the acquisition of the water right described, make ample provision for the growth of the city.

The intake of the pipe line is only half a mile downstream from the mouth of the canon of the river in the foothills. About six miles above this intake the river divides into two branches, the North, and the Main Forks. The water from both forks is normally clear and cold, since the source of both is springs and snowfields in the mountains. Under certain rainfall and flood conditions, however, the turbidity of both streams is pronounced for short periods. The turbidity which occurs is due to the washing of the light soils in the watersheds and is remarkably difficult to remove by sedimentation. The conditions which cause it frequently occur on different occasions in the watersheds of the two forks, so the water from one fork may be clear when that in the other is fouled.

The normal bacterial content of the water of the river above the intake is unusually low, due largely to the fact that little or no land on the watershed is cultivated and the resident population is extremely scant. On the other rand, much grazing land exists in the catchment area of the river and large numbers of camping parties frequent the mountains in this locality during the summer. Consequently, in designing the works the waters of both forks of the river were considered to be liable to immediate dangerous contamination, under certain conditions, and to more frequent contamination in the future.

Under these circumstances, the storage and sedimentation basin and the slow-sand filters were provided, in order that a uniformly clear, pure water might be delivered to the city. The only other alternative to these works would have been to extend the pipe line six miles up the canon to the junction of the two forks of the river, so water could be taken from the Main Fork only, which prior to the construction of the new works was considered to be free from turbidity, although subsequent observations have disproved this. Such an extension would have cost quite as much as the works that have been built, owing to the difficult and expensive character of the construction work required to make it. Moreover, the supply would have still been subject to periods of turbid water and to the possibility of dangerous contamination. The storage and sedimentation basin that has been built has sufficient capacity to supply the system, during the short periods when the turbidity of the river is the worst, without requiring any water to be drawn from the river during these periods. It also has enough capacity to permit a considerable percentage of the bacteria as well as the rarely occurring turbidity, to be removed by sedimentation. The slow-sand filters have already demonstrated that they will reduce the bacterial content well within what is considered a safe limit for a domestic supply.

Headworks. A loose-rock diverting dam, 6 ft. high and 10 ft. wide on top, has been built across the river at the intake where the width of the stream channel is about 125 ft. The bed of the channel in this vicinity is gravel and small boulders. The latter and a quantity of broken rock, in pieces containing from 2 to 6 cu. ft. each, were used in making the dam, the downstream face being built on a slope of about 5 to 1 and the upstream face 1 to 1. The dam was made only tight enough to raise the stream level above it, in order that water might be diverted into the intake. The loose-rock construction has already been subjected to as nearly severe flood conditions as may be expected to occur, without material damage, and it is considered to be as well adapted for the service required as a more expensive masonry structure.

The intake to the 20-in. wood-stave pipe line is simply a concrete chamber at one end of the diverting dam, with an opening, protected with a rack screen, connecting it with the river. A manhole is provided in the top of the chamber so that the latter may be entered. A vent is placed in the pipe line just below the intake to permit the escape of air that enters the line at the latter.

The pipe line is on the right bank of the river for about half a mile from the intake, and then crosses the river at a wide place in the channel of the latter, close to the upper end of the sedimentation basin. This first part of the pipe line involves no special features of construction, except the river crossing was made with cast-iron pipe.

Sedimentation Basin. The sedimentation basin and the filters are along the foot of a high hill, between the river and an irrigation ditch, which has its intake at the upper end of the sedimentation basin and skirts the base of the hill. The sedimentation basin was built to fit the ground, so is irregular in plan, its extreme width being 500 ft. and extreme length 1,400 ft. It is partly in excavation and partly in embankment. The embankments are 20 ft. wide on top, have a 1½ to 1 slope on the outer faces and a 2 to 1 slope on the inner faces. They were built with material from the excavation, which was hauled into place by teams and scrapers. The inner slopes are protected with hand-laid rip-rap, consisting of small glacial-drift boulders. The basin is not otherwise lined, but is practically water-tight. The outer slope of the upstream embankment is liable to wash during flood flows, so it is well protected with a layer of rip-rap of fair-sized boulders, the top of the embankment being placed 5 ft. above the highest known flood level, which occurred in 1904.

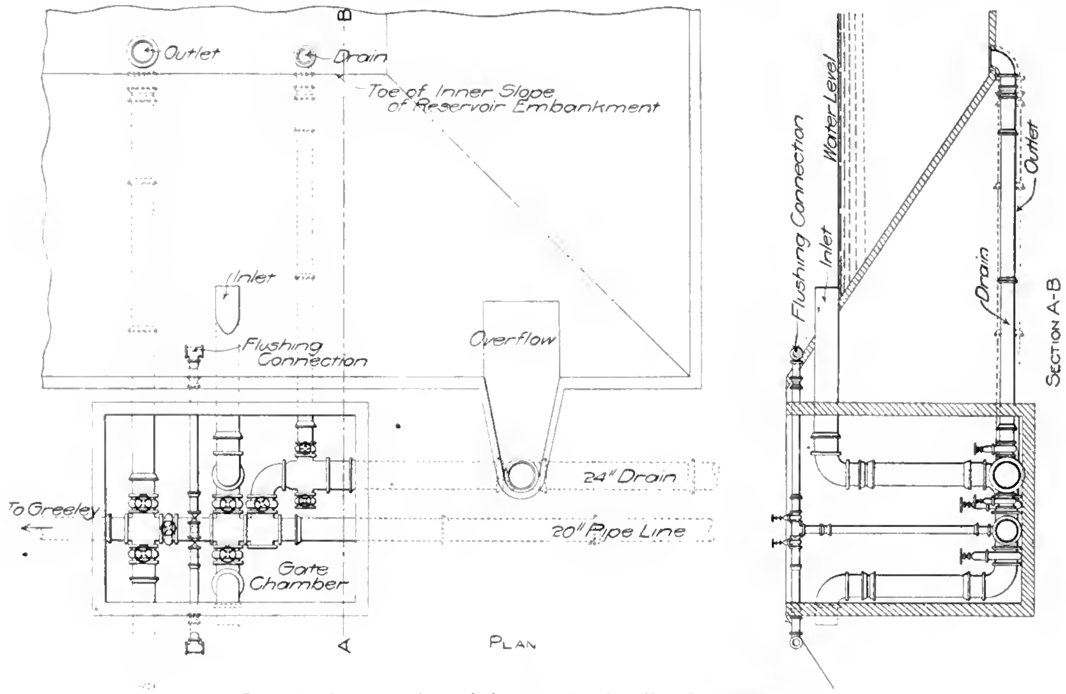
Receiving and Distributing Reservoir with Concrete Columns Ready for Wooden Roof.

The 20-in. wood-stave pipe line extends along the river side of the basin, close to the toe of the outer slope of the embankment on that side. An inlet connection to the basin from the pipe line is made at the outer, upstream corner. This connection is a 20-in. cast-iron pipe, laid under the embankment to a point 40 ft. inside the inner slope, and is provided with a gate valve so the flow in it may be controlled. The outlet from the basin is through a riser in an 8-ft. circular concrete chamber, in the downstream end of the basin, close to the inner toe of the slope of the embankment on the river side, the bottom of the basin sloping to this corner. Water can be drawn into the riser in the outlet chamber through four 20-in. connections, all at different levels, one of these is at the bottom and permits the basin to be drawn down entirely; the second is 8.5 ft. above the bottom; the third 6 ft. above the second, and the fourth is an overflow, which prevents the depth of the water in the basin becoming more than 16 ft. at the outlet. Each of the three lower connections is provided with a gate valve in the chamber. The connection between riser in the chamber and the 20-in. wood-stave line has a valve in it near the junction with that line; a valve is also placed in the latter near this connection. The arrangement of valves permits the basin to be by-passed, if desired, or the flow in the pipe line above the basin may be cut off and the supply drawn from the basin. The reservoir can also be drained by a 24-inch sewer leading to the river.

The site for the second sedimentation basin is immediately down stream from the first, the two basins being arranged, in fact, to have a common embankment at their adjacent ends. The two filters that have been built are 800 ft. downstream from the lower end of the proposed sedimentation basin, space being left on their upstream side for the two proposed additional filters and for the house and grounds of the attendant who is in charge of the filters and headworks.

Filters. The two filters which have been built are in a single open basin, 210 x 330 ft, in plan at the top, which is formed partly in excavation and partly by embankments. The embankments are 20 ft. wide on top and have both faces on a slope of 1½ to 1. The inner slopes of the embankments and the bottom of the filters are lined with 6 in. of concrete. A reinforced concrete division wall on the transverse center line of the basin separates the latter into the two independent filters, each with a filtering area of 1.25 acres. No covering was provided for the filters, as many years' experience in the operation of the open slow-sand filters of the Denver Union Water Co., at Denver, Colo., under climatic conditions very similar to those existing at the filters of this system is considered to show that the reduction in cost of operation produced by the covers, under the existing conditions, would not have justified the increased cost of such construction.

The operation of the filters is controlled from a 20 x 20 ft. concrete gate chamber built in the embankment, at the upstream end of the division wall. This chamber is surmounted by a substantial brick house of quite satisfactory appearance. The chamber contains all the necessary inlet, outlet and drainage connections for the two existing filters, and for the two proposed additional filters as well. The 20 in. wood-stave pipe line extends along the river side of the filters and has two 20-in. lines leading from it to the gate chamber, one for an inlet and one for an outlet. Both of these lines are cast-iron pipe laid under the embankment, which will be common to the two existing and the two proposed filters, when the latter are built. The inlet has two tees inserted in it in the gate chamber, with four 20-in. inlet connections, one for each filter, provided in these tees. As in all of the connections for the two proposed additional filters, the inlets provided for the latter are fitted with blank flanges. Each inlet connection is fitted with a gate valve and ends in an open chamber in the adjacent corner of the filter, the sides of this chamber being carried above the sand level in the filter. Four connections to the 20-in. outlet are provided, one for the underdrainage system of each filter; these connections are arranged in the gate chamber the same as the inlet connections.



Connections at Receiving and Distributing Reservoir.

A 12-in. drain leads from the gate chamber to the river. A 6-in. connection to this drain for each filter permits the water over the sand in the filters to be drawn off. An overflow connection to the 12-in. drain from each filter prevents the water in the filter exceeding a depth of 6 ft. above the bottom.

The underdrainage system of each filter consists of a 24-in. main drain, on the longitudinal center line of the filter, with 6 in. lateral drains. These drains are all vitrified sewer pipe, laid with open joints. The lateral drains are 14 ft. apart and extend to within 3 ft. of the sides of the filter. The end of the main drain distant from the outlet end is 0.7 ft. higher than the latter end, and each lateral has a fall of 0.4 ft., insuring drainage.

A minimum depth of 3 ft. of filtering materials is placed over the underdrains, 1 ft. of gravel at the bottom surrounding the underdrains, with 2 ft. of sand over it. Washed gravel from the river was found to be entirely satisfactory for the purpose. The gravel in the lower 7 in. of the 1-ft. layer was required to remain on a screen with 1-in. meshes, but to contain very few stones over 2 in. diameter. Over this coarse gravel is a 2½-in. layer of gravel, which will pass a screen with 1-in. meshes, but be retained on one with ⅜-in. meshes. The gravel in the remaining 2½ in. would all pass a screen with ⅜-in. meshes, but is coarser than ordinary sand, and free from fine material. Sand of excellent character was also obtained from the river. Two mechanical analyses of this sand are shown in the accompanying table, from which the high coefficient of uniformity is evident. Chemical analysis made of the same samples showed the percentage of carbonates contained in the water to be low, as might be expected, since the river water is practically free from salts at this point.

Table 1.—Analyses of Sand in Filters.

Mechanical Analyses— Mean Diameter.	Sample 1. Per Cent.	Sample 2. Per Cent.
Less than 0.13 m.m.	0.125	0.034
Between 0.13 and 0.27 m.m.	0.590	0.235
Between 0.27 and 1.00 m.m.	89.585	82.731
Between 1.00 and 5.00 m.m.	9.700	17.000
Over 5.00 m.m.	0.000	0.000
Total	100.000	100.000
Chemical Analysis to determine Carbonates—	Per cent.	Per Cent.
Lime (as carbonates)	0.42	0.36
Magnesia (as carbonates)	0.064	0.112
Total carbonates	0.484	0.472

The 6,800 cu. yd. of gravel and sand in the two filters were hauled about a mile from the river in wagons. The gravel was screened by hand, and the sand and gravel were washed in a flume, the same as gold was formerly washed in placer mining. A permanent incline, built in one corner of each filter, permitted the washed gravel and sand to be hauled into the filters in wagons, but it was found more advantageous and and equally satisfactory to dump the materials over the sides of the embankment and to distribute them by wheel barrows. The inclines are intended for use in removing the dirty sand scraped from the filters and in replacing clean sand, as it was impracticable to install mechanical sand handling apparatus.

The head-works of the supply system, including the filters, are operated by an attendant who has had long experience in the work of this character, and lives in a house provided, adjacent to the filters, by the city. The experienced attendant, at a salary somewhat in advance of the amount for which an inexperienced man could be secured is an unusual proceedure in the management of municipal works of the character and size of these, but the slight additional cost has already proved a profitable investment, as more uniform results from the filters and lower maintenance charges are thus assured.

The filters were placed in operation on Sept. 4, last, but the results of only a single series of tests to determine their bacteriological efficiency is available. Three samples of water taken from the inlet to the filters on Nov. 3 showed, after four days plating, 310, 320 and 335 colonies per cubic centimeter, respectively, while two samples taken from the effluent the same day developed only 38 and 47 colonies, after four days' plating. From this test the efficiency of the

filters was 86.79 per cent. In considering this efficiency it must be borne in mind that the bacterial content of the raw water is unusually low and that the water was practically free of sediment at the time. From Sept. 8 to Oct. 30, inclusive, a bacteriological analysis of the water delivered from the tap in the city was made each alternate day. An abstract of the results of these analyses is shown in the accompanying Table 2, from which the uniformly small number of bacteria is evident. The rather large number of bacteria from Sept. 8 to 16 inclusive, is considered to be due to the sediment and impurities in the pipe line and other parts of the new system.

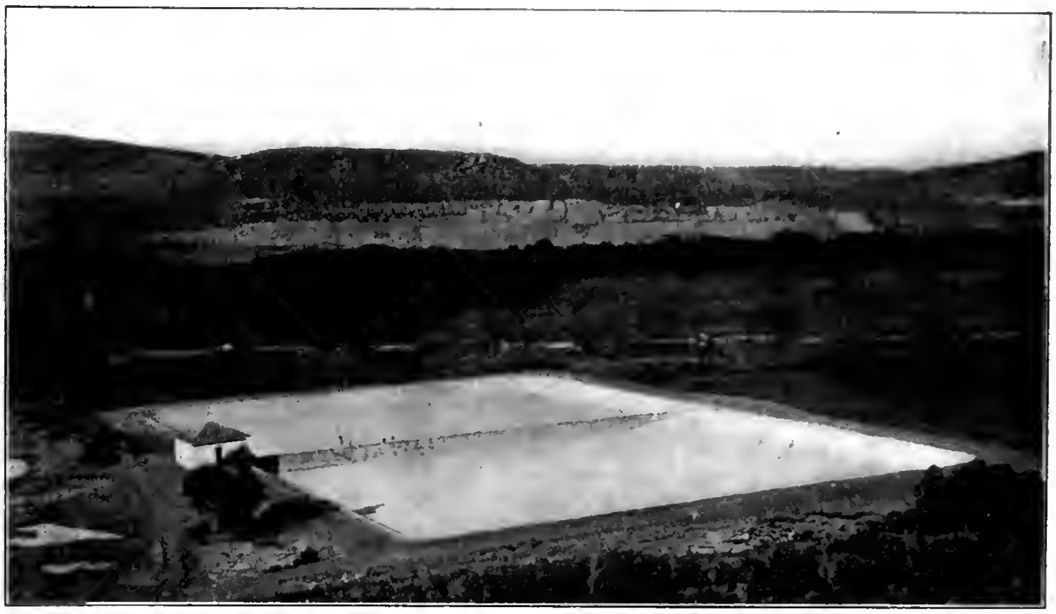
Pipe Line. The country drops away gradually towards Greeley from the filters, the latter being 340 ft. above the receiving and distribution reservoir, but the topography is rough and broken in many places. Considering this rough nature of the country, the pipe line has an exceptionally straight alignment and very satisfactory grades. In general, the line follows down the valley of the Cache La Poudre River. To within 8 miles of Greeley, it is up along the base of hills which skirt the right side of the valley, and then crosses the river and continues on the left side of the valley to Greeley. From the head-works to this crossing of the river, 8 miles from Greeley, the pipe line takes a nearly direct course and is laid on a remarkably smooth, even grade, with few special features, except the crossings of several streams and irrigation ditches, at which crossings cast-iron pipe was used. In crossing from the right to the left-hand side of the river valley, advantage was taken of a low divide on the left side of the valley which permitted the higher ground on that side to be reached. From this crossing to the receiving reservoir the country is particularly broken and hilly, but even under these adverse conditions a comparatively straight line, with few abrupt grades, was secured.

Automatic air valves are placed at summits in the line as required, and blow-off valves and connections at convenient low points. At a point about three miles from the receiving reservoir where the pipe rises to within 12 ft. of the hydraulic grade line a section of 20-in. pipe was placed on the line as a surge chamber.

Machine-banded wood-stave pipe was used for the entire line, except at stream crossings and the connections to the reservoirs and basins, for which crossings and connections cast-iron pipe was used. The staves were cut from Douglas fir, free from all defects that would impair their strength or water tightness, and were at least 1⅛ in. thick when put into the pipe. The edge of the staves were planed to true radial lines and then cut so as to form a double tongue and grooved joint between each two staves. The pipe is banded with double-galvanized wire, having a tensile strength of not less than 60,000 lb. and not more than 70,000 lb. The wire was spaced on the pipe according to the following formula: Spacing in inches $= 43000d^2 \div DH$, in which $d =$ diameter of the wire, $D =$ diameter of pipe and $H =$ head on the line in feet. The maximum spacing under any conditions was 3 in., and No. 4 Washburn & Moen's gauge wire was the smallest used.



The Two Slow-Sand Filters.

The pipe was made in 6 to 16 ft. lengths, over 50 per cent. of the lengths being at least 10 ft. long. The lengths were sawed square at the ends and turned smooth on the outside for a width of 4 in. from each end, to provide for the couplings used. These couplings are of wood-stave pipe, each 8 in. long, and are made just large enough to fit snugly over the turned ends of the pipe lengths. They are banded, with a factor of safety twice that of the pipe, with individual round wires not less than ½ in. in diameter, and of the same tensile strength as the banding of the pipe.

The lumber for the pipe was shipped to Greeley from the State of Washington in 2x4-in. and 2x6-in. sticks of varying lengths, the pipe being made in a factory built in connection with the work. This factory was erected close to the railroad in Greeley, in order to facilitate delivery of the pipe to the line. The factory building was a temporary frame structure, 40x125 ft. in plan. The equipment in it was all motor driven, thus greatly reducing the danger from fire. The staves were cut to shape from the square timbers by two planers, which also formed the tongues and grooves on the edges. The finished staves were placed in an accumulating machine, in which they were formed into the pipe lengths, and the ends of the lengths cut square and turned on the outside. The continuous bands were then wound on the lengths by another machine. The complete pipe lengths were finally delivered to a tank outside the building, in which they were dipped to receive an asphalt and tar coating, applied to protect the bands.

The location of the pipe line greatly simplified the delivery of the pipe from the factory to the trench, since the maximum haul from a railroad station at any point on the line was not over 2 miles. The pipes were hauled from the various railroad sidings to the work on ordinary four-wheel wagons, a single team being able to draw seven to nine 16-ft. sections at a load. Care was taken after the pipe left the factory to prevent injury to the coating, and after the pipe was in place all bands on which the coating had been injured were painted with asphalt and tar.

The pipe trench was made uniformly 30 in. wide and 4 ft. deep. With the exception of about 2,000 linear feet of rock work, the excavation was made with a Buckeye traction ditching machine. This machine worked to great advantage and greatly increased the speed and reduced the cost of the trenching. For nearly 7 miles from the intake of the pipe line, the trench was almost continuously in a stratum of gravel, containing numerous small boulders, with much of the gravel of a cementing nature. The balance of the trench, however, was mostly in hard clay, with the exception of about a mile of gravel and boulders near the receiving reservoir. The ditching machine dug from 600 to 1,000 ft. of trench in a 10-hr. day in the gravel and boulders, an average day's run in such materials being about 800 ft. In the clay and other soils the machine frequently finished 2,500 ft. of trench in a day, 1,600 ft. being normally dug under such conditions. Since the machine requires only four men to operate it, the cost of the trenching was very low. In fact, the contract price was only 9 cents per linear foot, but at least a fair profit was made at that very low price.

Receiving and Distributing Reservoir.—The 5,000,000-gal. receiving and distributing reservoir on the hill above the city is 224 ft. square in plan at the bottom, and is built in excavation and em-

bankments. The tops of the embankments are 16 ft. above the bottom of the reservoir and are 20 ft. wide on top, with 1½ to 1 slopes on both sides. The inner slopes of the embankments and the bottom of the reservoir are lined with 6 in. of concrete.

In order to exclude sunlight from the filtered water, and thus prevent growths of obnoxious algae in the reservoir, the latter was covered with a flat wooden roof carried by concrete columns. These columns are in regular transverse and longitudinal rows, spaced 14 ft. apart on centers in one direction and 18 ft. in the other. They are 18 in. square at the base, 12½ ft. high and 6 in. square at the top. Each column stands on a square pier, independent of the concrete lining of the bottom, and is reinforced with two vertical ½-in. Johnson corrugated bars. Although these columns have a comparatively small cross section, they were quite readily built by making the forms in two parts, an upper and a lower, and casting the lower 6 ft. of the columns before the top sections of the forms were placed.

The wooden roof has 6x6-in. timber girders, spaced 14 ft. apart on centers on the transverse rows of columns, with 2x8-in. joists, 4 ft. apart, in the opposite direction. The joists are braced together by a row of 2x4-in. bridging between each two girders. The flooring consists of 1x10-in. by 16-ft. roofing boards. The roof contains, alternately, one and two 30-in. by 16-ft. trapdoors in the 14x18-ft. bays.

This roof cost $6,000 complete, including the concrete columns. It is considered to be entirely satisfactory for the purpose, as the snowfall in the vicinity is relatively light, so no heavy live loads will be brought on it. As the maximum level in the reservoir is 1 ft. below the lowest part of the roof, and as no covering is to be placed over the roof, the lumber may also be expected to last a long time in the dry climate.

The additional receiving and distributing reservoir, which it is proposed to build when required, will be at one end of the present one, the two having a common end embankment. An 18x18-ft. concrete gate chamber, surmounted by a brick house, has been built in the incoming end of this embankment and is arranged with inlet and outlet connections for both reservoirs, so the future work will be greatly simplified. The 20-in. pipe line from the head works is laid longitudinally under this embankment, passing through the bottom of the gate chamber. Two tee connections are placed in the pipe line in the chamber, providing for an inlet and an outlet for each reservoir. Each of these inlets and outlets is fitted with a gate valve and the pipe line has a gate valve between the two tee connections, so water may be passed through either reservoir, or both reservoirs by-passed. The inlet to the reservoir delivers into a 2x3-ft. flume, 12 ft. long, which is suspended from the reservoir roof, close to the gate chamber. The outlet is connected to a sump in the bottom of the reservoir just outside the inner toe of the slope of the embankment. An overflow is provided so the maximum depth of water in the reservoir will be 12 ft. At this depth the water surface is 176 ft. above the central part of Greeley and produces 60 to 70 lb. pressure at the fire hydrants in the city.

The pipe line is connected in the gate chamber with a 20-in. waste pipe leading to an adjacent irrigating ditch, so it can be drained. An 8-in. connection to this waste pipe is also provided for each reservoir in the gate chamber. This connection ends in a sump in the bottom of the reservoir, so the reservoir may be drained. A standpipe, consisting of two sections of 20-in. cast-iron pipe, was placed on the pipe line near the gate chamber, in order to provide sufficient head to flush the reservoir when the latter is empty.

A 6-in. connection to the pipe line is made in the gate chamber and is carried into the reservoir, where it connects with three lines of 2-in. pipe extending across the reservoir with hose connections at suitable intervals.

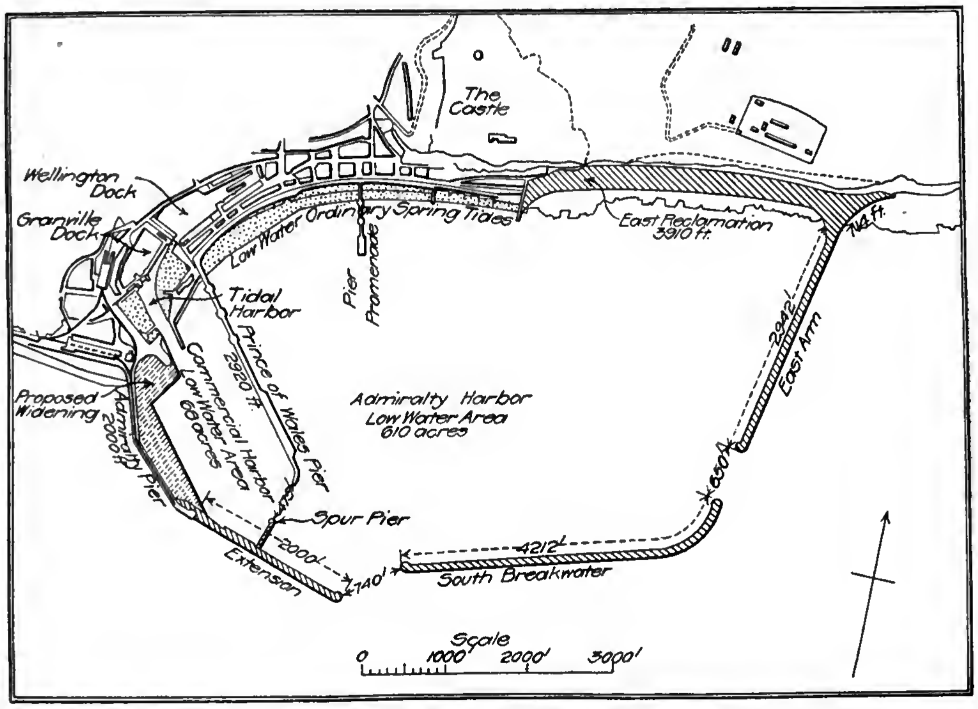
The new water supply system for Greeley, which has been described herewith, was designed by Mr. George G. Anderson, consulting civil and hydraulic engineer, of Colorado, and was built under his supervision by The Jacobson Bade Co., of Portland, Ore. The City Council of Greeley, to whom credit is largely due for the adoption of the various modern features of the system as suggested by the engineer, are as follows: Mr. F. J. Green, mayor, and Messrs. F. M. Barber, A. W. Jacobs, J. B. Phillips, C. H. Ward, D. H. Strohl and W. C. Wilson, of which Messrs. Wilson, Phillips and Ward were the water-works committee. The Pacific Coast Pipe Co., of Ballard, Wash., furnished the lumber and built the wood-stave pipe. The total cost of the entire system, including all construction, water-rights, rights-of-way, legal expenses and so forth, was between $360,000 and $365,000.

The Stadium in which the Olympic games will be held next year at the Franco-British Exhibition, London, is now under construction. It is oblong in plan, with straight sides and semi-circular ends, and measures 594x1,000 ft. over all. The arena besides the large turf-covered space for games, will contain a bicycle track 35 ft. wide, a running track 25 ft. wide, and a swimming tank 50x335 ft. The total capacity is about 75,000 persons. Seats are arranged in 32 tiers along the straight sides, while standing room arranged in 65 tiers is provided in the semi-circular ends. The inclined stringers supporting the tiers are of 15-in., 42-lb. I-beams, 20 ft. apart, and are carried by latticed-channel columns, braced longitudinally and transversely. The risers consist of channels fixed to the stringers by means of forged stools. The tiers are of reinforced concrete, averaging 2 in. thick, the steel consisting of indented bars 1-3 in. square, spaced 12 in. apart. Seats of wooden lath are to be fixed to the concrete. On the flat sides the seats are covered by a roof with a span of 61 ft. 8 in., having an overhang of 17 ft. 10 1-2 in. The roofing is of corrugated sheets. The space under the seats will be used for offices, restaurants, and like purposes. There is an open space 10 ft. wide in front of the seats from which numerous entrances are provided.

The Harbor Works at Dover, England.

By C. O. Burge, M. Inst. C. E.

A few months ago reference was made to these works in an article, more especially in connection with the proposed Channel Ferry, which, as was pointed out, is of special interest, as virtually making Dover a Continental as well as a British port. Atlantic passengers landing there will, when the ferry is established, be able to proceed without further change equally to any part of the Continent as well as Great Britain, and, vice versa, the same considerations applying to freight. In reference to the ferry, a deputation headed by Lord Weardale, the chairman of the ferry company, had an interview on Oct. 24 last with the president of the British Board of Trade, a Cabinet minister, who expressed the warm approval of the government



Harbor Works of Dover.

to the scheme, in preference to the rival one of the tunnel, now set aside. The deputation, besides the chairman, consisted of Sir C. Rivers Wilson, chairman of the Grand Trunk Ry., Canada; Admiral Sir Cyprian Bridge, Colonel Ivor Phillips and the Hon. George Peel. The French authorities were subsequently approached and also gave their approval of the scheme, which we may, therefore, hope to see put in hand at an early date. But apart from this, Dover as a present port of call for an increasing number of Atlantic liners claims our attention, while the British Admiralty have almost completed very large works, in order to make the port a naval base, and their operations are of considerable interest as affording one of the latest examples of harbor construction. Originally there was a commercial harbor only at the extreme west side of the port, consisting of a structure called the Admiralty pier, 2,000 ft. long, sheltering on the west the entrance to the tidal harbor, and the Wellington and Granville docks (see map), there being no shelter from south or east. This accommodated the cross channel traffic for years. So long ago, however, as the time of Sir Walter Raleigh the advantages of Dover as a naval port were recognized by that far-seeing statesman, though it was not till about two and a half centuries after his time, viz., in 1840, that steps were taken by the appointment of a commission to give effect to his ideas. The plans, subsequently improved, have now resulted in the following works:

The Prince of Wales Pier, 2,920 ft. long, dividing the commercial from the future Admi-

ralty harbor. This is roughly parallel to the original Admiralty pier and eastward of it and of the entrance to the tidal harbor; secondly, the extension of the latter pier, approximately easterly, to double its original length, making it 4,000 ft. long, and a northeasterly spur from it nearly midway on the extension, towards the head of the Prince of Wales pier, enclosing as the commercial harbor, 68 acres. The mouth of this is 475 ft. wide, facing nearly east, and is protected by the remainder of the Admiralty pier extension. The naval harbor, which has an area of 610 acres, lies to the eastward and is bounded on the west by the Prince of Wales pier and the extension, beyond the spur, of the addition to the original Admiralty pier; and on the east by a pier springing from the shore about 1½ miles east of the Prince of Wales pier and running south for 2,942 ft. The harbor is protected from the south by a breakwater extending from near the end of the pier just mentioned to within 740 ft. of the head, on the west, of the Admiralty pier extension. The gap between the east pier and the breakwater, 650 ft. wide, forms the eastern entrance. The breakwater is 4,212 ft. long and is so aligned as to finish westerly somewhat nearer to the shore than the pier head of the extension, so that the western 740-ft. entrance is partly sheltered from the west.

The government works also include a reclamation, 250 ft. wide, extending for 3,910 ft. from the foot of the cliffs on which the ancient Dover Castle stands, dominating, in the center, the whole harbor, to the root of the east pier. The depth of water at low water is only from 14 ft. to 19 ft. within 1,000 ft. from the coast line, increasing to from 30 to 40 ft. within a further belt of 1,000 ft., so it will be seen what increased accommodation will be afforded by the works outlined above. The "Dreadnought" and battleships of even greater size can be berthed alongside at almost any part of these piers. It is proposed also to connect the east pier, by rail through a tunnel under the cliff, with the railway, some distance inland, which connects Dover with Chatham and Woolwich, the great military and naval arsenals, so that the ships of war can thus be the more readily supplied with material. In conjunction with Sheerness, in the Thames estuary, Dover harbor will form an effective base for British naval operations in the North Sea.

As to the commercial harbor, the Admiralty have hitherto allowed the use, with some necessary interruptions, owing to construction operations, of the northeast side of the Prince of Wales pier for transatlantic service, but it is understood that, in order to make the division between the naval and commercial portion distinct, the transatlantic steamers will berth in the future within the latter division. Quite recently, we understand, an arrangement has been made between the railway company and the harbor board for the erection of a new station and wharf extension at the eastern side of the original Admiralty pier for the better accommodation of the ordinary cross-channel traffic, and though the site for the special landing device for the channel ferry is not yet definitely fixed, it must necessarily be close by.

A bill is to be promoted in the forthcoming session of the British Parliament to obtain powers to build two graving docks at Dover. The larger of the two will be about 950 ft. in length and 110 ft. wide, with a depth of 33 ft. It will be therefore capable of taking the largest ship in the British navy.

For ocean traffic to or from London and the ports of Northern Europe, Dover possesses, as a port of call, one great advantage in these days of record voyages. Such traffic must, in any case, pass close to the heads of the new harbor, so that there is no detour, while a call at Southampton entails a considerable one up Spithead and Southampton water at slow speed, while Plymouth Sound also requires a deviation from the direct route. A smaller advantage might be mentioned, that is, that Dover is only about one hour and a half by rail from London, and the terminus there is the most central in that city.

The harbor works, which have been mostly carried out by Messrs. S. Pearson & Son, are chiefly constructed of concrete blocks and granite. The Prince of Wales pier, however, for 1,200 ft. from the shore line, is of iron screw piles, the remainder of its full length of 2,920 ft. being of concrete. We are indebted to "Engineering" for the information on which the following outline of the concrete work is based: The bottom is of chalk and chalk marl, and marl and flint, very tenacious for anchorage purposes, and was considered, after levelling by divers, as a good foundation for the concrete blocks, which are 6 to 1, and range up to 40 tons in weight, the maximum size being 14 ft. by 11 ft. 6 in. by 6 ft. 6 in. high. The bond is formed by the variation in the size of the blocks. Above low water level the work is grouted with 2 to 1 cement mortar and is faced with granite, the face blocks being joggled with 4 to 1 concrete pins fitting into circular cavities in adjoining ones. The faces above low water have a slight batter, below they are stepped, the east pier being 40 ft. above and a maximum of 47 ft. below that level, the widths at top and bottom being 47.6 ft. and 54 ft. Along the seaward sides, there are aprons of 40-ton concrete blocks formed with a curve to dissipate the waves. The retaining wall for the reclamation is also of concrete blocks, and granite facing and coping, with filling in of chalk. The progress in the science of engineering construction is shown by the fact that 80 to 90 ft. per annum was the rate of progress in the original Admiralty pier finished in 1871, while the rate in the new harbor has ranged from 450 ft. to 1,500 ft. per annum.

Messrs. Coode, Son & Matthews, the head of which firm, Sir William Matthews, is at present President of the Institution of Civil Engineers, are the engineers, Mr. A. G. Vaughan-Lee, M. Inst. C. E., being in local charge. Major Sir H. Pilkington, R. E., K. C. B., represented the admiralty from 1895 to 1906.

Belt Conveyors are used extensively in the mine headworks of the New Kleinfontein Co., Transvaal. Of the seventeen belts used, the waste system contains five working in succession, the last two on top of a dump 130 ft. high. They handle an average of 1,358 tons of waste rock, sand and ashes per day and are 30 in. wide. The longest is 454 ft. between pulley centers. The second belt runs horizontally in a deep cut for 110 ft., then rises to the surface and continues at an inclination of 19½ deg. to the top of a light steel tower 60½ ft. high. Between this tower and a similar but higher one, 195 ft. distant, the third belt is carried by two inverted bow-string trusses. When the spoil had reached the top of the higher tower a fourth belt was installed and carried on a boom swung from a 60-ft. steel mast. The boom was originally 20 ft. long, but was extended in sections as the dump required, until it reached 140 ft. A fifth belt was then installed. It is carried on a 164-ft. double cantilever of two trusses, supported at the center on a turn-table carriage, which runs on a track 20 ft. from the edge of the dump. By this combination of a swinging boom and a traveling cantilever the discharge end moves in the arc of a circle through an angle of 170 deg., with the mast as the center. The belts are electrically driven, the speeds varying from 275 to 340 ft. per minute.

A Discussion of Smoke Prevention.

The Chamber of Commerce of Syracuse, N. Y., appointed a commitee some time ago to conduct an impartial investigation of the ways and means of abating smoke. This committee consisted of Dr. John A. Mathews, chairman, and Messrs. John H. Barr, W. H. Blauvelt, Carleton A. Chase, William Kent, J. D. Pennock and John E. Sweet. This committee has recently made a valuable report on the subject. It has reached the conclusion that in a place like Syracuse the abatement of smoke is desirable on aesthetic and economical grounds rather than one of public health. A study of what has been done elsewhere has also led the committee to the opinion that the passage of an ordinance, no matter how drastic, will not remedy the smoke evil. The enforcement of the ordinance must be rendered unnecessary by the hearty co-operation of steam users. When it can be demonstrated that economics may be effected by improved methods of firing, the enforcement of the ordinance becomes a voluntary act of enlightened self-interest on the part of the manufacturers.

Hand Firing.—The first remedy suggested by the committee for smoky chimneys is proper hand-firing, which seems to be given more attention in Great Britain and Europe than here. The committee points out that an inteligent fireman is worthy of good pay, for many ignorant and careless men doubtless waste more than their wages daily. This is especially true in small plants, and small plants preponderate in every city, and in these plants the possibility of great economics through the installation of mechanical stokers is small. Yet firemen can hardly be expected to know intuitively the chemistry of combustion, and certain it is that they have never been instructed in the fundamental principles of their occupation. Muscle and endurance have been considered the chief elements in the make-up of a fireman, and the arduous duties, too often performed in the dark, hot and ill-ventilated basements, have not attracted many men of intelligence.

The committee suggests that we might follow the example of the Prussian Government, which makes an annual appropriation for the purpose of giving instruction to firemen. Both academic instruction and practical demonstration is included in the course. In connection with Prussian government buildings and works, where stationary boilers are in use, it is required that: "As far as is in any way feasible, care should be taken that only such persons as have satisfactorily managed furnaces for a considerable time, shall be employed as independent firemen. If these persons have not gone through a satisfactory course at a fireman's school, opportunity should be given them as far as possible to attend one." Only when all methods of careful management and supervision of firemen and selection of fuel have failed to abate smoke, do the authorities recommend trying special appliances of a mechanical sort.

In St. Louis the Smoke Abatement Department causes to be posted in every boiler-room a list of "Directions for Firing." These are intended, primarily, for the users of low pressure steam heating plants. In such plants, especially, and in all other hand-firing boilers, efficiency is improved and smoke may be greatly lessened by close adherence to the following rules:

1—Fire frequently in small quantities and at regular intervals.

2—Break up lumps to fist size.

3—Carry a level surface over entire grate.

4—Avoid thin and bare spots on grate.

5—Keep the fires clean.

6—Fire one door at a time, and wait until that

fire is in good shape before charging the other door.

7—Leave furnace door slightly ajar for one minute after each firing.

These rules are good, if firemen will follow them, but the committee holds that a more certain solution of the problem in apartment houses and small buildings, where the demand for steam is too light to require the hot fire which is essential to perfect combustion and smokelessness, is the use of anthracite or smokeless coal or coke, or better still, to make use of central heating plants of sufficient capacity to ensure proper attention to economical methods of combustion and coal handling.

Prof. Goss, referring to the method of treating the small plant smoke nuisance, writes as follows: "The wisest and most effective course to follow with reference to such fires is to provide a satisfactory substitute and then abolish them. So far as such plants are now employed in the production of power, they can be rendered unnecessary through the cheaper and more effective distribution of electrical power. So far as steam from such boilers may at present be used for heating, they can be rendered of no effect through the supply of heat from a central station."

It seems to the committee that a combination of good hand firing and mechanical stoking will give real success, i. e., train men to operate scientifically the score or more of excellent mechanical devices now on the market. The committee believes the methods adopted by the Hamburg Smoke Abatement Society are so sound in principle, as to warrant publishing a description of their aims and work, by Mr. J. B. C. Kershaw, of London.

"The Hamburg Verein für Feuerungs-Betrieb und Rauchbekämpfung is, however, an entirely voluntary organization of steam-users, and its members are only bound by the common desire to obtain greater efficiency and less smoke from their steam-raising plants. The society has now (in 1906) been in existence three and a quarter years, and the following account of its organization, aims and work, is drawn from an explanatory pamphlet and from the two annual reports which have been issued since its inauguration in October, 1902.

"The work of the society is controlled by a committee of six to nine members, elected annually. The technical and scientific work is undertaken by the staff of experts retained by the society for this special work. At the date of the last report this staff consisted of a chief engineer, two assistant engineers, two instructors for firemen, and one clerk, while for special steam-raising and other trials, three additional assistants had also been employed. The chief engineer attends the committee meetings and takes part in the discussions relating to the work of the society. The funds of the society are drawn from three sources: From the annual subscription of its members; from payment for special work and reports for its members; from payments for outside work.

"The society is thus entirely self-supporting, and its success is dependent upon the value of the return it makes to its members for their contributions and fees. It is, therefore, gratifying to note that the membership shows steady growth. Starting with a few members in October, 1902, the register contained 60 firms and 249 boilers at the end of September, 1905, and fifteen months later these had increased to 115 firms and 351 boilers. The report for the year 1905 is not yet published, but I am informed by the chief engineer that the membership is now 150, with 420 boilers under their control.

"The objects of the society, as set forth in the rules, are the attainment of the highest possible efficiency from the heating and boiler plants of its members, with the least possible emission of smoke. To this end regular examination of these plants and of the methods of working them is undertaken by the expert staff of the society, and suggestions are made for improvements when such are required. The education and control of the firemen in the proper performance of their duties are also undertaken by the fireman-instructors on the staff of the society. Comparative tests of fuel, and tests of smoke-prevention and other appliances of a similar character, are also carried out by the expert staff, and the results are circulated amongst members of the society.

"Members of the society can demand that their boiler or heating-plant shall be regularly inspected, and that its working shall be tested and reported on at least three times a year. They have also the right to consult the chief engineer of the society regarding improvements and alterations in the design and working of their plant.

"They on their side are bound to allow the chief engineers and other members of his staff free access to their heating and boiler-plants at all times, and are bound to make the necessary provisions for conducting the tests. They are also required to carry out the suggestions made for improving the efficiency of the plant, especially as regards the abatement of smoke, and to submit to the chief engineer all plans for extension of the plant, or for change in the methods of work.

"Each boiler or heating-plant, when brought under the control of the expert staff of the society, is tested at the earliest possible date, and a written report upon the results of the examination is submitted to the owner. Should the firing have proved inefficient, one of the firemen instructors is sent to the works to give practical instruction to the firemen employed there, and tests of the plant are made at intervals until this fault is remedied. Defects in design are similarly dealt with.

"The annual subscription to the society for members without any boiler or heating-plant is 20 marks ($5.00). Members having boilers or furnaces which they desire to place under the control of the experts of the society, pay a further 20 marks annually for each boiler or furnace.

"The extra charges for tests and reports are based upon the time spent upon them and the number of experts employed. Engineers are charged for at the rate of 20 marks per day, and firemen-instructors at 5 marks per day. Special reports upon patented appliances are charged for at the customary rates; members receive a special discount of 30 per cent. on these, as compared with outsiders."

Steam Jets.—There are many forms of application of the steam jet to boilers. Sometimes the steam is applied below and sometimes above the grate. Below the grate the effect is perhaps slightly to increase the draft, but mainly to soften the clinkers. Above the grate the steam jet is essentially for the purpose of inducing a draft of air over the fire and to mix the air with the gases from the coal. The steam itself is not a source of any heat.

Many devices for smoke prevention which are based on the use of the steam jet are of little value, the committee says, and seem to be made only to sell. Others are carefully worked out in their details and are really of use, especially when properly applied to meet the special conditions, and when combined with a device for automatically adjusting the supply of air to the volume of gases produced. Based on the fact that the volume of gases is great immediately after fresh coal is charged and slowly falls off until the next firing, these devices open a damper above the fire immediately after the closing of the fire-door, and by a dash-pot arrangement this damper is slowly closed, thereby regulating the supply of air between the maximum and minimum amount needed.

A number of such devices are in successful use, and when properly applied and operated will prevent smoke. The cost of their installation is low compared with stokers, but they effect economy in coal consumption only to the extent to which they more perfectly burn the gases by the admission of neither too little nor too much air to meet the varying requirements of the fire.

Down-draft Furnace.—The principle ultilized in the operation of this furnace, according to the committee, is not unlike that of the under-feed stokers, inasmuch as the volatile hydrocarbons pass through the green fuel before reaching the combustion zone. The result is that the volatile gases are intimately mixed with the supply of air as they are distilled off and the conditions are favorable for complete combustion when these gases attain the ignition temperature.

The down-draft furnace, according to the committee, is effective in reduction of smoke when properly handled, and it is not difficult to secure very satisfactory results so far as smoke prevention is concerned. It has the advantage over mechanical stokers in small plants, since the relative economy of the down-draft furnace is substantially as high with a single boiler as with a large plant. The very complete combustion is favorable to good economy of fuel and the possibility of high temperature of the products of combustion may result in a very considerable increase in the effective capacity of the boiler. The down-draft furnace is usually hand-fired, though large plants are frequently fed by a so-called automatic gravity system.

This furnace is considered well adapted to single boilers or to plants too small to warrant the installation of automatic stokers. It may be expected to effectively reduce the smoke emitted from the stack under reasonably favorable conditions, and to do it economically. The down-draft furnace requires a good draft for the best results and is not so well adapted as certain forms of automatic stokers to plants which must be forced at times greatly in excess of normal capacity.

Mechanical Stokers.—The large number of mechanical stokers which have been developed may perhaps be conveniently divided into four types. First, the forwardly inclined grate, of which the Roney stoker is an example. Second, the V-shaped grate, of which the Murphy stoker is a representative. Third, the under-feed stoker. Fourth, the chain grate. There are a number of successful applications of the principles represented by all of these types, and there are records of very successful performances of installations of many variations of each type. While each has special features of excellence, yet some installations and conditions are better suited to one type and some to another, according to the committee, and it is of the greatest importance that in the selection of a stoker the owner should make sure that he has the type best suited to his conditions, and that the details of the particular apparatus are developed on sound mechanical lines and based on mature experience.

While it can hardly be called a mechanical stoker, the application of pulverized fuel, which has been made familiar by its extended use in cement burning, for example, has had some success in firing boilers. It can hardly be said, however, that this method has passed the experimental stage. It is claimed that combustion can always be maintained with entire absence of smoke and with great economy, in that only about the theoretical amount of air is required, and the coal is very thoroughly burned, the remaining ash being a fine, clean powder. The very high temperatures are attended with some practical difficulties, which perhaps may be overcome with more experience.

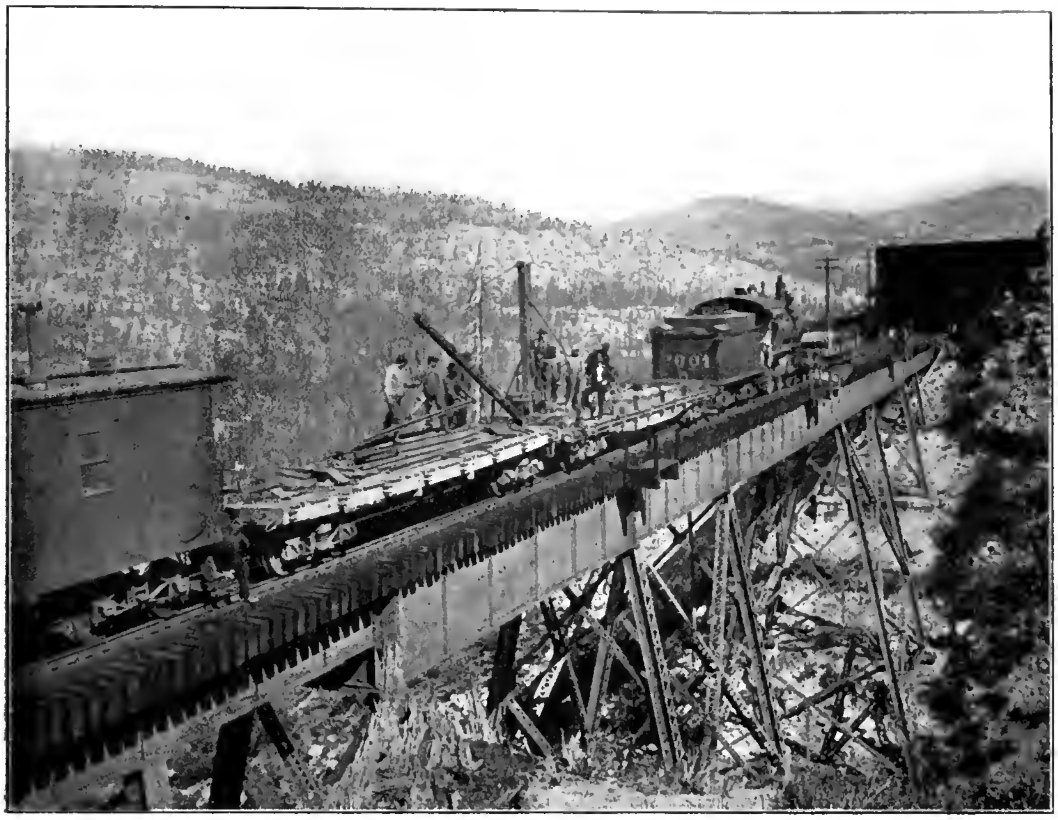
From the point of view of smoke prevention the automatic stoker is merely a means for feeding the coal uniformly into the fire, and therefore uniform production of hydrocarbon gases. Uniform conditions make it much easier to maintain perfect combustion of the hydrocarbons, and hence to prevent smoke, but very many installations of automatic stokers smoke very badly, often quite as badly as furnaces with poor hand-firing

In order to prevent smoke, it is quite as necessary to maintain the proper conditions for good combustion with stokers as without them. To insure these conditions, it is customary to build a fire-brick arch over the stoker, either in the shape of a Dutch oven in front of the boiler setting, which is usually the better plan where room permits, or the arch is thrown across the fire-box between the fire and the boiler. It is usually quite difficult to maintain an arch in this position, owing to the high temperature to which the brick work is subjected on both sides, and many devices have been put forward to maintain these arches. One type, which appears so far to be quite successful, consists of special shaped bricks, which are perforated, so that air from the outside is permitted to travel the whole length of the arch within the chambers or flues formed by these perforations, and is delivered, considerably heated, at the rear end of the arch, where it supplies the air for the final combustion of the gases. The heat absorbed by this air keeps the bricks sufficiently cool to prevent their destruction. The Dutch oven construction has the advantage that this arch is free to radiate its heat through the top, and it is, therefore, relatively easy to maintain.

Smokestack Cinders from locomotives are being used for making producer gas at two places in Germany by the railway administration. The plant at Koenigsberg has three generators and three double-acting gas engines, each of 180 h. p. capacity. The engines are direct connected to electric generators. The other plant has two gas generators and two single-acting gas engines, each of 90 h. p. Both plants are said to be giving satisfaction, the consumption of cinders being reported from 1.3 to 2.4 lbs. per horse power, varying with the load.

Southern Pacific Improvements.

Pending the final reports of the engineers who are at work upon plans for the electrification of its lines across the Sierras, the Southern Pacific Co. is carrying out improvements which will immediately have the effect of greatly bettering traffic conditions between Sacramento and Truckee. By these improvements the company has theoretically increased by 50 per cent. the efficiency of its freight service across the mountains by additional sidings, while the great freight terminal at Roseville, on which work is now well under way, will further facilitate the handling of transcontinental traffic.



Construction Train on the Cascades Bridge in California.

The Turntable at Roseville, Cal.

The immediate effect of these track extensions is shown in the fact that beginning last month the possible capacity of trains across the mountains has been increased from 30 to 45 cars, and the likelihood of another congestion of transcontinental freight, such as this year witnessed, would seem to be avoided.

The Southern Pacific line to Ogden is a single track, and traffic is carried on in both directions at once by the use of sidings or passing tracks. Between Roseville and Truckee there are 24 of these passing tracks, and the average length of each has been 1,950 feet. Half of the 24 are in the 46 miles of snow-sheds, which inclose the road between Blue Canyon and Truckee. The large consolidation locomotives have pulled freight trains whose greatest possible capacity, limited by the length of the sidings, was about 30 box and flat cars. To each of these sidings is being added some 700 ft. of new track, and with the 24 sidings, each 2,600 ft. long, it will be possible to dispatch freight trains hauled by three engines, of 45 cars each. With 45 cars moving in the same time that has been required to move two-thirds that number, it is patent how the saving in train movements will facilitate the handling of traffic.

What a great undertaking was the lengthening of these sidings is apparent when it is remembered that all of them are on a mountain division, where for the most part the roadbed is a shelf blasted out of the solid rock, and that half of the sidings lie in the snow sheds where every foot of extension means the reconstruction and widening of a corresponding length of shed.

The work, which is under the general supervision of District Engineer R. M. Drake, is being carried out by Assistant Resident Engineer E. C. Morrison. It began about the middle of July. The graders and track layers comprised 400 Greeks, 160 Hindus, and 50 Italians in addition to 50 or 60 native workmen. Three and a half miles of steel track was laid, and it was necessary to build 6,000 ft. of double snowshed at a cost of $16 a foot. Seven gangs of 20 carpenters each were employed on this new work and in making repairs in the sheds. Seven million feet of lumber, which came from mills along the line, was used.

Between Smart and Tunnel 13 the excavation

was in loose rock, which was removed without great difficulty, except at Crystal Lake, where the work was in granite, which yielded only to Burleigh drills and a great deal of Giant powder. At Summit, which is, as its name denotes, at the top of the mountains, an entirely new track 3,100 ft. in length has been put in to handle the traffic which always congests at such a point. Here, too, the 65-ft. steel turntable was taken out and replaced by an 80-ft. table, to accommodate the largest engines.

In addition to the sidings, a double track is being laid between Truckee and Winsted, a distance of 2.7 miles. A year ago work was begun on a double track between Elvas and Loomis, 21 miles apart. This is complete, except for the 6 miles between Roseville and Loomis.

The heaviest grade in the Sierras is 2.2 per cent. at a point between Summit and Truckee on the eastern slope. Between Blue Canyon and a point 6 miles west of Truckee there are 13 tunnels. Tunnel No. 6, at Summit, is 1,800 ft. in length.

There are five regular eastbound passenger trains each day and the same number of westbound passengers and often these run in two or three sections. Besides many extra passenger trains there are ten freight trains each way daily. On a road as busy as this the importance of the lengthening of the frequent sidings, or passing tracks, which all but equal a double track line, can hardly be over-estimated.

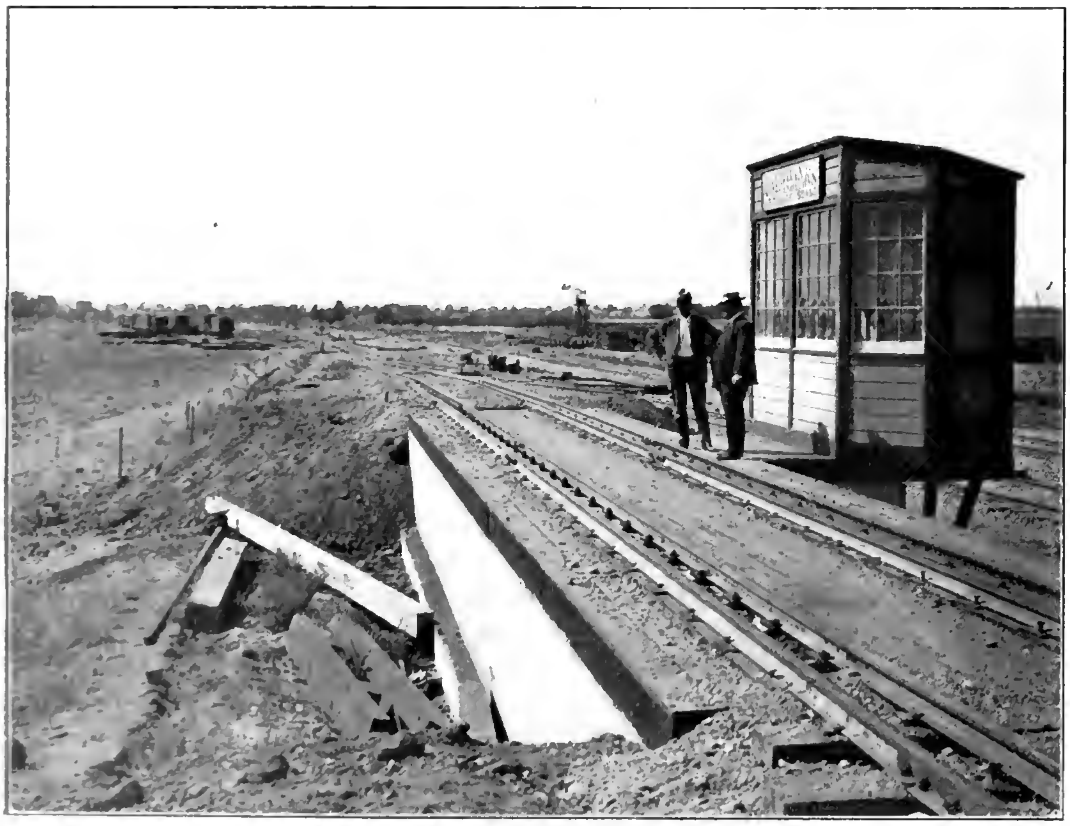
The great terminal being constructed at Roseville will affect the traffic of practically all the Pacific Coast. It will have a bearing upon the transcontinental traffic that goes across the Sierras to Ogden and the traffic that parallels the Pacific Ocean from Los Angeles to Portland. Roseville is the natural distributing point for freight in transit, for two reasons. The grades between that place and Sacramento are slight and the track straight, while from Roseville eastward the grades are heavy with many curves; consequently long trains can be brought to Roseville economically and broken up into smaller trains. In the second place, Roseville is the junction between the Ogden and the Shasta routes, and freight trains containing cars destined in both directions can be brought there to be broken up.

In the Roseville yard, which is 4 miles in length, the last of 50 miles of trackage is being laid. The receiving, departure and classification tracks, where the greatest volume of work will be done, comprise 27 miles. There are 3 miles of repair tracks and the remainder are storage and warehouse tracks and industry spurs.

The first of two roundhouses, which are to be identical, is completed. This roundhouse contains 32 stalls, divided into four compartments separated by brick firewalls and automatic fire doors.

The machine shop, where repairs will be made, is ready for its equipment. Engineers' quarters adjoin the roundhouses. Buildings yet to be completed are the car repair shop, two sandhouses, freight house, icing plant to accommodate 20 cars at a time, a commodious two-story clubhouse, two office buildings, an emergency hospital where a staff of nurses will be maintained, and a lumber shed. Large rest corrals for cattle in transit will be provided. The machine shops and the two large turntables will be operated by electricity.

Water Tank on Southern Pacific Line at Roseville, Cal.



The Hump in the Yards at Roseville, Cal.

There are two main receiving and departure yards, an eastbound and a westbound, each 3,000 ft. in length. Into these trains will run as they arrive. The road engine will then uncouple and go to the roundhouse and a switch engine will push the train up the gravity hump. On the hump each car as it rolls along is weighed automatically and the weight recorded. One by one the cars are uncoupled and run down by gravity into the classification yards, the switchmen being provided with switching lists. When a classification track is filled with cars bound for a certain destination a switch engine pushes the train around the hump, instead of over it, to a departure track, a road engine is brought out and the train dispatched. When these yards are in operation a great deal of eastbound freight will be brought by way of Stockton and will not go into Sacramento at all.

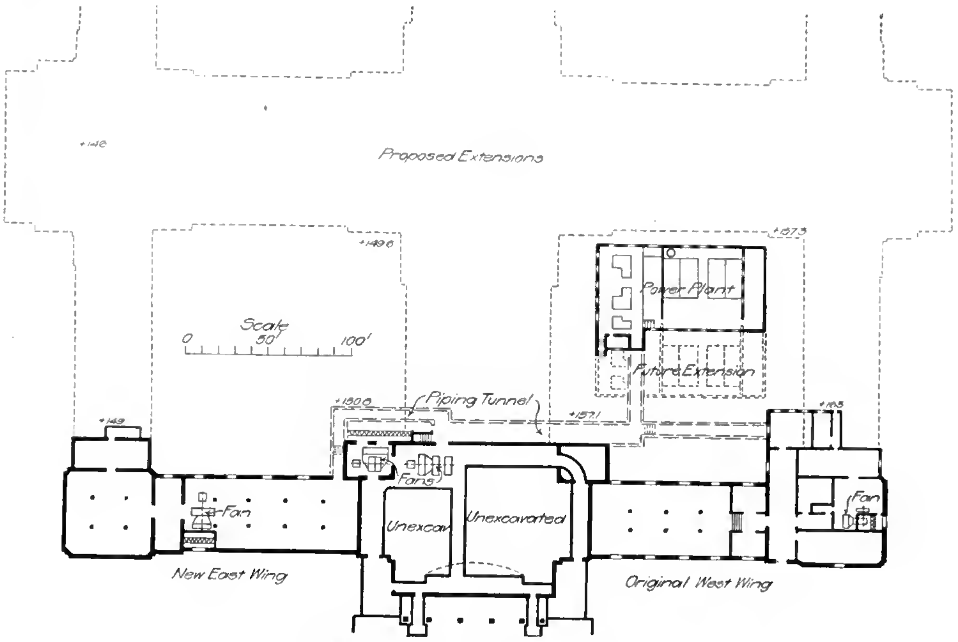
At the west end of the yards a subway will be built under the tracks so that vehicles and pedestrians may cross without danger from the many trains. A 350,000-gal. steel water tank, fed from a reservoir in the foothills above Rocklin, will supply the yards with water through 3 miles of 8-in. pipe. Oil will be supplied from a 55,000-bbl. tank and a 65,000-gal. auxiliary tank and will be conducted through steam-heated pipes. In addition to the water column near the handsome new depot, there will be six water columns and as many oil columns conveniently located about the yards. Locomotives will be able to take oil and water at the same time.

The work at Roseville, which is under the direction of Assistant Engineer Norman Collyer, was begun in June, 1906, and will be completed next summer.

Mechanical Plant of the Brooklyn Institute Building.—I.

The Brooklyn Institute of Arts and Sciences has recently completed large extensions of its buildings at Eastern Parkway and Washington Avenue, near Prospect Park, Brooklyn, in the course of enlarging its museums and broadening its educational scheme. The entire northerly facade, over 500 ft. in length, has been completed of a structure that was laid out a number of years ago on a magnificent plan, to be erected in sections as the development of the work requires, and to embrace eventually a building over 570 ft. square with four open interior courts. A third section of the structure has recently been completed, the addition of which to the two earlier sections of the building has necessitated an entire revision of the power and mechanical equipments in order to accommodate the extended and enlarged services of the building and has resulted in the installation of a new power plant in a separate building which will amply accommodate the division now completed and is capable of expansion to provide for a considerable portion of the extensions of the main building projected. The mechanical services have from the beginning been operated by an isolated plant of the institute and includes heating, mechanical ventilation and electric supply for lighting and power purposes, and at present require a power plant of 700 boiler horse power capacity. An interesting feature of the present power lay-out is that while the new power plant was laid out on a carefully studied plan with permanent construction and provision for considerable future extension, it is of a temporary nature as it cannot be extended sufficiently on the present plan to provide adequately for all the extensions to the main building that are contemplated. As it will, however, be a number of years before the main structure shall have been extended to a point beyond the capacity of the present power plant, it has been arranged to proceed with the power scheme as at present laid out, which will provide for the extensions to the main building until fully one-half completed, whereupon the power requirements of the ultimate extension shall become defined and a suitable location for the necessary enlargement of plant be provided.

The institute building as now completed with the new detached power house is shown in ground plan, together with an outline of the extensions proposed, in an accompanying drawing. The building is, as above stated, laid out on the plan of a large hollow square about 575 ft. square, with interconnecting interior wings that will form four open interior courts, about 150 ft. square. In one of these courts the power plant was located, that at the rear of the present westerly wing being selected as most convenient for piping and power connections to the older sections of the building. In this court, space is available for extension of the plant to double its present capacity without interfering with the main building or any of the extensions contemplated. The portion of the structure at present completed was erected in three sections, of which the wing to the west of the central portion, 48 ft. wide x 175 ft. long, was the first to be constructed, about 9 years ago, the central or entrance division, 114 x 124 ft. in size next, being completed in 1902, while the easterly wing, similar in size to the original west wing, is the portion just recently completed. The two side wings are three stories and basement in height with the exception of the new easterly wing which, owing to a depression of the grade at that point, has a sub-basement and cellar in addition, while the central portion has a large auditorium with gallery in the basement above which are two floors devoted to corridor purposes, and on the third floor level a magnificent sculpture hall connecting with the art galleries and rising to a dome surmounting this portion of the building. The west wing of the building is, with the exception of the third floor, devoted to museum purposes, with lecture rooms in the basement, while the new easterly wing provides laboratories, work and study rooms and upon the third floor an extension of the art gallery of the west wing. The building is of massive wall bearing construction with an exterior of stone and is of as nearly fire-proof construction as possible.



Plan of the Present Building of the Brooklyn Institute.

The main building has large quantities of side window and skylight glass exposure and is situated on an eminence in one of the highest sections of Brooklyn, so that its exposure is particularly severe, rendering the provisions for heating of special importance. The heating is accomplished throughout the entire building by direct radiation, the ventilation provided being independent of heating in all cases. The system is operated throughout at low pressure, using exhaust steam from the power plant and from the steam-using machinery in the various sections of the building and all radiation, both direct and the tempering coils of the ventilating systems, are fitted with pump condensation returns and vapor lines operated on the Paul system. All radiation is also fitted for automatic temperature control, utilizing the Johnson system with thermostats in the rooms heated governing motor valves on the radiation supply connections. The heating surfaces were proportioned with considerable care in all parts of the building, owing to the large interiors to be heated and the excessive exposure, and the radiator locations chosen are also the result of careful study. The total amount of direct radiation installed in the building is approximately 17,500 sq ft., which is exclusive of over 7,650 sq. ft. in the tempering coils of the ventilating system; of the direct radiation 5,200 sq ft. is in the original west wing, about 5,300 in the central wing and 7,000 sq. ft. in the new east wing which, although of the same size in plan as the original west wing, has a considerably greater exposure due to the addition of a sub-basement floor above ground level, permitted by the depression in the grade at that portion of the grounds.

A feature of the heating installation is the concealment of practically all radiators in exhibition rooms and in all public portions of the building; in all the basement and sub-basement work rooms and laboratories and in auxiliary rooms the radiators installed are exposed. Also all piping is concealed, the rising lines from the basement or cellar being run in chases in the wall construction with connections to the radiators behind partitions or under the floor construction. The radiators are all installed in the usual locations under window-sills to counteract window glass exposure and for the concealed units, recesses or pockets have in all cases been provided under the sills for grilled enclosures to contain them. In the auditorium, the few radiators which are installed under the four rear windows, are located in special pockets having intake openings near the floor line and delivery registers in the sills. The radiator units are installed in varying heights in accordance to the height of window sill and where low sills are encountered they are in some instances installed of the 3-column type, necessitating a recess 15 in. deep. The recesses are all lined with galvanized iron and asbestos board and are faced with removable brass band screens. A convenient feature of the enclosing screens is the provision of small door openings, about 12 in. square, at the lower side on either end for access to the motor valves on the radiators of the temperature regulation system, which obviates the necessity of removing the screens in their entirety whenever access to the valves is necessary.

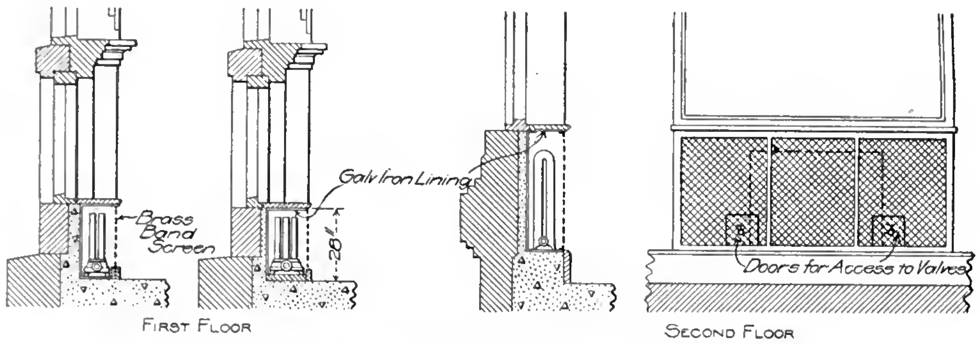
Large amounts of surface are provided in skylight coils to counteract the exposure of the large skylight areas, practically the entire third floor of the east and west wings being devoid of side window lighting, on account of a peculiar cornice construction of the exterior of the building, and thus fitted with skylighting for use as picture galleries and sculpture exhibition halls. These coils are of 1¼-in. iron pipe, surrounding the skylight and varying in surface for the different sizes of the skylights up to 720 sq. ft. of heating surface. In the roof of the central portion there are a number of small skylights surrounding the central dome, which are fitted with coils from 50 to 60 sq. ft. each. The coils are in all cases installed under the upper outside lights, being screened from the galleries by the lower ground glass lights, and under them are suspended drip pans of heavy galvanized iron construction with connections to sewer to dispose of any leakage of condensation that might occur.

Steam is supplied to the direct radiation in the building by a total of 46 riser lines, of which there are 14 in both the west wing and the central portion and 18 in the new east wing. These risers vary in size from 2-in. to 3-in. pipe, the 2-in. size predominating and of these eight are extended to the roof to supply skylight coils in both the easterly and westerly wings and 11 to the dome of the central portion for the same

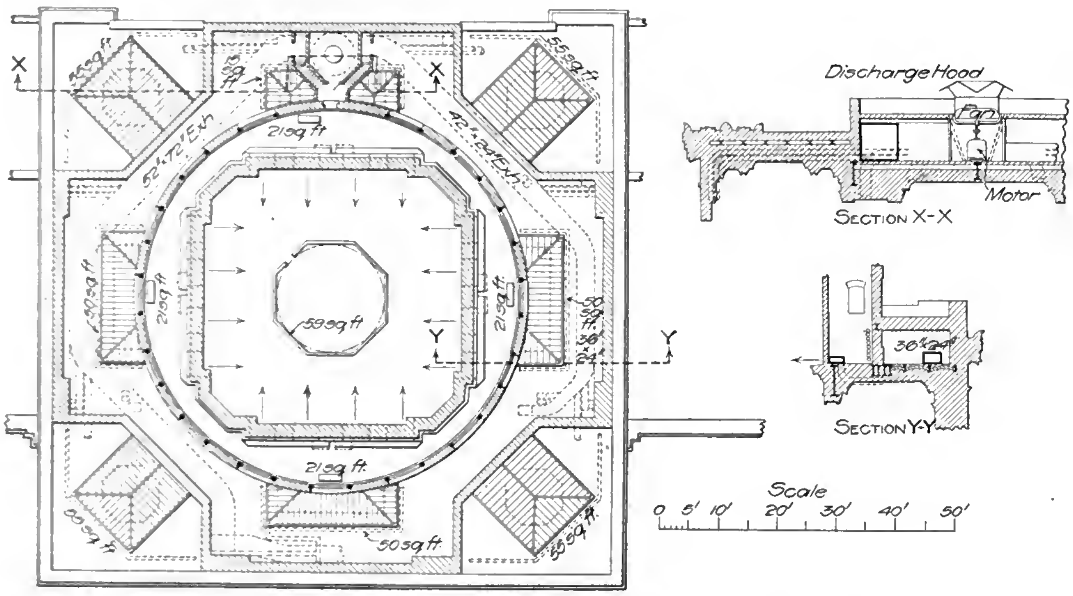
purpose. The risers connect in the basement or sub-basement into distributing mains, which, owing to the construction of the three different sections of the building at different times, are arranged in three different divisions. Those supplying the central portion and east wing originate in a low-pressure exhaust steam main from the power plant of the building, while that of the older west wing is an independent system supplied with exhaust steam from an engine driving the ventilating blower and from the steam pumps with make-up from the high pressure steam system when the exhaust is insufficient for proper heating. This latter main in the basement of the old west wing is an 8-in. line into which connects a 5-in. exhaust main from the original steam-using equipment in this portion and a 6-in. live steam make-up connection through a reducing valve, and which is carried around on the basement ceiling making connections with the riser lines and the tempering coil of the fresh air supply fan for that division of the building. The central portion of the building is supplied by a 10-in. and the east wing by an 8-in. low-pressure heating main, which in either case encircles its basement, reducing in size as connections are made to the risers. In addition to the riser lines, steam is supplied to the tempering coils of a ventilating blower in the east wing and to those of two blowers in the central portion. The 8-in. and 10-in. basement mains connect with a 12-in. low-pressure heating main that originates in the exhaust steam system of the power plant some distance away, the supply main being run from the power plant to the basement of the building through a piping and wiring tunnel underground at the rear. This heating main has in the power plant a live steam supplementary connection consisting of a 6x12-in. Kieley pressure reducing valve for adding live steam to the system when the exhaust supply is insufficient. The system in the west wing having no low-pressure connection from the main power plant, is supplied with high pressure for this equipment through a 7-in. main which is extended to the basement of this portion through another division of the piping tunnel connecting the power plant with the main building.

Condensation is returned from all radiation by direct pump returns, return pumps being installed in each of the three sections of the building heated, which deliver direct to a return tank in the power plant, air and vapor being removed from the radiation separately through connections to a Paul system. Return risers parallel all of the steam supply risers to the upper floors which are of unusually large sizes ranging from 1½ to 2½-in. pipe, and connect into condensation gathering mains in the basement or sub-basement that lead in each section of the building to a pair of return pumps. These pumps are 6x4x6-in. Deane duplex steam pumps operated under control of Kieley pump governors, receiving steam from high pressure lines carried over from the main power plant and exhausting through grease extractors into the local divisions of the low-pressure heating main. There are two of these pumps in both east and west wings so that the fan system tempering coils and the direct radiation may be operated separately if desired, while in the central portion of the building there are three such pumps, there being two fan systems with tempering coils here in addition to the direct radiation, and the connections to each group are so interconnected and by-passed, that either unit is interchangeable upon any of the services. The pumps of the central portion deliver through a 3½-in. connection and those of the east wing through a 2½-in. line into a common 4-in. condensation main that leads through the tunnel to a return tank in the power house, while the returns for the west wing are delivered through an independent 3-in. line which leads also to the return tank. The Paul system of returns consists of air lines paralleling the steam supply and return risers, which connect with air valves on all direct and indirect radiation and lead to exhausters which are in this plant located in the piping tunnel near the power plant. These air return mains are 1½-in. lines from the central portion and east wing and 1¼-in. from the west wing, and extend through the piping tunnels to a point opposite the power house where connection is made to an equipment of two Paul exhausters in duplicate, either one of which is of capacity sufficient to operate the entire building.

Power Plant:—The new temporary power house was, as above stated, located in what will be one of the open interior courts of the building, as extended, so that further building construction may be carried on in the process of extension entirely without interference to the power services. The court at the rear of the westerly wing of the structure was selected as the more convenient location for connection to present piping systems of the older sections of the building, in which projected court space, an available free area of about 150 ft. square was afforded. The plant was laid out for capacity of 700 boiler h.p., with building and equipment arranged for approximately doubling this initial capacity by extension to the front toward the present west wing, by means of which a duplicate equipment of that now in place may easily be installed, which will provide plant capacity sufficient for fully one-half of the extension of the museum building as projected. When it shall become desirable to increase the building beyond this extent in future years, it is the plan to provide a new power plant of the increased size necessary, in some other portion of the building or make such other provisions for the mechanical services of the building as may then become desirable, the present plant in the interior court space to be subsequently removed.



Typical Radiator Enclosures underneath Window Sills.



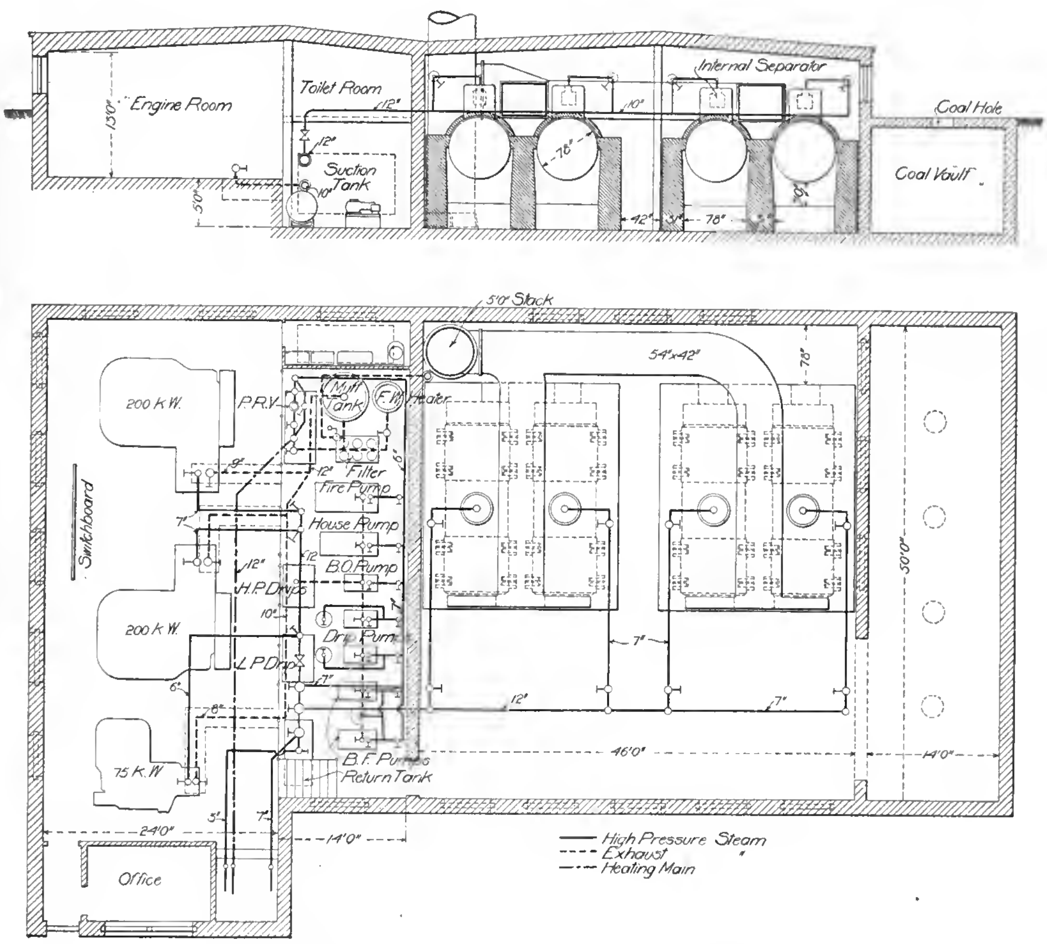
Arrangement of Radiation underneath Special Skylight at Base of Dome.

As the plant is destined to remain in service a number of years, before being supplanted by one of greater magnitude, the power house was designed of comparatively substantial construction of brick with concrete floors and roof, and is of ample size for convenient arrangement of apparatus. The exterior of the building is severely plain and for minimizing the interference with the lighting of the west wing of the museum from the rear, it is depressed, with its floor level from 6 to 12 ft. below grade, the roof of this structure rising, in fact, but about 10 ft. above grade. The structure as at present built is 88 ft. in length by 53 ft. wide, with a 14 x 24-ft. extension at one end over the piping tunnel that connects with the museum building. The extension proposed for doubling the capacity of the plant will increase the width to about 90 ft., so that the structure will be practically square, as indicated in the museum ground plan. The power house is divided into a 38-ft. engine and pump room and a 46-ft. boiler room, the engine room having a 13-ft. clear headroom, with floor depressed 6 ft. below grade, while the boiler room floor is depressed 5 ft. below this level, giving a clear headroom of 18 ft. A section of the engine room, 14 ft. in width, adjacent to the division wall, is depressed to the boiler room floor level to accommodate the extensive equipment of pumping units, filters, feed water heaters, etc. In the wing extension off the engine room there is an 8 x 13-ft. office for the chief engineer, with floor on level of the exterior grade, and in the opposite end of the engine room, over the pump floor, a 5 x 13-ft. toilet room. Ample lighting is afforded throughout by windows above grade near the roof line on all sides.

The question of fuel handling was simplified by the depression of the boiler room floor below grade, as an underground bunker communicating with the boiler room was thus made possible, onto the top of which coal wagons may be driven directly for dumping through coal holes in the

roof. Such a bunker, 14 x 50 ft. inside measurement, was constructed at the westerly end of the boiler room, with a reinforced concrete roof on level with grade at that point and containing four coal holes, through which fuel may be dumped. The bunker has a clear inside height of 11 ft., and about 30 ft. of it is used for coal, so that when filled to the roof it has a capacity for about 150 tons of coal. The coal is wheeled to the firing floor in barrows. Ashes are removed to the surface in barrows on a hydraulic elevator at the rear of the boiler room for hauling away in ash carts.

The boiler equipment consists of four 6½ x 18-ft. horizontal return tubular boilers, built by the Coatesville Boiler Works, which are conveniently arranged in two settings, with a 4½-ft. space between them, a 6½-ft. space at the rear and facing a 20-ft. firing floor. Each unit has 120 lap-welded tubes 3½ in. in diameter, giving a total heating surface of approximately 2,300 sq. ft., and has a 36-in. dome over the center sheet, in which is fitted a Potter mesh separator and superheater. Each boiler is set in a substantial brick setting, with flush cast-iron fronts, each shell being supported by eight lugs with roller bearings and each has grates 6½ ft. square, with fire brick bridge walls rising to within 14 in. of the bottom of the shell. The smoke connections consist of a 42 x 54-in. breeching over the middle of each double setting, connecting at the front with the smoke boxes of either boiler and at the rear into a cross breeching leading to the stack in the rear corner of the room. This stack is a 60-in. unlined stack of ⅜-in. wought iron plate and rises to a height of 125 ft. above the grade. Each flue connection has a hand-operated tight-closing damper, while in the main breeching connection to the stack there is a main damper operated by a Spencer automatic damper regulator for control of the draft by the steam pressure.



Present Power Plant of the Brooklyn Institute.

The boiler feed system consists of an equipment of two 7½ x 5 x 6-in. Deane duplex pumps, which draw from the condensation return tank or from the city water mains and deliver through a 3-in. boiler feed main over the boilers. The latter has a 2-in. branch to each boiler, which connects into a Fox water arch for preheating and has a check and two stop valves. The delivery from the pumps is connected to pass the feed first to a Ward feed water filter and then to a Berryman feed heater, which is inductively connected to the exhaust steam main of the plant. The delivery from two Nathan monitor injectors, which have been installed to supplement the feed pumps, is also conected to pass through the filter and heater, either of which may, however, be by-passed if desired. The Ward filter is of the usual cast-iron chamber type, having six cylinders, 12 in. in diameter by 7 ft. in height, which are fitted with cast-zinc bars and animal charcoal. The Berryman heater is a 39-in. by 13-ft. heater, containing 215 sq. ft. of surface made up of 2 in. seamless brass tubing. Each of the boiler shells has a 3-in. protected blow-off connection from the lower rear end, which leads out to the rear of the setting to a 3-in. blow-off main connecting with a 3 x 8-ft. cylindrical blow-off tank at the rear of the pump space in the engine room. This tank has a cooling coil, consisting of 60 lin. ft. of 3-in. brass pipes, for partially cooling the hot blow-off discharge, after which it is raised to the sewer by a 6 x 4 x 6-in. Deane blow-off pump. Vapor from this tank is removed by a 2½-in. connection to a 4-in. vapor riser that is carried up alongside of the smoke stack to a copper exhaust head.

The high-pressure steam piping of the plant is laid out with a simple boiler room header, delivering into a distributing header in the engine room, which is of extra heavy piping throughout and without duplication. The boiler branches are double valved 7-in. connections, which deliver into a 12-in. header arranged longitudinally over the center of the firing floor and below the level of the boiler branches to facilitate drainage. This line extends through the division wall to the 8-in. distributing header in the engine room, from which a 5-in. and two 7-in. branches are taken off to supply electrical generating units, a 7-in. line to supply a pump and auxiliary machinery header, and a 3-in. and a 7-in. branch to the museum building to supply steam using apparatus there located. The auxiliary header supplies the equipment of seven steam pumps and, in addition, has a 6-in. connection to the reducing valve, through which live steam is supplied to the low-pressure exhaust heating system for use when the exhaust supply is insufficient for adequate heating. The high-pressure lines in both the power plant and in the tunnel ways to the museum building are well drained through Nason traps, each drip point, as well as also the steam separators at the steam using units, being dripped separately through a trap with by-pass. These traps all deliver into a return line that connects with a 3 x 5-ft. drip tank, from which the condensation is returned to the boilers by a 6 x 4 x 6-in. Worthington duplex pump under control of a Kieley pump governor. The piping used is standard full-weight wrought-iron pipe, with extra heavy flange fittings and corrugated copper gaskets and fitted with extra heavy pattern gate valves having bronze discs and seats. All piping, both high and low pressure, is insulated with magnesia pipe covering, canvas jacketed, while the domes of the boilers, the feed water heater, filter and all tanks, separators, etc., are covered with magnesia blocks 1½ in. thick, protected with canvas jacketing. The smoke connections and also the stack up to the roof are covered with similar 1½-in. magnesia block, on wire netting over a 2-in. air space, finished with hard plaster and painted with black japan varnish.

The exhaust steam system which serves as the basis of the low-pressure heating supply, consists of a 12-in. header in the pump pit directly underneath the high pressure header which has a 6-in and two 9-in. connections from the generator engine and a 5-in. connection from an auxiliary line from the pumps. This header leads directly to a muffler tank at the southerly end of the pump pit and to an inductive connection to the feed water heater, with near the latter, a connection to a 10-in. back-pressure valve that delivers through a 10-in. riser to an exhaust head near the top of a smoke stack for atmospheric relief in case of excessive pressure on the exhaust system. The muffler tank is a Potter muffler and oil separator, 4 ft. in diameter by 6 ft. high, containing 24 galvanized wire discs and from this a 12-in. connection is extended to the Museum building for the low pressure heating supply. Near the muffler tank the live steam supplementary steam supply connection, above referred to, is made, there being in addition a by-pass around the reducing valve permitting of manual control if desired. Drainage from the exhaust system is effected by a low-pressure drip system, having connection to the cylinders of all engines and pumps, to the exhaust heads, the muffler tank and the feed heater, and delivering into a 3x5-ft. cylindrical drip tank. The low-pressure drip is like that from the high-pressure system, removed by a 6x4x6-in. Deane duplex pump under control of a Kieley pump governor, but being contaminated with lubricating oil, is wasted to the sewer. The drip connections from the engine and pump cylinders to this line are made separately through steam traps.

The electrical current supply for power and lighting purposes is generated by three direct connected units, two of 200-kw. capacity and one of 75-kw., which are conveniently and accessibly arranged with the smaller unit near the center of the projected building as shown in the ground plan. The engines are all simple high-speed machines built by the Harrisburg Foundry & Machine Works of Harrisburg, Pa., the larger

unit having 22x20-in. cylinders and a rating when operating at 200 r.p.m., with an initial steam pressure of 80 lb., of 320 h. p., while the smaller unit has a 15x14-in. cylinder and a rating, at 275 r. p. m., of 120 h.p. The engines have 7 and 5-in. steam supply connections respectively, each with a DeRycke steam separator, and each engine is fitted with a Manzel oil pump for cylinder lubrication. The engines are direct connected to Keystone multipolar direct-current compound-wound generators built by the Burke Electric Co., of Erie, Pa. These generators are wound for 125 volts and are designed to deliver full load for 24 hr. per day without undue heating.

The generator circuits are controlled upon a 3-panel switchboard of Tennessee marble in the engine room which contains the necessary indicating instruments, circuit breakers, rheostats and switches for the regulation and control of the generators, but the distribution at this plant is arranged in a novel manner, current being delivered from the generator panels, direct to independent distribution switchboards in each of the three sections of the museum building, from which the local feeder circuits are independently controlled. This arrangement effected a considerable simplification of the switchboard equipment for the plant and places the control of the distribution at points where it is most effective locally.

In the west wing of the museum building, the first section to be built, connection is made to a distribution switchboard which served the early lighting plant installed originally in the basement of that section; here the lighting circuits of this wing and an electric elevator are controlled upon the distribution originally laid out. In the central wing, there are two switchboards, one for general lighting distribution and the other lighting control for a large auditorium in the basement, the latter having a complete equipment for theatrical effects, including four dimmers. In the new easterly wing there has also been installed a similar switchboard for local lighting distribution. Each of the wings has a separate feeder connection from the power plant switchboard for direct supply and there are inter-connecting circuits between the local distribution boards in reserve for emergency purposes.

The power plant equipment and heating system of the institution were designed by Mr. Alfred R. Wolff, New York. The contractor for the power plant equipment was the E. Rutzler Co., New York. The electrical equipment and distribution system was laid out by Mr. Freemont Wilson, New York. Messrs. McKim, Mead and White, New York, are the architects for the buildings of the Institute.

(To be continued.)

Electric Heating is being tried in France for drying paper, in place of steam. Where the machine permits it is considered preferable to place the resistance, in which the heat is developed electrically, against the inside metal walls of the cylinders. A special advantage claimed for this system of heating is said to be the ease with which the temperature of the cylinder can be regulated while in operation. In the case of a machine producing 132 lbs. of paper per hour, which paper reaches the dryers with 50 per cent. of water to be evaporated, the electric heating must be capable of evaporating 66 lbs. of water per hour. In such a case, in order to avoid injuring the paper, progressive drying is recommended with three cylinders having a temperature of 158°, 212° and 250° Fahr., respectively. While such drying calls for a considerable amount of current, it is believed in the French plants where the experiments are being conducted that the cost is not excessive where current is furnished by hydro-electric plants belonging to the mills.

Coal Mining and Coke Making in the Trinidad, Colorado, District.

The chief known coal deposits of the Rocky Mountain region exist in a belt along the eastern base of the main range, extending southward from the Canadian boundary fully 1,000 miles, through Montana, Wyoming, Colorado and New Mexico. Although the coal-bearing formations are not continuous throughout this belt, which is of varying width in different sections, they have been found in about 60 per cent. of the distance. Another less extensive area of coal measures occurs along the western base of the Rocky Mountains in Wyoming, Utah, Colorado and New Mexico. Between the deposits on the eastern and those on the western slope are numerous isolated areas of coal measures, but in most of these the strata have been so much disturbed that coal-mining operations are carried on with difficulty. Coal from the various deposits has been mined extensively in southern and western Wyoming, in various parts of Colorado, in sections of Utah and in northern New Mexico for many years, but by far the greatest output has been maintained in Colorado. The principal fields of operation in that state are in the eastern and central part, near Denver, in the Walsenburg district, 175 miles to the south of Denver, in the Trinidad district at the extreme southern part of the state, and a few isolated sections along the western slope of the mountains. The coal fields of the Trinidad district were among the first in the state to be opened, and have been developed recently until the mining operations in that district are already the most extensive west of the Mississippi River, while new developments are being made continuously.

The portion of the Trinidad district that has been developed is approximately 20 miles wide, from the north to the south, and 45 miles wide, from the east to the west. The coal measures of this district are known to continue to the east from the present developments, but to the north they end in the measures of the Walsenburg district. The western boundary is quite well defined, however, by a practically continuous vertical strata of granite that extends almost exactly from north to south for several hundred miles close to the eastern base of the mountains. A range of mountains along the southern edge of the district interrupts the coal measures there, but extensive mining operations in coal of the same general characteristics are carried on in northern New Mexico, in the vicinity of Raton.

The workable coal measures in the Trinidad district are above an almost uniformly continuous stratum of bed rock, generally termed Trinidad sandstone, which lies at varying depths, depending on the topography of the country. Three principal series of coal veins, with an occasional occurrence of a fourth series, exist above this sandstone. First, is the Berwind series directly over the sandstone; then, about 60 ft. above that is the Hastings series and 30 ft. above the Hastings is a third rather indefinite series that is workable in a few localities. The fourth series, termed the Del Agua, is approximately 200 ft. above the third indefinite series, but thus far only a few mines are operated in it. The coal veins in all of these series frequently vary greatly in thickness and quality in short distances, so that mining operations are carried on with no small uncertainty. The veins that are worked range from 4 to 7 ft. in thickness, the average normal thickness being about 6 ft.

The average analysis of the coal produced in the district is about as follows: 60 per cent. of fixed carbon, 30 per cent. of volatile carbon and 10 per cent. of ash. First grade coke for blast furnaces and smelters can be produced readily from this coal, and as very little coking coal has been developed west of the Mississippi River, or, in fact, west of Pennsylvania and West Virginia, a great demand for coke for various purposes exists in the mining regions readily reached by rail from this district. The character of the coal and the demand for coke has consequently resulted in the installation in the Trinidad district of a large number of coke-oven plants of large magnitude. As only the slack and the smaller sizes of the run-of-mine coal are generally used in this district in making coke, the coal output is correspondingly large, the coal being of excellent quality for steam and commercial purposes.

The principal operator in the Trinidad district is the Colorado Fuel & Iron Co., which owns a large number of properties in Colorado, Wyoming, Utah and New Mexico. The largest single property of this company is the extensive steel works at Pueblo. These works embrace 6 blast furnaces and have a normal output of about 42,000 tons of steel rails each month, besides various other products. An outline of the plant, equipment and methods of Colorado Fuel & Iron Co. in the Trinidad district will serve, therefore, to show the character and extent of the workings in the latter.

Most of the recent developments of this company in the Trinidad district are along the southern division of the Colorado & Wyoming R. R. This division extends up the canyon of the Las Animas River from a connection with the main line of the Atchison, Topeka & Santa Fe R. R. at Jansen, 2 miles from Trinidad, to Tercio, a distance of 31 miles, and was built to develop the coal lands of the region through which it passes. The construction and maintenance of this railroad are at least equal to those of any of the trunk-line roads in the same region. The difference in elevation between Jansen and Tercio is about 1,831 ft., but the maximum grade in the first twelve miles of the railroad is 1 per cent. and in the remainder of the distance the maximum is 2 per cent. These comparatively moderate grades in the rough country traversed were obtained by following quite closely the course of the river. Since the balance of traffic is very largely down-hill toward Jansen, the existing grades introduce few operating difficulties.

In the construction of the railroad the embankments were made 16 ft. wide on top and the roadway in excavation 18 ft. wide in rock and 20 ft. in earth. The track has 75 lb. and 80 lb. rails laid on native and Texas pine ties. Tie plates are used on all curves, so the soft wood ties are quite satisfactory. Nine miles of the track from Jansen to a station called Segundo are ballasted with crushed stone; the yards and much of the balance of the line are ballasted with waste from the washeries at the coking plants and with coke braize. The curves above 4 degrees are spiraled, and maximum grades are compensated for curves.

The principal stream crossings are made on four single-span and two double-span steel bridges, carried by concrete abutments. The spans are each 105 ft. long, of the lattice truss type, and are designed according to Cooper's E 50 loading. The remaining stream crossings are small and are made on pile trestles or masonry culverts.

The principal yard on the line is at Segundo, where an eight-stall round house and a repair shop is maintained. This division of the Colorado & Wyoming R. R., together with other divisions, has three hundred 100,000-lb. capacity Ingolsby bottom-dump coal cars, which are used exclusively in the operations of the Colorado Fuel & Iron Co. Coal from the mines is hauled in these cars, while coke from the oven plants is hauled in regulation coke cars from various foreign lines.

The company operates five mines and two extensive coking plants on this division of the Colorado & Wyoming R. R. The first and larg-

est of these mines is at Primero, on a three-mile branch that leaves the main railroad just above Segundo. This mine has produced from 2,500 to 3,000 tons of coal a day and was at one time one of the heaviest producers west of Pennsylvania. In a straight line Primero is only a mile from Segundo, but it is 300 ft. above the latter, so the branch of the railroad had to swing around the hills to avoid exceeding the maximum grade of 2 per cent. Like practically all of the mines in the Trinidad district, the one at Primero is worked from a number of drift entries and slopes; in fact, none of the mines in the district are worked from shafts. Six working entries, with the necessary ventilating openings, are used in taking out coal. Two of these openings are on one side and the remainder on the opposite side of the canyon up which the railroad is built. The mining operations are carried on by the room and pillar system from side entries. The physical character of the coal is such that it can be removed readily with picks and shovels with comparatively little blasting. For this reason no under-cutting or other mining machines are employed. The same condition likewise exists throughout the district, all mining being done by hand.

The main entry of Primero is over 6,500 ft. long and has a maximum grade of 4 per cent. The mine cars are collected to it from the side entries by electric locomotives and are hauled from the inner end to the mouth of this entry in strings of 10 to 12 by a wire-rope haulage cable, operated by an Ottumwa steam hoisting engine, with two 72-in. drums. The cars in the other three hauling entries, adjacent to the main entry, are collected and delivered to a point on the side of the canyon near the mouth of the main entry by electric locomotives. The two entries on the opposite side of the canyon are also served by electric locomotives.

A 3,000-ton double tipple, built across the canyon and over the railroad tracks, is arranged so cars from either side of the canyon may be delivered to either of the two tipples, which are of the Mitchell automatic-dumping type. The cars are hauled from the mouth of the entries to the tipple by three 25-ton locomotives. The coal is passed over grizzlies as it falls through the tipples into the railroad cars below, in order to remove the slack and fine coal. The coal retained by the grizzlies is shipped for general consumption, while the remainder is taken to Segundo in standard-gauge cars to be used in making coke.

Power for operating the main haulage cable and the electric locomotives is supplied from a central station. This station contains six 100-h. p. return tubular boilers, which furnish steam to operate the haulage engine for the main entry and also to two 18 x 17-in. Ridgway engines, each belted to a 120-h.-p. Jeffrey generator. The water supply for the camp, in connection with the mine, is raised from the Las Animas River to a reservoir on a hill above the mine and camp by pumps at Segundo.

At Segundo two coal washers, each with a capacity of 1,200 to 1,500 tons a day, and 800 beehive coke ovens are in operation. The slack and fine coal from three separate mining operations, besides Primero, are delivered to these two washeries. One of these mines is an extensive new development on the main line of the Santa Fe R. R. at Morley, about 10 miles south of Trinidad, and the other two are on the Colorado & Wyoming R. R. adjacent to Segundo; one of these two is also a new mine at Frederick, a mile below Segundo, and the other is a smaller mine at Quinto, above Segundo. The slack and fine coal are delivered to Segundo from all four of these mines in the 100,000-lb. Ingolsby dump cars. The two washery buildings are located so their transverse center lines are coincident, but they are spaced apart to provide room for two standard-gauge tracks between them. Two 400-ton storage hoppers are placed under these tracks, adjacent to one end of the washeries, to receive the slack and coal from the various mines. A large coal crusher is also installed at one side of the tracks near the end of the hoppers, in order that run-of-mine coal may be reduced before being introduced to the washeries.

Washery, Coke Ovens and Railroad Yards at Segundo.

A flight conveyor in each of the track hoppers delivers to a bucket elevator extending to a bin in the top of one of the washeries. The arrangement of the both latter and, in fact, of all the washeries operated by the Colorado Fuel & Iron Co. in Trinidad district is the same. The elevator delivers to a bin, from which the coal passes through a toothed roll crusher, thence through shaking or rotary screens, in which it is sized. The different sizes pass through washing jigs that deliver the washed coal to a rotary screen, in which it is partially dried. This screen delivers in turn to a disintegrator, the output of the latter being raised to overhead storage bins with a capacity of 630 tons. The waste from the washing jigs is passed to settling basins and is finally drawn off into cars, in which it is hauled to the spoil bank.

The 800 ovens are in a group on the opposite side of the washery buildings from the track hoppers, with 100 ovens in a row and two rows to a battery. These ovens, and all of those in the district are of the bee-hive type, with an internal diameter of 13 ft. The washed coal is delivered from the storage bins at the washeries in 6-ton 4-wheel larry cars. These cars operate from the storage bins to the ovens on trestles and thence along the top of each pair of rows of the ovens on a track carried by I-beams, supported by masonry piers in the spaces between the ovens. The grade of the tracks on the trestles is such that the loaded cars go down to the ovens by gravity; the empty cars are pulled back up to storage bins by wire haulage cables, operated by steam-driven hoisting engines at the washeries. The larry cars, however, are being equipped to operate electrically, and trolley wires are being installed to deliver power to them.

As originally built all of the ovens in the various coking plants of the Colorado Fuel & Iron Co. were operated by hand. The pairs of rows of ovens were built with a wharf along each side of the row and with two standard-gauge railroad tracks between each two pairs of rows. Arrangements are now being made at Segundo and at several other coke-oven plants of the company to install electrically operated Covington machines for pulling coke from the ovens and loading it into cars. To this end the wharves are being lowered and a standard-gauge track laid on each of them at the new grade. The pulling-machine which serves one row of ovens will operate on the track close to that row and load coke into cars on the track across the space between the pairs of rows. The two tracks in each space will be connected by cross-overs at intervals, in order that the machines on the adjacent tracks may operate without interference. The only changes in the ovens thus required by the installation of the pulling machines is the widening of the oven doors from the old standard of 34 in. to 48 in. This change increases the capacity of the machines from 20 to 40 ovens in 24 hr. with 72-hr. coke, the corresponding capacities being even greater with the 48-hr. coke, which is produced in most of the coke-oven plants of this company.

A central station supplies power to operate the engines of the washeries and for the various other equipment at Segundo. The boiler room of this station contains ten 100-h.-p. return tubular boilers, which are equipped with fans for producing induced draft, so they may be fired with coke braize mixed with fine coal. The fuel is delivered to the boiler house in cars and is raised to overhead storage bins by bucket elevators. From these bins it flows to the firing floor by gravity and is fed by hand. The ashes are carried by a conveyor from the boilers to a storage bin over the track along the building. A 150-kw. 250-volt Thompson-Ryan generator, direct connected to a 240-h.-p. McEwen engine, has been installed to supply power to operate the larry cars and coke-pulling machines. Until all the power produced by this unit is required at Segundo for these purposes it will be transmitted to the mine at Frederick to operate the electric locomotives which are to be installed there to collect the mine cars and deliver them to the tipple at the railroad. As soon as more power is required at Segundo another generator similar to the one now in service will be installed.

The water supply for both Segundo and Primero is obtained from the Las Animas River. A pumping station on the bank of the river at the former contains two 500-gal. Jeansville compound duplex pumps, supplied with steam by two 100-h.-p. boilers. One of these pumps delivers against a head of 175 lb. to an 8-in. main extending to a 50 x 70 x 12-ft. reservoir at Primero, and the other delivers through an 8-in. main to a reservoir of the same size on the hill above Segundo. The discharges of the two pumps are cross-connected, so either pump may deliver to either reservoir. The water is piped from the reservoirs to all parts of the adjacent camps, so an ample supply for general use, do-

mestic consumption and fire protection is available.

The next operation of importance on the Colorado & Wyoming R. R. is at the present terminus of the latter at Tercio, where a large output of coal is maintained, two washeries are erected and 600 coke ovens have been installed. The coal veins at this point are inclined 40 to 60 degrees from the horizontal, so the coal is mined from them in a manner different than that followed in the balance of the operations of the company, where the coal is in nearly horizontal veins. Three entries adjacent to the washeries are at present in service, and a fourth is being opened across the canyon in which the washeries and coke ovens are situated. The adjacent entries are 350 ft. apart, and advantage is taken of the inclination of the coal veins by driving branches from the main entries on the upper side only. The coal can thus be delivered by gravity from the working face directly into cars on a track in the main entry, and in some instances it is delivered from an upper to a lower entry in this manner to reduce haulage. Where necessary, gates are built over the lower ends of the side entries to retain the coal until it can be delivered to the cars.

A tipple has been extended across the canyon, in order that coal may be delivered to cars on the railroad tracks, or to the washeries from the entries on both sides. The coal from the entries on the side adjacent to the washeries is passed through a tipple at the washeries; the coal retained by the grizzlies in this tipple goes into railroad cars, and the balance is delivered directly into storage bins in the washeries. The arrangement and equipment of the washeries is the same as those of Segundo. The 600 coke ovens are in four rows adjacent to the washeries. Washed slack and coal is delivered to them in larry cars operated by gravity in a manner similar to that followed at Segundo. Arrangements are being made, however, to operate these cars electrically and also to install four Covington coke-pulling machines in connection with the ovens.

New power equipment, consisting of a 150-kw. 440-volt alternating-current General Electric generator and a 150-kw. 220-volt direct-current General Electric generator, each of which is direct-connected to a 250-h.-p. high-speed Chuse engine. The 220-volt unit will supply power to operate the larry cars and coke-pulling machines at Tercio. The mine cars, which are now hauled entirely by mules, will be collected and delivered to the mouth of the entries by electric locomotives and then operated on inclines, leading down to the tipple and washeries by wire-rope haulage on electrically-driven hoists. The output of the 440-volt unit will be transmitted to a new mine at Cornell, two miles beyond the present end of the railroad, where it will be utilized by electric hoists and electric locomotives. Steam for the various units in the power station and washeries is furnished by six 100-h.-p. return tubular boilers.

The water supply for Tercio is obtained from a 900,000-gal. storage reservoir, which is supplied from a mountain stream by gravity. Another reservoir site in an adjacent valley will render available a storage capacity of 70,000,000 gal. of water by constructing a dam about 1,000 ft. long and with a maximum height of 67 ft. The construction of this dam will insure an ample supply of water for the present and subsequent developments of the company along the Colorado & Wyoming R. R. Since the average rainfall in the Trinidad district is about 13 in., and as practically all of the normal flow of the streams in this region have been appropriated for irrigation or other purposes, a good water supply is very valuable and is difficult to secure.

The other operations of the Colorado Fuel & Iron Co. in the Trinidad district are all adjacent to Trinidad. One of the oldest mines is at Starkville, on the main line of the Atchison, Topeka & Santa Fe R. R., five miles south of Trinidad. This mine was opened in 1865 and was operated for years by the railroad company. The slack and fine coal are now passed through a standard washery and utilized in 200 coke ovens adjacent to the mines, while the balance of the output of the latter is delivered to the railroad company. The workings of this mine and of one at Engleville, which adjoins it, underlie an area of about 10 square miles and are believed to be the most extensive west of Pennsylvania. One air course, 7½ miles in length, is in service, and the main hauling entry is 4½ miles long. The mine cars are collected by electric locomotives and delivered to the mouth of the entries by them or by rope haulage. A new entry, 10,200 ft. long and with a maximum grade of 4 per cent., which has recently been opened, will be operated by a continuous ⅞-in. rope haul driven by an Ottumwa hoisting engine, with 84-in. drums.

The electric locomotives are supplied with power by two 120-kw. Jeffry generators, each direct connected to a 200-h.-p. Ridgway engine. Coke-pulling machines are to be installed at the ovens of this plant and will also be supplied with power by these units. Steam for the engines of the electrical units, the haulage engine and the engine in the washery is supplied by five 100-h.-p. and three 125-h.-p. return tubular boilers.

A new mine that is being developed at Morley, about 6 miles south of Starkville, is indicative of the class of equipment that is being installed in the new developments in the Trinidad district. This development at present consists of an entry on one side and two entries on the opposite side of a narrow canyon, in which the main-line tracks of the Atchison, Topeka & Santa Fe R. R. are laid. A tipple has been erected across the canyon and the railroad tracks, in order that coal may be delivered easily from entries on either side. As one of the entries is on a slope, the mine cars will be hauled in this entry by a steam-driven rope haulage system. In the other entries and on the inside 10-ton Westinghouse electric locomotives will be used for hauling cars.

Two 150-kw. 250-volt direct-current General Electric generators, each direct connected to a 200-h.-p. Chuse engine, are to be installed to furnish power for the locomotives. Four 100-h.-p. return tubular boilers have been installed to furnish steam, and additional boilers will be provided as needed.

The houses for the miners employed in this development are all built of concrete blocks and have stone foundations. Water for domestic consumption and for the power station is obtained by a gravity supply line, 2½ miles long, which terminates in a storage reservoir.

The oldest coke oven plant in the Trinidad district is at El Moro, just north of Trinidad, where 240 ovens have been erected, and 200 more ovens are under construction. The new ovens are to be equipped with electrically operated coke-pulling machines. The slack and fine coal utilized in these ovens is obtained from the mine at Engleville, which is five miles distant. This mine was also one of the first to be worked in the district and is very extensive, having one main haulage entry 9,000 ft. in length and a second haulage entry 6,000 ft. long. Rope haulage systems are operated in both of these entries, one system in connection with an Ottumwa hoisting engine and the other with a Jackson hoisting engine.

Washery and Tipple at Sopris.

The entire output of a mine at Sopris, four miles southwest of Trinidad, is used in making coke for the steel works at Pueblo, as the coal obtained from this mine is specially adapted for such purposes. The Sopris development, which has been worked for many years, has 276 beehive coke ovens operated in connection with it. The mine cars are drawn to the mouth of the main entry by a rope-haulage system, operated by a Bullock hoisting engine; and thence three-quarters of a mile to a tipple at the washery operated in connection with the coke ovens by a second haulage system operated by an Ottumwa engine. The waste from the washeries is conveyed across a canyon to a spoil bank by an aerial tramway having a 1,600-ft. span.

The principal remaining operation of the Colorado Fuel & Iron Co. in the Trinidad district is at Berwind and Tabasco, 17 miles northwest of Trinidad. Coal is mined extensively at Berwind, and the slack and fine coal delivered to a coke oven plant at Tabasco, which is 1½ miles from the mines. The latter is operated with electric locomotives for collecting cars and with a rope haulage system in the entry. A power station containing six 100-h.-p. boilers and three 120-kw. Jeffrey generators, each belted to a McEwen engine, is installed at this mine.

A washery with a capacity of 1,000 tons in 10 hr. is operated in connection with the coke oven

plant at Tabasco. This plant contains 320 ovens, which have been equipped with electrically operated coke-pulling machines. The larry cars delivering coal from the washery to the ovens are operated by rope haulage system.

The difficulty of obtaining water in this region is illustrated in the case of the supply for Berwind and Tabasco. Water has to be obtained from an abandoned mine 12 miles distant. It is pumped that distance through a 10-in. pipe line and against a head of 250 lb. into a storage reservoir at each of the towns.

Camps or towns of unusually good character have been built and are well maintained by the company in connection with each of the developments which have been mentioned. This has been done, notwithstanding the fact that building materials are very expensive in the practically barren country in which the district is located, because experience has shown that laborers of the class available for work in the mines will not provide even reasonably decent quarters if left to themselves. In the older camps the houses are generally frame on stone foundations, but they are built along regular streets and are kept in good condition. The concrete block houses in Morley are an example of more recent construction. Water is piped to all parts of each town, and connections are provided for domestic service, with hydrants for fire protection. Good schools are maintained in each community and the general welfare of the inhabitants is otherwise well cared for. A large general store is operated in each town by a subsidiary organization of the Colorado Fuel & Iron Co., the prices charged in the stores being uniformly reasonable for the isolated district in which the latter are situated.

Mr. E. H. Weitzel, as chief engineer of the fuel department of the Colorado Fuel & Iron Co., has direction of the construction and maintenance of the coal mines and coke plants of the company. The construction and maintenance of the Colorado & Wyoming R. R. and of the various water supply systems of the company are under the supervision of Mr. R. M. Hosea, chief engineer.

A GYROSCOPE FOR STEADYING SHIPS was given a public test last month off the river Tyne on the "Seebar," formerly a first-class German torpedo boat, measuring 116 ft. in length, 11.7 ft. beam, with a displacement of 56.2 tons. The apparatus consists of a heavy fly-wheel rotating about an axis, and carried by a frame which can oscillate about a horizontal axis, the oscillating motion of the frame being checked by brakes. The wheel is one meter in diameter, weighs 1,106 lb. and makes 1,600 r.p.m. and is steam driven. The periphery is provided with blades and works like a turbine, the wheel being enclosed in a casing. In the tests with the gyroscope out of action the roll was about 14 deg., according to "The Engineer," London, while the boat was kept steady with the machine acting.

The Woodbury Viaduct.

The double-track viaduct of the Erie & Jersey R. R. at Woodbury, N. Y., crosses Bonney Brook at a height of about 72 ft. and is 590 ft. long between face walls of approaches. It is made with plate girder spans, from 40 to 82½ ft. long, supported on two 40-ft. single towers, one 80-ft. double tower and two single bents. The axle is partly on a tangent and partly on a 2-deg. curve, and the location and design were made difficult by the crossing of the contours at an acute angle and by the necessity for clearance of the proposed highway and of the existing track and a future track of the Newburgh Short Line, which intersects the axis of the viaduct at such an acute angle that neither track could be located entirely under one span, and provision was necessary for each track to pass between the vertical columns of a transverse bent, thus necessitating unusual clearance and special transverse and sway-bracing in the viaduct.

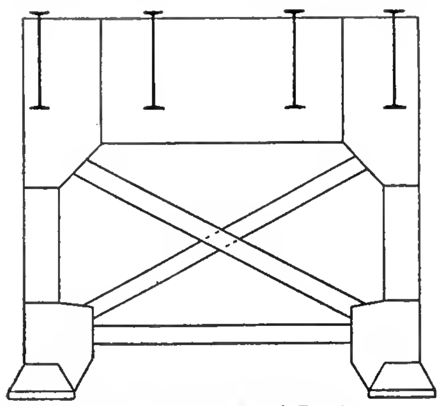


Diagram of Braced Bent.

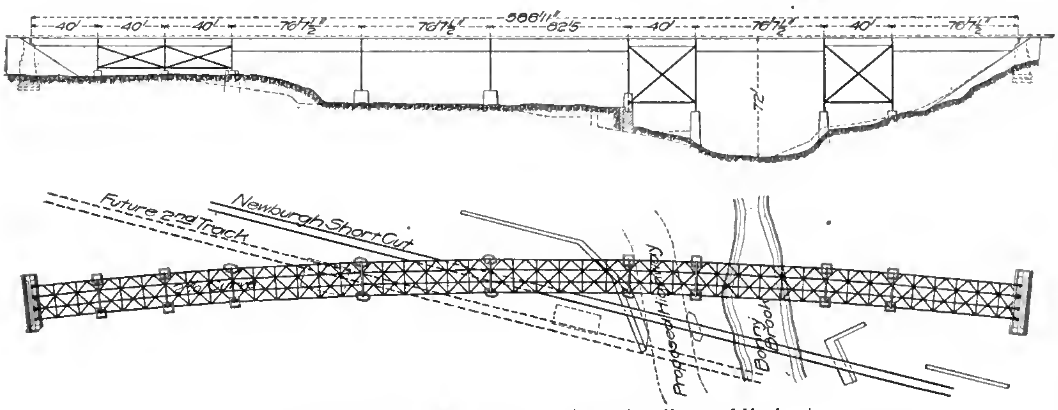
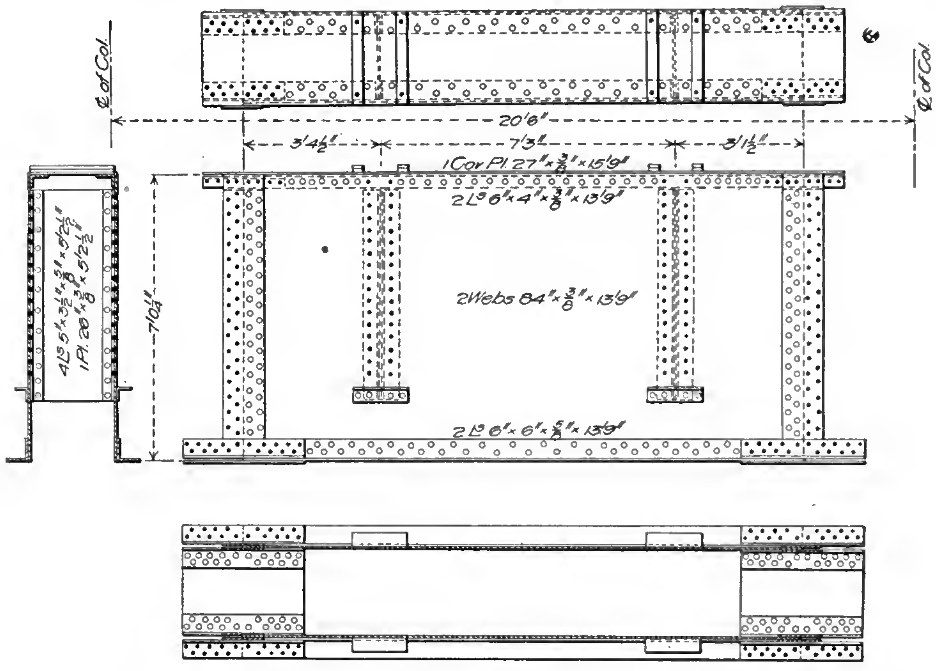


Part Plan and Elevation of the Woodbury Viaduct.

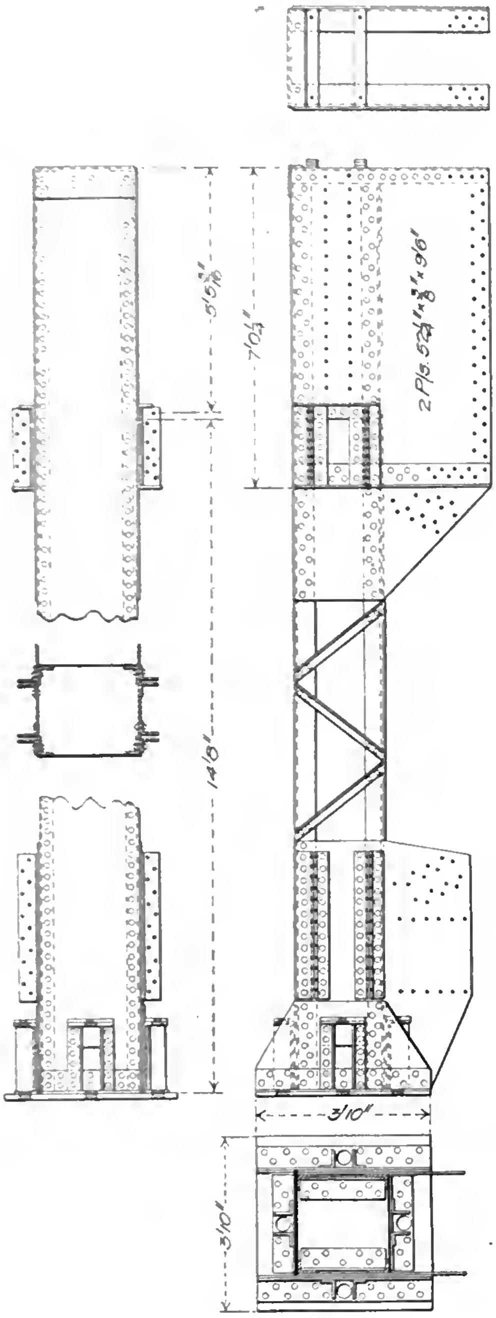
The sub-structure consists of concrete abutments carried down to a considerable depth through embankment to the solid earth, and of separate piers under the column bents. The latter are rectangular in cross section, except where, in order to provide clearance for the railroad tracks and highway, they are made oblique to the axis of the viaduct and are six-sided. There are four lines of longitudinal girders, 6 ft. 6 in., 7 ft. 3 in. and 6 ft. 6 in. apart, which received the ties on their top flanges, and are braced together in the usual way with transverse vertical frames and lateral angles connecting all four lines. The 40-ft. girders are 5½ ft. deep and are fixed at both ends; all remaining girders have a uniform depth of 9 ft. and are fixed at both ends, except for sliding bearings at two expansion joints on opposite sides of the brook.

The most interesting features of construction are in the design of single bents 5 and 6, though which there is clearance for the Short Line trains. The concrete pedestals for each column are built up to a height of about 10 ft. above the base of rail, so as to afford mass and protection against impact, and are seated on wide offset footings, which give them stability. The columns, nearly 31 ft. long over all, are, like all other columns in the viaduct, 20 ft. 6 in. apart, transversely on centers, and extend to the tops of the transverse girders, which in this case are 10 ft. deep. Below the transverse girder and connected to its bottom flange there is a portal bracing nearly 6 ft. deep, substantially equivalent to a transverse lattice girder with curved knee braces at each end.

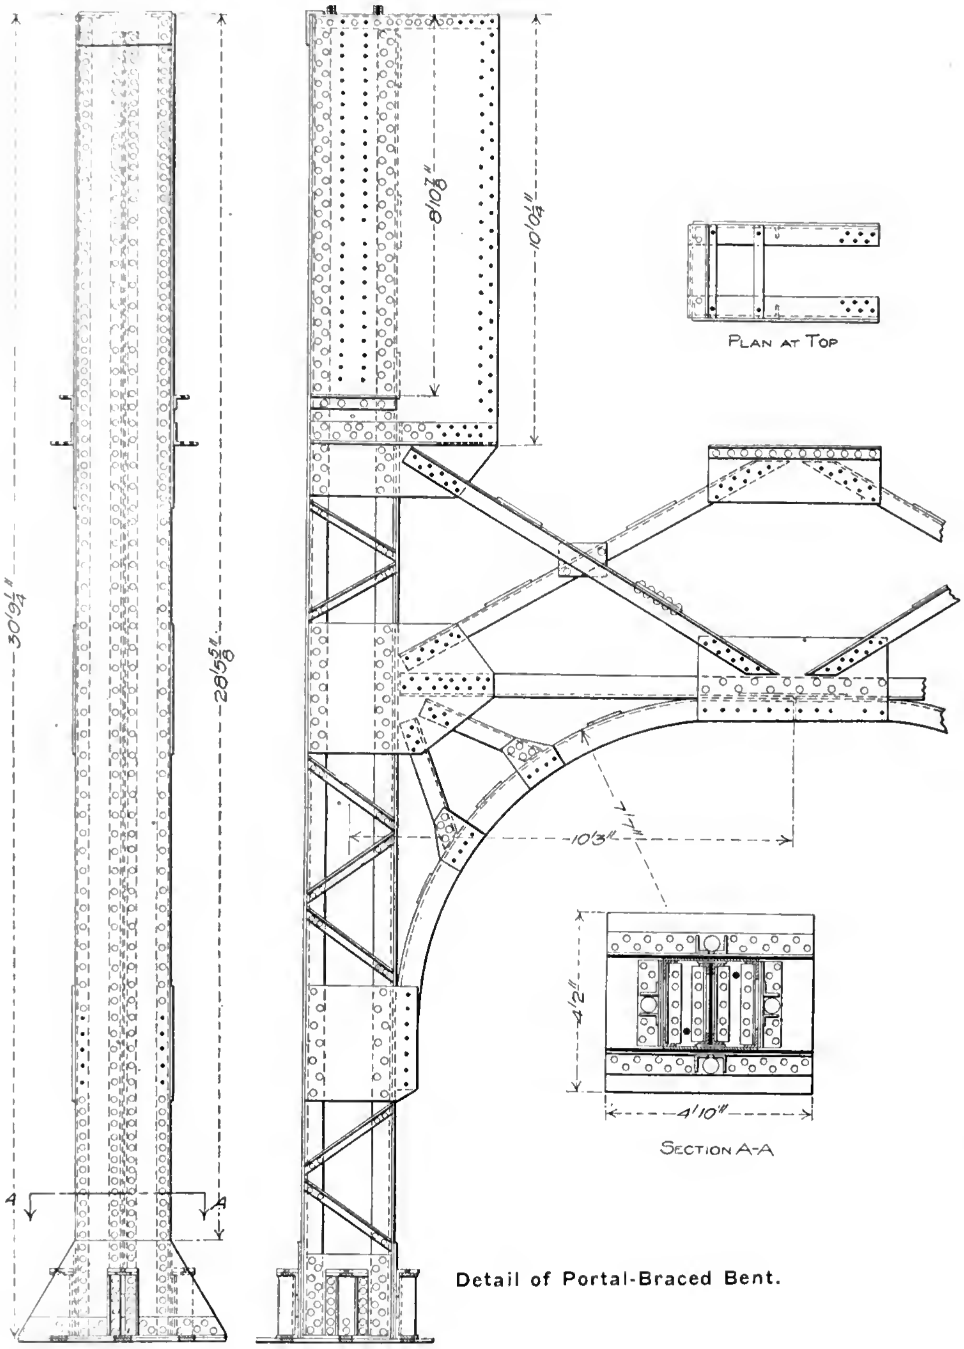
Each column has an I-shaped cross-section, made with two built channels having their webs perpendicular to the axis of the viaduct, and their flanges turned in and latticed, and an I-shaped interior rib, with its web parallel to the axis of the viaduct and its flanges riveted to the webs of the outside channel. Each column is made with four 6 x 6 x ⅝ and four 6 x 4 x ⅝ in. flange angles and two 27 x ⅝-in. and two 24 x ½-in. web plates. The 50 x 1¼ x 58-in. base plate is stiffened by two extended flange plates riveted to the column side plates, riveted across the bottoms of the column flanges, and has four holes for long 3½-in. anchor bolts, with nuts at their upper end bearing on reinforced shelf angles riveted to the column flanges. On one column the holes through the base plate are 4 in. in diameter, and on the other they are slotted 4 x 6 in. to allow for temperature expansion.



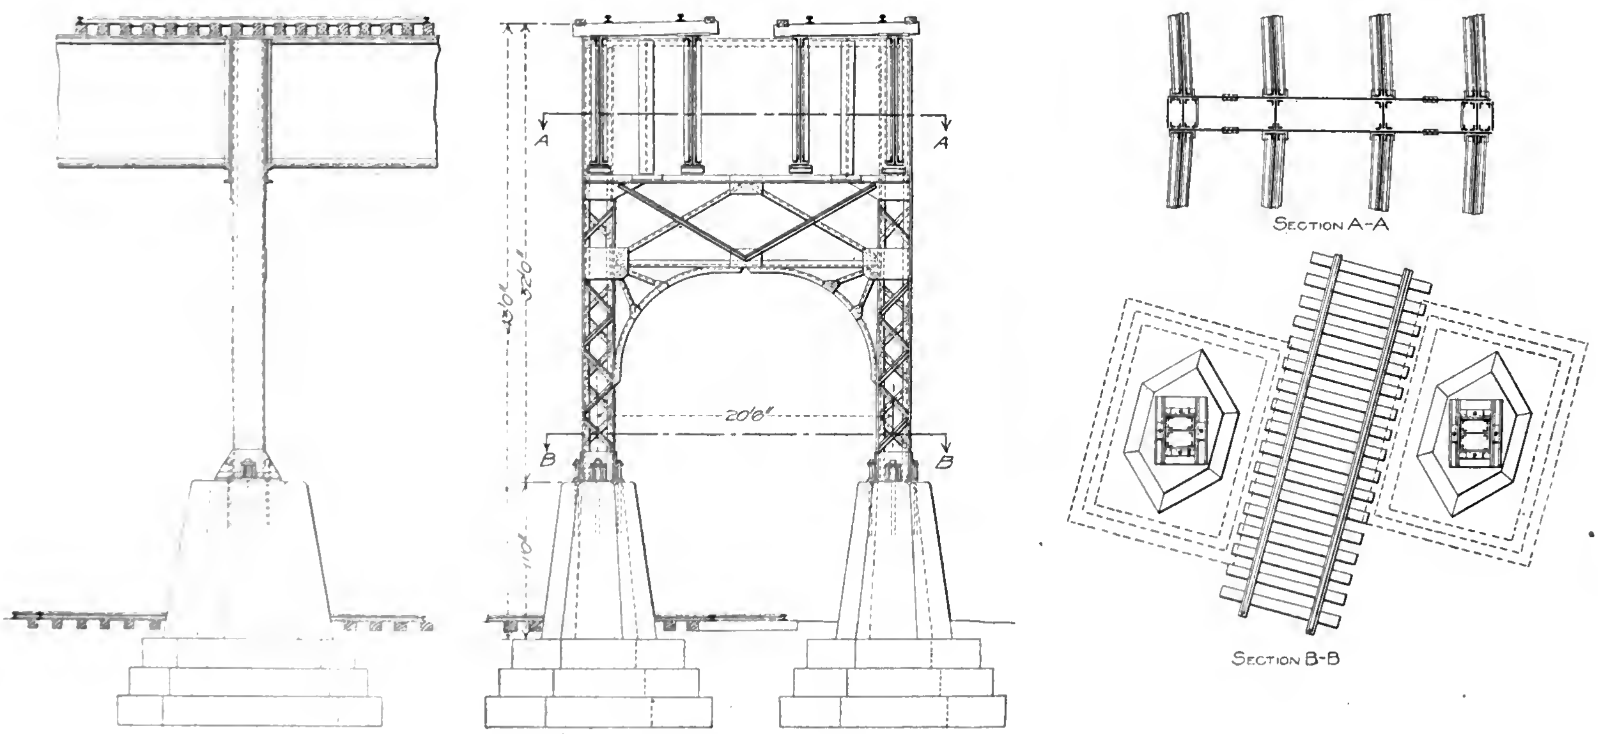
Transverse Girder, Woodbury Viaduct.



Column for Transverse Bent.



Detail of Portal-Braced Bent.



Portal Bent and Girders of the Woodbury Viaduct.

At the upper end of the column pairs of 52½ x 7-16-in., plates 11 ft. 3 in. long are riveted across the flanges projecting on the inner side to form the end sections of the double-web transverse girders connecting the columns. The plates are field-riveted to the ends of the longitudinal girders and to the web cover splice plates of the transverse girders. The portal bracing below the transverse girders is made with pairs of 5 x 3½-in. straight angles and pairs of 6 x 6 x ⅝-in. curved angles, all shipped loose and field-riveted to gusset connection plates.

The tower bents are each made with two vertical posts having their tops web-connected to the full depth of the double web transverse plate girders similar to those in the single bents, but different from them in that they have horizontal bottom struts and X-bracing in both longitudinal and transverse panels. The columns have open rectangular cross-sections made with pairs of built channels, with their flanges turned in and latticed, and have wide projecting flange plates to form jaws, receiving the transverse bracing with pairs of vertical connection angles shop-riveted to them to receive the gusset connection plates of the longitudinal bracing. They have 46 x 1¼ x 46-in. base plates, with anchor belt connections similar to those of the single bent columns. Each column is made with two 26 x 7-16-in. web plate and four 5 x 3½ x 7-16-in. flange angles latticed together with 2½-in. zigzag angles having two rivets in each end.

The center sections of the transverse girders are webspliced to the projecting flange cover plates in the tops of the columns and are made with a pair of 84 x ⅜-in. web plates 13 ft. 9 in. long and 2 ft. 2 in. apart, with their ends faced to make butt joints with the end sections between the cover plates, which are shop-riveted to them and field-riveted to the column plates. The webs are connected by vertical longitudinal diaphragms in the lines of the longitudinal girders, and the latter have 34 field rivets in each connection, besides being seated, for convenience in erection, on horizontal bracket angles. At the ends of the 76 and 82 ft. spans the transverse girders are similar to those above described, except that they are 10 ft. deep. All of the horizontal and diagonal tower struts have I-shape cross-sections made with pairs of angles back to back latticed; all of them are 2 ft. deep over all to correspond with the width of the post, and one diagonal in each panel is made continuous, while the other is cut to clear it and spliced across it with flange cover plates riveted to both members.

The Erie Railroad's Construction Department is under Mr. J. M. Graham, vice-president, and Mr. Francis Lee Stuart, chief engineer, under whose direction the viaduct, including the foundations, was designed by Mr. Mason R. Strong, engineer of bridges and buildings. The erection will be done by the Bridge and Building Department, under the charge of Mr. W. H. Wilkinson, inspector of bridges. The steel work was fabricated by the American Bridge Co.

THE SURPRISE SIGNAL TESTS made during October on the Pennsylvania R. R. were the most satisfactory ever made. There were 2,245 of these tests and of them 98.8 per cent. were absolutely successful and the remaining 1.2 per cent. were marked deficient merely because the signals were passed only a few feet. Taken as a whole, the October record was 1.2 per cent. better than that of September, the best previous month. Fifteen entire divisions received a perfect rating, while only ten divisions were so rated during September. Five divisions were above 97 per cent. and only one fell below 90 per cent. The skill attained by the trainmen in observing signals is shown by the fact that there was but one failure in the 952 tests on the very busy lines of the Schuylkill division.

The State's Responsibility in Road Improvement.

A paper by Director A. Marston, Iowa Highway Commission, in the "Iowa Engineer," published by the Engineering Department of the Iowa State College.

There is going on at the present time an extended discussion regarding the relative functions of central and local authorities in the government of our country. This is the result of an unconscious movement in the United States toward the centralization of government functions, a movement which has resulted from the necessities of our complex modern conditions. It is found that disjointed, local efforts are no longer sufficient to meet the conditions of the present time. Laws which were entirely satisfactory when our factories consisted of a few hands working with the owner, in close personal relations with him, are no longer sufficient to meet the conditions imposed by the great trusts of to-day.

What is true of governmental functions in general is also true of the administration of our roads. In the old days the requirements were met sufficiently well by entrusting the entire control and improvement of the roads to local authorities. But at the present time it is believed that the state should assume part of the responsibility, and that an enormous waste and inefficiency result from leaving road administration entirely to disjointed local managements.

The fact is, our country roads have come to occupy a place in the life of our population enormously important as compared with the old conditions. Formerly each farmer was, to a large extent, his own manufacturer and consumer and he used little not produced or made on the farm. At the present time he takes full advantage of the world's factories, commerce, literature, and art, and finds it is economical to leave the manufacture of most of the articles which he uses to the world's factories. The result is that the road which connects him with the nearest satisfactory market has become a vital link in his everyday life.

It has been very commonly supposed that success in agriculture is the result simply of the use of the best methods of cultivation and management on the farm itself, whereas, in reality the successful agriculturist of to-day must take an active part in the transaction of business entirely outside of his immediate farming operations. He needs to know the prices prevailing in the world's markets each day, and to be able to buy and sell at any time of the year, independent of weather conditions.

His intellectual and social life, also, are exceedingly important as compared with former conditions. He must be able to receive his mail every day of the year, delivered at his home. He must be able to procure the best journals and books at will, and in every way must keep in close touch with the intelligence of the world.

In fact, we may say that the radius of the country world at the present day has been enormously enlarged, as compared with former times. Looking back to my boyhood days, I can see the picture of the portion of the world's surface closely known to me, as I presume each man can who was reared in the country. Extending out a few miles in each direction from the home place was a region intimately known to us, and it was mainly with the people living in this region that we had social and business relations of mutual advantage. We thought we were doing well to receive our mail once each week, and if any message was to be given to a neighbor it had to be transmitted by word of mouth. How different are the conditions at the present time! My father, who *then* seemed to me to be a man of advanced age, now receives his Chicago paper every day, and if he wishes to communicate with his neighbors he has but to take down the telephone receiver.

Nor should we confine our point of view to the country alone. The modern tendency is toward grouping our population in cities and towns. In Iowa the prosperity of the cities depends mainly upon the magnitude of the territory tributary to them, and upon the regularity and surety with which the inhabitants of the tributary territory can maintain their business relations with the city. Any city which can secure the permanent improvement of the principal roads radiating out from it in all directions, will thereby do much to extend its tributary territory and to insure its business prosperity.

In the investigations of the Iowa Highway Commission of the statistics of the use of Iowa roads, that which has come out most promiently has been the exceeding importance of what might be called the light travel over these roads; that is, their use for other purposs than for the hauling of heavy loads. It is impossible to estimate the money value to the people of Iowa of having good, hard roads at all seasons of the year and under all conditions of weather, for the transaction of the business of the state, and for securing social and intellectual advantages which would otherwise be unattainable.

It is, however, a sad fact that country road improvement has not kept pace at all with the other advances of civilization in America. The present conditions are rapidly becoming intolerable. They constitute what might be termed, and will soon be regarded as, a disgrace to the state.

Yet, we are expending, at the present time, enormous sums upon our roads. The figures for the last three years are as follows:

Year.	County Road Tax.	Township Road Tax.	County Bridge Tax.	Total.
1903	$547,309.92	$2,283,129.65	$1,628,720.88	$4,459,160.45
1904	550,409.42	1,749,395.23	1,947,423.53	4,259,228.18
1905	518,535.71	1,923,431.81	1,773,304.08	4,215,271.60

Taking into account the money value of the poll taxes, and the sums from other sources than those above enumerated that are expended upon the roads of Iowa, it is probable that the total annual expenditures for road purposes are between $4,500,000 and $5,000,000.

To form some idea of the magnitude of this great sum we may compare it with the total expenditures for state purposes in Iowa during the fiscal year ending June 30, 1906, which were $4,165,639.81. It appears, therefore, that the money expended on Iowa roads in one year is considerably in excess of the total sum required to run the state government, and to support the state asylums, penitentiaries and other charitable and penal institutions, together with the State Normal School, the State University, and the State College.

To administer this smaller fund we elect a state legislature with all its attendant expenses, but as yet Iowa has not taken, as a state, an active part in administering the expenditures of the road funds. Apparently, however, the inevitable force of progress is compelling the state to participate more actively in securing efficient results from its large expenditures on roads.

It is a matter of common knowledge that we do not, under the present system, secure the results to which we are entitled, for the amount of money expended, although our road officers are almost universally absolutely honest, and have the best of intentions. The fault is in the system, in the lack of the *training* of the men, and not in the men themselves. It will be of interest to inquire what results we could reasonably expect from the money now being spent upon our state roads with proper system, and with thoroughly trained men.

In the first place, we may say that Iowa has approximately 100,000 miles of country roads and that at a maximum expense of five dollars per mile, or a total of $500,000 annually, these roads

could be maintained in good condition during almost all the year by the proper systematic use of the road drag. If, therefore, our road work were systematized under well trained, responsible men, $500,000 could be expended each year with results which would be many times more valuable than at present attained with the expenditures of our entire road funds.

In the second place, nearly all the moneys expended for bridges should be put into permanent structures, such as concrete culverts, and steel bridges with masonry abutments. If this policy were followed for a considerable period of years the annual amount required for bridges would greatly diminish. In this way $1,500,000 to $2,000,000 could be profitably spent annually for a number of years to come.

In the third place, $1,000,000 per year could be concentrated upon the improvement of the main traveled roads of the state, including the surfacing of such roads with gravel, broken stone, or other material suitable for making permanent improvement. At prices which have actually realized in the state, this would be sufficent to build 1,000 to 1,500 miles of gravel road per year, two hundred to four hundred miles of stone road.

In the fourth place, there would be left $1,000,000 to $1,500,000 for general administration and for grading. The grading done wit hthis fund should be devoted to building good, substantial grades and side ditches, in accordance with road engineer's plans, instead of patching a little here and a little there. Several million cubic yards of earth per year could be moved with this fund.

It is not too much to say that if the administration of the road funds of Iowa were under the management of one of our great railway systems, all the above results would be secured, and that within a comparatively limited number of years we would have a system of roads that would be the admiration of the world, without taxing ourselves any more than we now do. It is impossible, of course, to actually secure such perfect business administration, while still leaving the control of our road funds as closely to the people who pay the taxes as is right and desirable under our system of government. But we should approach much nearer to this ideal than at present. Under the present conditions we see little improvement from year to year, and the money seems to go to just about keep up the roads in their present condition.

To systematize and concentrate our road work must be our endeavor if we would improve present conditions.

Until recently, our state has taken no part in road administration further than to pass uniform road laws. This is a function of state government which has, of course, been recognized in every state in the union. But while the laws are uniform in each particular state, in their administration we find wide difference in practice in different parts of Iowa. There is, perhaps, a more pressing need for an exact and uniform enforcement of our present road laws than for the enactment of new laws. For example, the laws require a proper accounting of road funds, yet we find that the actual system of accounting is often hardly worthy of the name.

Of recent years there has been a general movement in the United States towards more active participation by the state in road administration, and this has shown itself in the creation of state highway commissions. California, Connecticut, Idaho, Illinois, Iowa, Minnesota, Massachusetts, Michigan, Missouri, New Hampshire, New Jersey, New York, Ohio, Pennsylvania, Vermont and Washington have created such commissions. Taking the cases of some of our neighboring states, it may be stated that Illinois appropriates $50,000 per year for its highway commission; that Missouri has just provided for a state highway engineer, with an appropriation of $12,000 per year for expenses and has further provided for a county road engineer in each county of the state. Iowa has provided that the Iowa State College shall constitute a highway commission. and has appropriated $5,000 per year, which amount is the lowest provided by any state for its highway commission.

The duties of these highway commissions vary from mainly investigation and advisory work, to active building and maintenance of state roads. The work of our own commission may be said to have just begun. So far, we have been making a thorough preliminary study of road conditions in Iowa, have prepared and distributed road bulletins, have prepared and have been furnishing to road officers standard plans for culverts, bridges, and road construction, have inaugurated an annual road school for the training of road officers, have furnished expert advice to road officers calling for it, both by correspondence and personal visit, and have been endeavoring to assist further in the road work in all ways possible.

Another very important method by which the states of our country have been taking active part in road work in recent years is state aid. Connecticut has available about $225,000 per year for the construction of state roads, the state paying ninety-five per cent. of the cost. Massachusetts appropriated in 1905 about $550,000, paying seventy-five per cent of the total cost. In New Hampshire the amount is $125,000 per year, the state paying from twenty-five to seventy-five per cent. of the cost. New Jersey, which shares with Massachusetts the honor of pioneering the way in state road construction, expends annually $400,000, paying one-third of the cost. New York has recently appropriated $50,000,000 for state roads, to be expended in ten years, and pays fifty per cent of the cost. Pennsylvania appropriated $6,356,232, to be expended in five years ending 1909, and pays seventy-five per cent of the cost. Washington pays fifty per cent of the cost of all roads built by the state highway commissioner. Michigan pays "state rewards" for gravel and macadam roads, ranging from two hundred fifty to one thousand dollars per mile, according to the kind of road built, when same have been constructed according to the plans and specifications of the state highway commissioner and have received his approval.

While there might be much doubt in the minds of many people whether as yet Iowa has reached the time for extending state aid for hard roads, yet all who have studied those built under this system in our eastern states must admit that they are the finest roads in the world. And the plan is so popular with the tax-payers who foot the bills that in every state having such a system there are continual demands for the construction of many more such roads than can possibly be built. At the same time those making the requests understand that they have personally to pay a large part of the cost in addition to the amount paid by the state. The macadamized roads built by New Jersey, Massachusetts and New York under the system of state aid road construction are ideal, and are unsurpassed in the world, whereas, a few years ago these same states had roads equal to the worst.

In conclusion we may inquire what can be done in Iowa by the state to secure better roads. I will enumerate certain things which we believe our state could well undertake.

In the first place the state should systematize our road work.

(1) Its highway commission will supply to all road officers desiring them standard plans for culverts, bridges and road construction. We believe the state should require that all plans and specifications for large bridges be submitted to and approved by the commission, and that the construction of culverts and roads should, in general, be carried out in accordance with standard plans.

(2) The highway commission should supply road experts to respond to the call of road officers for advice and assistance.

(3) The state should by law provide for a road engineer in each county of the state, who should be a trained and well qualified road expert, who should make surveys and prepare plans for all important road work, and under whom in general the road work of the county should be placed. These county road engineers should be required to make regular reports to the highway commission, and to keep in close touch with it.

(4) The local road officers of each township should be required to make regular reports to the county engineer, and in general to work in consultation with him.

(5) Means should be provided for educating and training road officers. The present Road School should have its facilities for such work greatly extended and, if necessary, should hold a number of sessions each year in different parts of the state, so as to make it more convenient for road officers to attend.

In the second place our present road funds should be expended in such a way as to secure better results for the money.

(6) Systematic dragging of all earth roads, except unused byways, should be required, and should be carried out under road officers who can be held responsible for results.

(7) The expenditures for culverts should be devoted mainly to the building of permanent concrete structures.

(8) All large steel bridges should be built in accordance with definite plans and specifications prepared by competent engineers and let to the lowest responsible bidder, after being properly advertised.

(9) The county road fund should be increased one mill, and in general the road work should be to a considerable extent concentrated on main traveled highways.

(10) Wherever practicable, a beginning should be made at surfacing the principal roads with the best gravel or stone or other hard material locally available.

In the third place, the state should by direct appropriation provide for the building by the State Highway Commission of sections of experimental road in different parts of the state. In no other way can the best materials available in Iowa be discovered and the cost of good roads construction be ascertained.

The road question in Iowa is one of the most important to be solved by our people. The traffic on these roads is so large that if teams could be collected in one string to do the annual traveling in one day, at thirty miles per day, this string of teams would reach more than one and one-half times around the entire earth. In every way is the attainment of good roads most vital to our people. We must believe that the problem will be successfully solved in our state, and that Iowa roads, as well as Iowa agriculture, will in the future be found in the first rank.

A HYDRAULIC DREDGE designed for the removal of 4,500 tons of sand per hour from a depth of 70 ft. below water level has been built by Ferguson Brothers, Port Glasgow, Scotland, for dredging the Thames estuary. The spoil will be carried in hoppers aboard the dredger itself until ready for discharging. The vessel is twin-screw, 330 ft. long, 55 ft. 6 in. wide and draws 23 ft. There are two suction pipes, connected to Gwynne centrifugal pumps. The work to be done consists in constructing a channel 1,000 ft. wide and 30 ft. deep at low water through Leigh Middle Shoal, the total being about 6,000,000 cu. yd.

A Few Tests and Experiments with Reinforced Concrete.

By R. T. Surtees, C. E., Newton-le-Willows, Lancashire, England.

During the last few years, reinforced concrete for building and engineering works has made such headway that the limits of its application appear almost boundless. Construction of great intricacy and daring has been successfully carried out with it, whilst the failures have been few, those that have taken place being traceable to the inexperience or carelessness that may be found in all departments of works and labor. It is no doubt a material, or system of building that requires a considerable amount of care to ensure success, and whilst the principal amount of labor in connection with it may be got from the unskilled, the leading hands should be experienced and able to see the object of the designer and ensure it being carried out. Care should be taken in the selection of proper materials, according to the work required of them, and it is surprising what useful tests can be made at a cost warrantable for jobs of comparatively small dimensions. The writer was once nearly led into disaster by what appeared a hard gravel, apparently admirably suited for concrete, but on leaving a handful near a warm steam pipe, was surprised to find after a few hours, a number of cracks in each piece, so very small as to look like fine hairs. On breaking them up they were found to be nodules of clay encased with a thin coating of hard material, and it required only a comparatively small rise in temperature to cause them to burst, making them most dangerous to use for concrete. Failures have been reported from concrete made with aggregates containing a small percentage of sulphur, such as is found in certain blast furnace slags, etc., but it is doubtful as to what was the precise cause, and perhaps if careful and intelligent investigation had been carried out, it would have been found to be due to the imperfect proportioning and mixing of the materials and not to the constituents.

It has been found that iron cramps after being surrounded with concrete for hundreds of years, have been proved to be in perfect condition, whilst it has been equally proved that steel embedded in concrete floors for only a few years has been affected to such an extent that the wonder was that a collapse had not taken place.

What is the cause of this great difference? Is it the chemical composition of the steel or the aggregate, or is it due to the mixing and placing of the concrete? The following experiments have been carried out with a view of ascertaining a correct answer to these questions, so far as the aggregate or the concrete is concerned, and to many, I am afraid, the results will be in one or two instances, not quite what might be expected.

With aggregates of various materials, concrete blocks were made up in which were inserted pieces of steel, with their ends projecting out of the mass for a few inches. These blocks were immersed in water at frequent intervals, for a period extending over twelve months, when the projecting ends of the steel were found to be highly corroded. They were then submitted to the action of steam from a boiling solution of acid, until the exposed steel was, in most instances practically destroyed. The blocks were then cut open so that the embedded portions of the steel could be inspected. Fig. 1 is from a photograph of some of these blocks, the concrete in which was made with an aggregate composed of blast furnace slag from the works of the Wigan Coal & Iron Co., Lancashire. Figs. 2 and 3 show other blocks made with boiler furnace clinker, crushed bricks, and a mixture of brick and clinker, included in Table 1, which also gives the results of the experiments:

TABLE 1.—EFFECT OF WATER AND ACID VAPOR ON STEEL IN CONCRETE.

No.	Aggregate.	Sulphur. Per Ct.	Concrete Over Steel. In.	Remarks.
1	Slag	2.07	1¾	Steet unaffected
2	"	2.07	½	" "
3	"	....	⅜	" "
4	"	....	1¾	" "
5	"	....	1¾	" "
6	"	....	½	" "
7	"	2.07	¾	" "
8	"	2.07	1½	" "

23	Brickbats	....	2	" " "
25	Br'k. and clin.	....	2	" " "
27	Brickbats	....	1¾	" " "

In Nos. 2, 3, 6 and 7, the bars were nearer the outside of the blocks than is usual in reinforced work, and yet nothing penetrated the concrete far enough to cause rust to form on the steel.

The amount of sulphur in Nos. 1, 2, 7 and 8 was sufficient to color the concrete to a dark green, and there appeared to be no deleterious action set up on the steel.

There was a large amount of iron in the clinker which did not show any effect on the embedded steel when the concrete was properly consolidated and without voids.

In all cases where the steel showed corrosion, the concrete had not been properly graded, or made free from honeycombs or voids, which in most cases were easily traceable right from the steel to the outside of the blocks when examined.

The whole of the concrete used was made with aggregates containing the run of the crusher, none of the fine dust being kept out.

These experiments indicate that to preserve the steel effectually the aggregate for the concrete should be carefully graded to ensure the filling of the voids, that the concrete should be carefully mixed, placed, and consolidated, and even if this mixture does contain certain chemical impurities, there is small likelihood of rust being formed. Great care should be exercised to prevent the possibility of air spaces, honeycombs, or cracks on the outer surface extending into the mass far enough to allow an air passage to reach the steel, for if unnoticed or allowed to remain, rust will form, which may burst off part of the concrete, and so weaken the structure that disaster will eventually result. A case which recently came under the writer's notice was caused by the timbers being removed by the workmen before the concrete had been properly set, when its own weight had caused it to fall away from the steel just enough to cause a crack extending a considerable distance along the rods. No attempt had been made to remedy this, and after the contractor had handed over the work, the evil results began to appear. In a case of this kind, the rusting of the steel may perhaps not be the least danger incurred, for the concrete might be materially damaged, whilst its adhesion to the steel would be far from what it ought to have been.

Tests of the Permeability of Concrete and the Protection of Steel.

Cinders, pan breeze and such like are undoubtedly attended with a certain amount of danger in their use as aggregates in concrete having direct contact with steel. When soft they will not stand ramming without crushing, and the crushed parts may not be coated with cement, consequently dampness may make through to the detriment of the steel. Cinder concretes have no doubt been the cause of failures, and in the hands of careless contractors are most dangerous to allow. A concrete made with them may, however, with advantage be used under certain floors, or in partitions where it is required to take nails for fixing boards or other timbers. It is also a poor conductor of sound and useful as deafening.

Under no conditions is a rich concrete, having an aggregate of hard, sound material, proportioned and placed so as to secure the greatest density, more necessary than for an impermeable concrete. A concrete of this kind is often required for cellars, reservoirs, tanks, pipes and such like. Fig. 4 shows a method of carrying out experiments with a view to securing the best results, the apparatus being of simple construc-

tion, will allow the test to be carried out on most jobs at little expense. In each of the four large pipes shown are blocks of concrete, 5 in. in thickness, moulded inside. The larger pipes are connected to the town's water supply by means of the small pipe along the top, which allowed a pressure of 40 lb. per square inch, means being provided to allow the enclosed air to escape. The arrangement shown is also connected to a small boiler feed pump by which the pressure could be increased to 260 lb. per square inch, the town's pressure being shut off by a small valve when this was being applied. Table 2 gives the composition of the concrete in each pipe.

The aggregates included the fine stuff contained in the whole run of the crusher. The pipes were allowed to stand under damp cloths for two days, and afterwards were immersed in water for eighteen days, the test being applied on the twenty-first day after the concrete was placed. The results of the tests are given in Table 2.

TABLE 2.—PERMEABILITY TESTS OF CONCRETE.

NOTE: The tests were continued at about the last rate until the thirtieth day, when the experiment was considered finished.

Having proved a satisfactory mixture, from the materials to hand, an attempt was next made to find out the best conditions under which the concrete would set, for should contraction take place, cracks might occur, through which water could pass. With this object in view, four more pipes were used, in each of which was placed a thickness of 5 in. of concrete, prepared in a similar manner to those giving the best results in the preceding experiment. No. 1 was placed in a position to set where a hot sun could get at it during most part of the day, No. 2 was placed in a shaded place, and Nos. 3 and 4 were allowed two days under a damp cloth, twenty-eight days immersed in water, and all were put under pressure on the thirtieth day. The concrete in No. 1 had contracted in setting as water passed between the pipe and the block of concrete inside. No. 2 showed a very slight dampness which soon took up, while Nos. 3 and 4 were perfectly watertight. The set of pipes shown in Fig. 4 were made up of Nos. 3 and 4 of the former experiment, renumbered respectively 1 and 2, with Nos. 3 and 4 of the latter. The pressure was again applied, being gradually increased up to 260 lb. per square inch, and after two days with it varying between 50 lb per square inch and this. During this time no signs of dampness appeared on the underside. One of the blocks was cut out to see how far the water had penetrated into the mass of concrete, where it was seen to be traceable for a distance of only 1⅛ in. Whilst it may not be a difficult matter to make blocks of this size to stand such high pressures, it could hardly be expected that a long, thin wall of the same materials would give the same results, there being so many other factors to contend against.

Following this investigation a step further, a reinforced concrete pipe was made, as seen in Fig. 5. This was first made with an open end, and after the concrete had set, a short length of cast iron pipe,—for a special purpose other than connecting the hydraulic pressures—was moulded on to the end, the longitudinal steel reinforcing rods passing through the pipe and well into the concrete securing the cap. After connecting up the pipes, pressure at the rate of 30 lb. per square inch was applied, being gradually increased until it reached 120 lb., with no signs of dampness appearing on the outside of the pipe. This pressure was maintained for three hours, and on attempting to raise it higher, the joint between the first-made concrete and that fixing the cap gave way; as the object of the experiment had been attained, no further attempt was made to reconnect it.

Reinforced concrete pipes without the assistance of internal metal tubes to stand a pressure of this severity require great care in their construction, and a little remissness in mixing, placing or consolidating the concrete may lead to failure.

To secure the best results under direct compressional loads, as in columns and such like structures, it is imperative that the main or vertical reinforcing bars should be so fixed as to secure the requisite size of core, to be hooped or bound with a wire, wrapped spirally around the steel skeleton, to the bars of which it may be tied

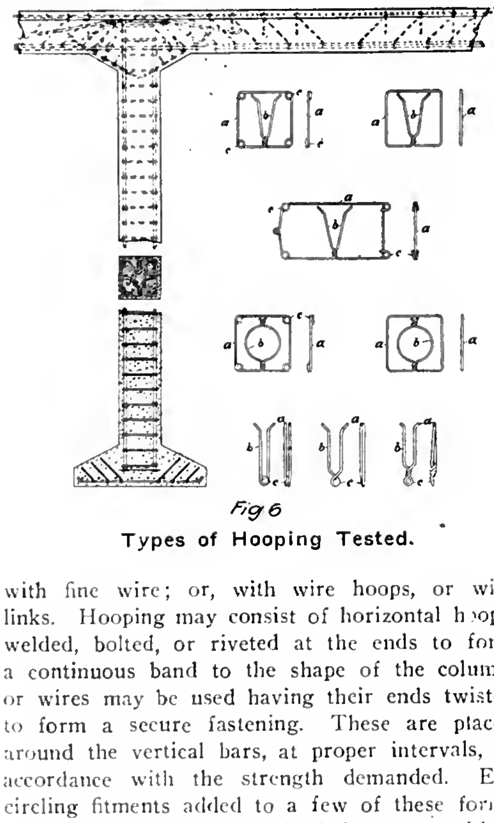

Fig 6

Types of Hooping Tested.

with fine wire; or, with wire hoops, or with links. Hooping may consist of horizontal hoops, welded, bolted, or riveted at the ends to form a continuous band to the shape of the column, or wires may be used having their ends twisted to form a secure fastening. These are placed around the vertical bars, at proper intervals, in accordance with the strength demanded. Encircling fitments added to a few of these forms of hoops, to hold the bars in their exact position, are well worth the little extra expense, as they serve both to connect the bars together and hold them apart from each other, so that the core cannot be otherwise than the size and shape designed.

The spirally wrapped skeleton has often been throught one of the strongest systems, but is difficult to apply, and as the whole skeleton has to be built up in position before any of the concrete is placed, it makes this difficult to do. What may be gained in a stronger skeleton may be lost in weaker concrete; and should the continuous wire wrapping get damaged at any one place in its length, it materially weakens the whole structure, whilst one break in it practically destroys the whole length of hooping. With any form of skeleton, however well it may be made, care is required in ramming the concrete, and care should be taken to ensure as little obstruction as possible to this part of the work. Even if the steel is made up into units, they may be thrust out of place by careless workmen who do not realize the importance of what they are doing. It has been contended that the advantage said to attend a spirally wrapped hooping lay in the fact that the spaces between the spirals were not in the same horizontal plane right round the column, as in the case with plain link hooping. This is doubtful, nor does the following experiments bear this out.

The arms of the hoop were arranged, see Fig. 6, in the mass of concrete in different directions to those of the next adjoining hoop, thus further reinforcing the core against that bulging action which is always set up when the load is applied. It is also probable that the horizontal hooping, as heretofore tested against wire wrapping, may have had the ends of the links simply laid side by side in the concrete, as was formerly the common practice, instead of having them securely twisted to form a tie, which ensures a structure being fully 23 per cent. stronger. It may be a comparatively simple matter to keep the steel members in their correct position in making a small test piece, but in actual work the difficulty is great, as every worker in reinforced concrete knows. Instances have been found where the steel members have been found to be far different to where the designer intended they should have been placed, and even in test pieces where every care has been taken to ensure correct work, members have been discovered out of place. Systems giving simplicity in design and execution, with secure fixing of the steel as the work proceeds have much to commend them.

It cannot be expected to make a structure of greater strength than its component parts, therefore, we may look to get the best results under compressional loading, with a concrete having an aggregate of the hardest materials.

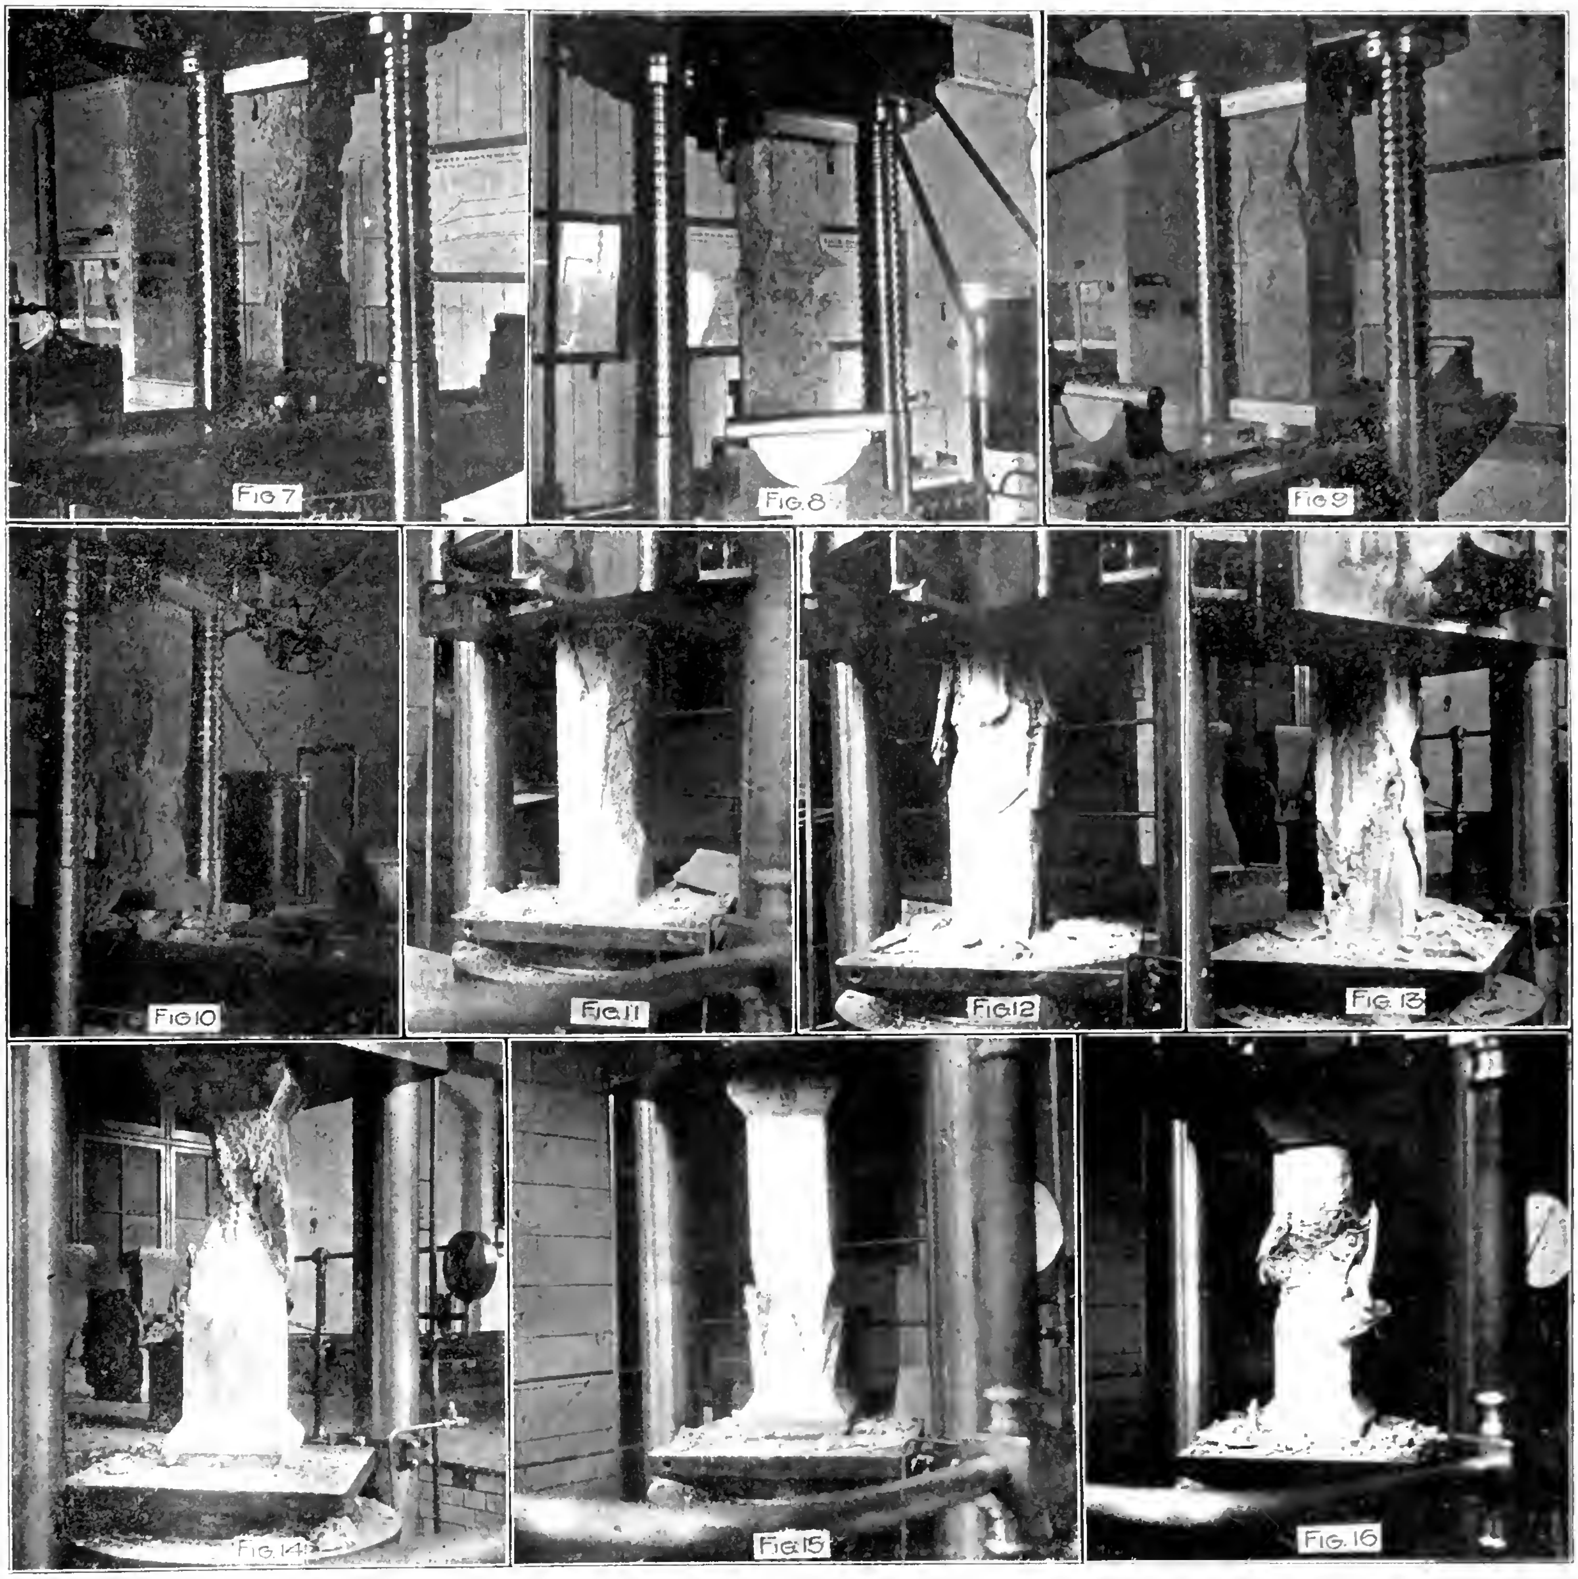
Fig. 7, 8, 9 and 10 show a set of columns made as nearly as possible under identical conditions as regards aggregates, sand, mixing, placing and consolidating the concrete, special efforts being made to ensure that the whole should be as uniform as possible. Fig. 7 and 8 had the longitudinal bars spirally wrapped and Fig. 9 and 10 had horizontal hoopings, as illustrated in Fig. 6, the steel in each instance being of the same weight throughout. Fig. 7 is of particular interest, inasmuch as it indicates a peculiar twisting action, which is perhaps attributable to this form of hooping when under load. As it happened, the pin which holds the table of the testing machine in position, had been accidentally left out, thus leaving it free to move on its pivot, and after the application of the pressure, the column began to twist to failure, the table moving around in unison therewith, destruction being achieved with a load of 49 tons. Fig. 8 was tested with the table fixed and failed under a load of 55 tons. Fig. 9 failed under 85½ tons and Fig. 10 under 91½ tons. The specimens were all 2 ft. 6 in. long by 8 in. square.

Figures 11, 12 and 13 and Figs. 14, 15 and 16 illustrate respectively two sets of columns, the experiments being carried out as before, the concrete being prepared and the work executed with a view to securing uniformity throughout. The longitudinal bars were 13/16 in. in diameter in all cases, there being a slight difference in the spacing of the hoops, which were of the link and strut pattern.

No.	Crushed at.	Length.	Size.
11	134½ tons	3 ft.	10 x 10 in.
12	176 "	3 "	"
13	209 "	3 "	"
14	219 "	4 "	"
15	197 "	4 "	"
16	215 "	4 "	"

It will be seen that Fig. 14, which is made with concrete having no reinforcing steel in it, comes out stronger than any of the others. In

this case the failure took place suddenly and with a loud report, as of an explosion, whilst pieces of the concrete flew about the room with dangerous velocity. It is undoubtedly one of those freaks which sometimes develop even after the greatest care has been devoted to the work of construction. In this case the whole of the details connected with their construction were



Method of Failure of Reinforced Concrete Columns.

personally supervised by competent engineers representing three different authorities.

If it were possible, in actual work, to consistently obtain a concrete of this superior quality and strength, reinforcing would not be so much necessary. After breaking, the sample of concrete showed to be very dense, with practically no pinholes in it, and hundreds of attempts might be made to make another to give such good results, without success. It shows the advantage of having the soft concrete of the right consistency and that there be no obstruction to its efficient consolidation, such as jarring after it has begun to set.

The mixture used in the manufacture of the last two sets of columns, was just something less than a wet one, and with those having the steel skeleton in the moulds, the concrete could not be so thoroughly rammed as where there was no such obstruction. A bigger rammer could also be used. It is undoubtedly due to these causes that such a high result was obtained in this particular specimen. Fig. 16 shows excellent design and construction.

In the columns comprising the last six experiments, the concrete was mixed in a machine of the revolving drum type, which, after repeated tests, the writer is convinced, made a concrete which was 16 per cent. stronger than could be turned out by hand mixing.

Concrete in Bags.

Bags of concrete are often used in constructing foundations under water, but caution should be exercised, Mr. W. D. Cay states in "Engineering," to see that the protecting ends of such bags are not subjected to the pounding of a heavy sea or its equivalent. In his opinion there must be ample mixing facilities, the materials must be collected close to the hoppers of the mixers, and large cars or skips used to transfer the concrete to a box in a hopper barge, in which the bag has previously been placed. The barge should be taken rapidly to the site of deposit, the bag being sewn up during transit and when brought into position the pulling of a trigger releases the doors of the box and the bag falls slowly down through the water to its place.

The Harlem Creek Sewer, St. Louis, Mo.

The Harlem Creek sewer, in St. Louis, Mo., is being constructed to carry to the Mississippi River the combined domestic sewage flow and storm-water run-off from a residential section of 6,000 acres in the northern part of the city. The area which will be served by the sewer lies about a mile back from the river, and between it and the latter is a stretch of low, flat river bottom land that is only slightly above extreme high water in the river. Back of this bottom land the country is considerably rough and broken, but is fairly well built up as a residence district. The storm-water run-off accordingly reaches the drainage outlets quickly, thus requiring large sewers to carry it away.

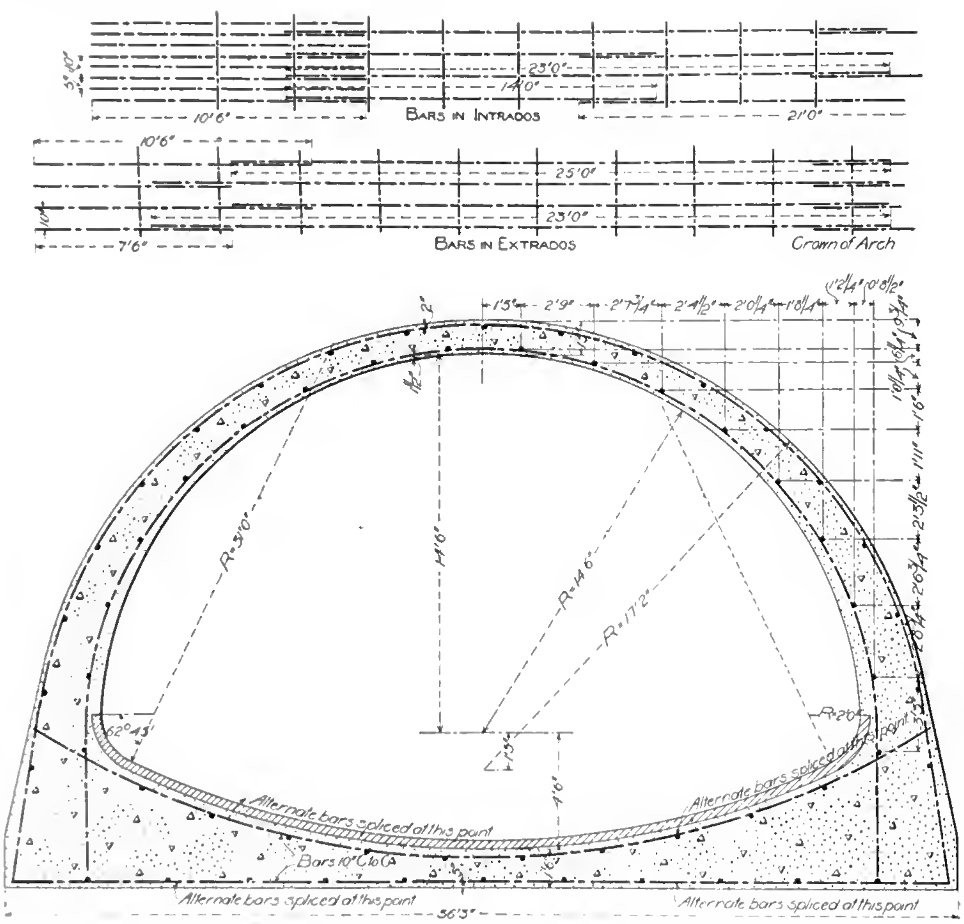
The Harlem Creek sewer has a total length of approximately a mile, extending from an outlet in the low area, about 1,500 ft. from the foot of the higher ground, back up into the hills for nearly 3,700 ft. The sewer has a semi-circular arch, with a flat, inverted semi-circular arch invert, and is built of reinforced concrete. In the first 1,000 ft. from the outlet the intrados of the arch has a radius of 14.5 ft. and the invert a radius of 29 ft. In this length the cross section of the sewer has an area of 411 sq. ft., giving a hydraulic radius of 6.41 ft., and the sewer is laid on a grade of 3 in. to 100 ft., which produces a velocity of 18.9 ft. per second and a carrying capacity of 7,480 cu. ft. per second. The arch of the sewer in the next 1,400 ft. has a radius of 13.5 ft., and the invert of 27 ft., the cross-section being 379 sq. ft., the hydraulic radius 6.2 ft., the velocity 18.2 ft. per second and the carrying capacity 6,714 cu. ft per second. The remainder of the sewer has an arch with a radius of 12.5 ft. and an invert radius of 25 ft., the cross-section being 327 sq ft., the hydraulic radius 5.76 ft., the velocity 17.8 ft. per second and the carrying capacity 5,570 cu. ft. per second.

Since the sewer is over a mile in length and has such a large section, the saving of the smallest quantities per linear foot results in a very considerable economy in the structure as a whole. A semi-circular section was selected because of the simplicity of form work required for it, of the determination of waterway areas, and of the belief that all uncertainties of loading considered, it would come as near being the economical form as any that might be designed.

The low area which is crossed by the sewer will doubtless eventually be occupied by railroad yards, as it is crossed by several trunk lines, which already have considerable yard facilities in this area. A switch track also extends from these yards up the valley that is occupied by the sewer. The latter was accordingly designed to carry the loads that will be brought on it by these tracks. The selection of a conduit section on the basis of loading alone necessarily involves some definite assumptions as to loads. They must be considered either vertical, or partly vertical and partly horizontal, and if so, the ratio of the horizontal to the vertical must be assumed. The variation in the height of fill, the nature of the filling material, the manner of placing, the amount of moisture and so forth all affect these assumptions to such an extent as to make a selection on such a basis rather impracticable. The largest section, with a 29-ft. clear span, was assumed to have a 15-ft. fill over the top of the arch, and also to carry the heaviest railroad loading combined with a 7-ft. fill. In order to provide for the most unfavorable condition of back filling, the loads were assumed to have such position as to produce maximum bending moments without regard to continuity. It was found that this method in the case of the 15-ft. fill also provided amply for the railroad loads.

The stresses in the various sections were determined from the analysis of circular ribs with fixed ends in Prof. Chas. E. Green's treatise on arches. The determination of constants for the horizontal forces had to be made from the general equations and involved considerable labor, but the work proved very much worth while, as the horizontal forces were found to reduce the bending moments from the vertical loads. To illustrate this point: The bending moment at the crown of the 29-ft. arch, due to vertical load, was found to be about 208,000 in pounds, but of the opposite sign, leaving a resultant positive bending moment, which results in a tension in the intrados of the arch of about 108,000 in pounds, or a reduction of nearly 50 per cent.

The advantage of reinforced concrete over plain is considered to be very clearly shown by



Reinforcement in Maximum Section of Harlem Creek Sewer.

the stress conditions existing at the crown. The resultant bending moment being 108,000 inch pounds, while the total thrust was but 18,000 lb., gives an eccentricity of 6 in. To keep the thrust inside the middle third, or to cause no tension, would therefore require a thickness of about 36 in. But assuming a section of reinforced concrete 15 in. thick, the combined stress due to thrust and bending moment would be:

$$f = 108{,}000 \div (12 \times 15) \pm 6 \times 108{,}000 \div (12 \times 25) = 100 \pm 240.$$

The stream carrying capacity required for the sewer was obtained by McMath's formula for determining run-off, which is $Q = pr\sqrt[5]{(A^4 s)}$; Q being the quantity in cubic feet per second; p, the percentage of the total rainfall in inches; A, the area in acres and s, the slope of the surface. It was assumed that 75 per cent. of the rainfall would reach the sewers and that the maximum rate of rainfall would be 2.75 in. per hour. In estimating the carrying capacity of the sewer, n in Kutter's formula was assumed to be 0.013 for the brick lining, which is provided for the invert of the sewer.

The concrete in the invert and up to the springing line of the sewer was made in the proportion of 1 part Red Ring Portland cement, 3 parts river sand and 6 parts crushed limestone, the pieces of which vary from ¼ in. to 1 in. in size. In ordinary soil about 4 cu. yd. of this class of concrete was required per linear foot of sewer. The arch concrete was made in the proportions 1:2:5, 2 cu. yd. per linear foot of sewer being required. The proportions of the two mixtures are varied to suit the percentage of voids in the sand and broken stone.

The details of the reinforcement of the sewer section are clearly shown in an accompanying illustration and need little explanation, Johnson corrugated bars being used for reinforcing. All transverse reinforcement is made with 1-in. bars, and all longitudinal reinforcement with ½-in. bars.

The construction of the sewer presented no special difficulties, the sewer extending down the valley of a small crooked stream, which carries a large volume of water during floods, but is very low during dry seasons. The channel of the stream is cut across several times to avoid curves in the sewer. The construction has been handled in alternate sections between these crossings, in order that the flow of the stream might be handled easily. The extrados of the sewer is from 4 ft. to 20 ft. below the natural surface until the edge of the low area is reached and across that area filling has to be provided in places to cover the sewer. As the trench has to be opened 2.5 ft. wider on each side than the base of the sewer, or to a total width of 41 ft. in the large section, it involves a large amount of excavation. Across the portion of the low area in which construction was carried on the soil is river silt to a depth of a few feet, under which is a stratum of limestone; in the higher ground the soil covering over the limestone is considerably thicker. The preliminary estimates indicated that 13,000 cu. yd. of rock and 50,000 cu. yd. of earth would have to be moved in building the sewer. It was also expected that considerable quicksand would be encountered, but at the time these notes were prepared no difficulty had been

experienced from this source. The earth excavation has been made by hand, the excavated material being handled out of the trench in buckets by stiff-leg derricks. The limestone rock, which is of an excellent quality and is crushed for use in making concrete, is loosened by blasting and stored along the sides of the trench. The contractor has installed a No. 3 Gates gyratory crusher in which the rock is reduced. The output of this crusher is raised to an elevated storage bin by a bucket elevator which delivers to a screen that separates the stone into the following three sizes: screenings, ¼-in. to ½-in. pieces and ½-in. to 1-in. pieces. The screenings are not used in the concrete, sand being employed for the fine aggregate.

Mr. H. F. Fardwell is sewer commissioner, and Mr. J. A. Hooke is assistant sewer commissioner of St. Louis, in charge of the construction of this sewer.

Letters to the Editor.

COST OF ENGINEERING WORKS.

SIR: I read with deep interest your editorial on "The Cost of Engineering Works," and thoroughly agree with you that it is unjust and unfair to attempt "to discredit the evidence of an eminent engineer of twenty to forty years' active professioal work," and such an attempt to so discredit such an engineer should be frowned down upon by the entire engineering profession.

When, however, an eminent engineer, goes upon the witness stand as an expert, he cannot object to inquiries as to the exact nature of his "active professional work," and upon which he bases his expert opinion. In a recent case which came under my observation, one such expert, of high standing and reputation, had actually no construction experience for over twenty years in which he was responsible for the results obtained, and his memory of his experience prior to that time proved to be extremely hazy. It will perhaps not be denied by anyone that in the engineering profession construction methods have somewhat progressed during the last twenty years.

Very truly,

ALEXANDER POTTER.

New York, Dec. 2.

CONCRETE COKE OVENS.

SIR: In reference to a letter in your issue of Nov. 16th upon the subject of "Concrete Coke Ovens," during the winter of 1906-7, the writer designed and supervised the construction of 350 beehive coke ovens, which are probably of the type referred to by your correspondent. In these ovens the ring wall foundations, larry-track columns, and battery retaining walls are of concrete, the ovens and oven floors being of fire brick. The battery retaining walls are 12 in. thick and reinforced with plain round rods. The observed temperatures on the outside and inside of this wall were 120° and 250° Fahr., respectively. It is not probable that the inner face of the wall is ever subjected to a higher temperature than 400° Laboratory tests would indicate that concrete is improved rather than injured by a steady heat of this temperature.

The ovens are the property of the Carbon Coal & Coke Co., of Trinidad, Colo., a subsidary concern of the American Smelting & Refining Co., and were first fired up in August, 1907. No bad effects have been observed to date and the writer sees no reason why ovens of this type should not come into general use wherever a considerable number of ovens are to be built at one time.

Very truly yours,

LINDSAY DUNCAN.

McGill. Nev., Nov. 26.

STEAM TURBINE ECONOMY.

SIR: Permit me to verify the statements made in your issue of Oct. 12, in connection with an economy test on a large turbine of the Parsons type at the station of the New York Edison Co. The accuracy of the results has been called into question, and I therefore desire, first, to uphold the accuracy of your published reports, and, second, to correct a popular misconception regarding comparison of turbine economies under different operating conditions.

The point at issue is whether the water rate of 14.9 lb. per kilowatt-hour, developed by the New York Edison turbine, represents higher economy than 12.5 lb. per kilowatt-hour, which is said to have been developed by a large Curtis turbine at the station of the Chicago Edison Co. Presumably the latter figures have been incorrectly quoted from a test recently reported on a 9,000-kw. turbine at the station of the Chicago Edison Co., which showed a maximum economy of 12.9 lb. per kilowatt-hour at 10,000 kw. load.

Now, as far as I am able to ascertain, the basic facts are these: Taking both machines at their point of maximum economy, the Westinghouse-Parsons turbine developed a water rate of approximately 15.1 lb. per kilowatt-hour output at the switchboard for two consecutive hours with an average steam pressure of 175 lb. gauge, 97° superheat and 27.3 in. vacuum. Correcting to contract conditions, 175 lb. pressure, 100° superheat and 28 in. vacuum, this is equivalent to 14.73 lb. per kilowatt-hour. The Curtis turbine, on the other hand, developed 12.9 lb. per kilowatt-hour, with 176 lb. pressure, 147° superheat and 29.5 in. vacuum. Correcting to the above contract conditions by percentages advocated by the builders of these machines, it develops that the equivalent water rate at the same load, is 15.08 lb. per kilowatt-hour. These results might be reduced still further, to a basis of dry-saturated steam, and still be within the limits of your published statement regarding the economic record established by the New York Edison tests, I believe the above figures will be sufficient for the point in view.

The inference drawn from the above, is that economy tests are not comparable from either a technical or a commercial standpoint, unless respective operating conditions are known, so that it is manifestly improper to question the accuracy of your published report upon such a superficial basis. And, in making comparisons, such as these (which heretofore have seemed neither necessary nor opportune), I do so purely in the interest of a clear understanding of the situation, not for the purpose of drawing illusive conclusions even though the latter may be quite tenable on careful analysis. In examining the performance of prime movers, we must not simply accept the rate of consumption of heat energy in the form of steam, gas or oil, but make comparisons on a true, scientific basis, else the results will quickly lead to erroneous conclusions. The sooner these principles are clearly understood and appreciated at their true value, the sooner will the apparently great disparity between turbine tests, such as those above outlined, be dispelled.

And herein, by the way, lies the greatest fallacy in the ceaseless struggle for high economies. Every engineer is, of course, interested from a personal standpoint, in the attainment of the highest cyclical efficiency for all forms of prime movers; but high efficiency, *per se*, means little from a commercial standpoint unless the cost of attaining it is reckoned. This is particularly true of the extreme operating conditions assiduously cultivated in turbine operation. Unquestionably, the results are spectacular, but when we take into consideration the extra cost, maintenance, the complexity of the additional auxiliary equipment, and the losses incident thereto, our enthusiasm wanes, and we intuitively seek a lower plane where efficiency and cost form a more reasonable balance.

J. R. BIBBINS.

CONCRETE PILES.

SIR: In a recent paper read by Mr. Charles R. Gow before the Boston Society of Civil Engineers, relating to experience in molding and sinking concrete piles, Mr. Gow referred to concrete piles constructed or built in place and those cast and driven. Piles constructed as mentioned were limited as to their length and their carrying capacity by reason of natural formation of soil penetrated, the composition of the material under and around the pile, which ultimately carried the load, and an approximate load of thirty tons was considered safe. Quoting Mr. Gow, "The extreme length of many of the piles introduced a serious question as to how best to handle them and avoid breakage. Piles up to 30 ft. in length could be picked up by the end without producing any undue strain; but over 30 ft. long, they almost invariably crack."

There has been considerable interest manifested of late in concrete pile construction. Further observations are hereby submitted relating to reinforced concrete piles produced by the rolling process, which is a decided departure from that introduced by Mr. Gow in his report. A specially designed machine for manufacturing and rolling round piles has been produced. Reinforced piles of various lengths and diameters have been made and used, giving considerable satisfaction.

Piles manufactured as stated can be driven by an ordinary pile-driving plant or a water jet. Experience has shown that they can be driven through all kinds of soil and endure the roughest kind of treatment without injury. Such piles were driven for the Erie Railroad at Susquehanna, Pa., under the foundation of the power house. They were constructed in various lengths up to 34 ft., and from 14 to 16 in. in diameter. The material penetrated was clay filling, furnace slag, and river silt to rock. On the Brighton Beach & Coney Island branch of the Brooklyn Rapid Transit Ry. four station foundations were constructed, using longer lengths, driven to compact gravel.

It has been observed that a concrete pile, in order to compete with a wooden pile, should be able to carry a much larger load than 30 tons by reason of its cost, and friction should not be relied upon to sustain the pile, as friction as a condition limits its application. When longer lengths are used and the piles driven to a firm foundation, 100 tons can be safely carried. Consequently fewer concrete piles can be used, replacing a larger number of wooden ones. The frictional resistance is no more than the pressure brought to bear by the displaced material through which the pile penetrates. Piles constructed in place where the displaced material is removed, have practically no frictional resistance, as shown by sinking tubes in deep well construction. They are easily driven after the material has been removed, with no great resistance. Piles built in place are very imperfectly reinforced, often not reinforced at all, which limits their carrying capacity.

Referring to the piles driven, manufactured as before stated, they were made by a machine set up at a convenient place. The reinforcing members consisted of a central tube, 2 in. in diameter, to which was fastened a steel wire fabric, 6 ft. wide and the same length as the pile, made of No. 16 steel wire, spaced every half in., securely fastened to the tube; eight square steel bars were fastened to the mesh and placed parallel to the vertical axis of the pile, equally distant apart. The diameter of these bars varies with the length of the pile. The ratio of the

diameters has been determined by previous experiment. A pile 62 ft. long requires the bar to be 1 in. in diameter. They are arranged in such a way that when wound in the convolution of the mesh they occupy positions near the circumference of the pile equally distant apart. The function of these bars is two-fold. They reinforce the pile against breakage by reason of its own weight and add to the carrying capacity as well. The fabric with bars in place is placed in the machine, over which a layer of concrete is deposited.

The concrete consists of a mixture of one part of cement, two of sand, and three of coarse gravel, evenly distributed over the wire fabric. The whole is then made into a roll by the machine and bound about every 6 in. with a No. 10 malleable steel wire and fastened, which forms a hooping the entire length of the pile. The pile is removed from the machine on a long car, transported to a convenient place, plastered on the outside and pointed, and in seventeen days it is ready for use. Being round, it can be handled with great ease, rolled down inclines, dragged by a hawser attached to one end, or suspended in the middle, dropped from a platform or flat car and rolled down an embankment, all of which has been done to test the capabilities of handling piles constructed in this way.

In construction, compression is used by heavy rollers that squeeze out all voids. The concrete becomes a dense, homogeneous mass. The finished roll, before the concrete sets, is so firm that it can be rolled around without inury. It takes twenty minutes to make a pile 35 ft. long.

This reinforcement of a pile with interlaced wire mesh, wound in convolution about a central steel tube, under compression rollers and bound about the exterior at regular intervals, produces a hooped column action throught out at a recent test made as to the load capacity of columns); and also a close connection of concrete and steel, whereby a simultaneous working of the two materials is obtained, when a load is applied.

The piles made for the foundation mentioned in Brooklyn, were rolled off skids, up an incline, to flat cars, transported to embankments 30 ft high, dropped off the cars, rolled down the embankment. When used a hawser was attached to one end, and in one case they were dragged 200 ft. over two tracks, by a winch driven by a pile driver. No cracks or defects could be discovered. They were driven by an ordinary pile driving hammer, weighing 2,500 lb. A cylindrical cap was used, containing a diaphragm. Below the diaphragm on top of the pile was a coil of old rope; above the diaphragm was 6 in. of sawdust and a wooden follower block, that received the blows of the hammer. The piles were of various lengths, from 30 to 35 ft., driven through the embankment to hard, compact gravel.

The piles driven at Greenfield Ave. station required 450 blows to drive them to hard, compact gravel, where they refused to move any further. The hammer was dropped 15 ft. and weighed 2,300 lb. A mixture of concrete of 1, 2 and 3, using gravel, seems to be far superior for pile construction than any other mixture, and is recommended particularly where water is to be encountered.

ALEXANDER CRAWFORD CHENOWETH.

Brooklyn, Dec. 7.

REINFORCED CONCRETE BEAMS.

SIR: Perhaps in this era of reinforced concrete construction, you may deem it advisable to submit the enclosed diagrams to your readers. They were devised by the writer some time ago, while designing structures for the U. S. Reclamation Service in the West, and have saved him many hours of unnecessary work. By using a slide rule in obtaining the bending moments, and then the diagrams, the depth of a beam and the necessary reinforcement can be determined in a few minutes.

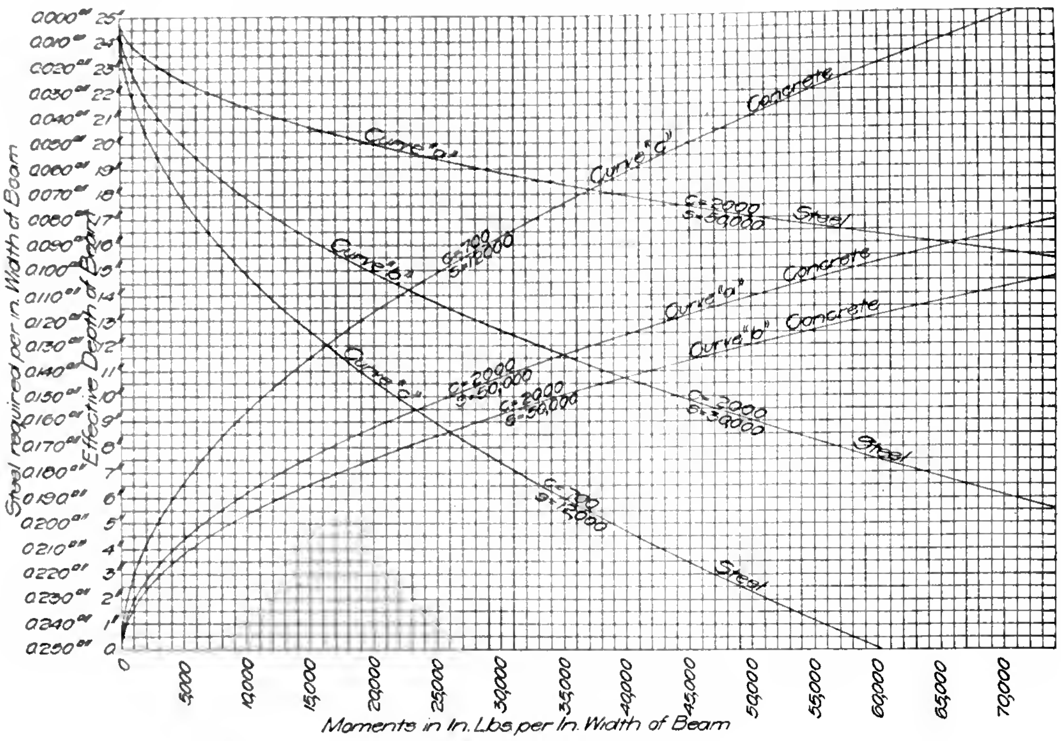


Diagram "A" for the Design of Reinforced Concrete Beams.

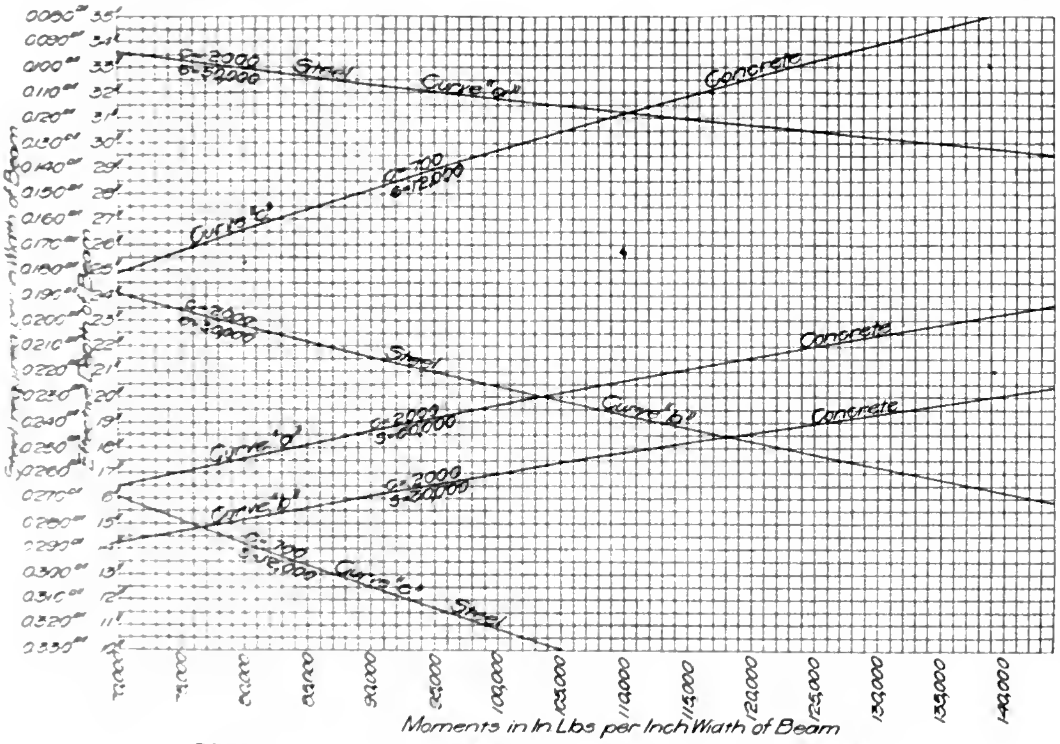

Diagram "B" for the Design of Reinforced Concrete Beams.

The bending moment in inch-pounds per inch width of beam is first obtained and multiplied by the factor of safety desired. Apply this to the bottom of the diagram, run up the vertical lines until the curve for concrete is intersected, and then run horizontally to the side of the diagram where the depth of the beam will be obtained. From 2½ to 3 in. more must be allowed for the covering of the bars. The same process followed to an intersection with the steel curve and then to the side of the diagram will give the steel required per inch width of beam.

Curves *a* are for a compressive strength in the concrete of 2,000 lb. per square inch and an elastic limit in the steel of 50,000 lb. Curves *b* are for a compressive strength in the concrete of 2,000 lb. and an elastic limit in the steel of 30,000 lb. With curve *c*, the factor of safety is already applied, or, rather, safe unit stresses of 700 lb. for concrete and 12,000 lb. for steel are used. The bending moment as found is applied directly to the bottom of the diagram. These diagrams are based on Taylor and Thompson's straight-line formula, the theory of which can be found in their book on "Concrete, Plain and Reinforced."

Very truly,

HENRY A. YOUNG.

Camaguey, Nov. 18.

PRIZES FOR TRACK SUPERVISORS to the value of $5,400 were distributed by the Pennsylvania R. R. in October for the tracks maintained in the safest and most perfect condition. The largest prize, $1,200, was for the line best maintained during the year, and the next largest, $1,000, for the division showing the greatest improvement. The remainder of the sum was divided into four $800 prizes for divisions showing especially good maintenance and improvement.

THE ENGINEERING RECORD

PUBLISHED WEEKLY BY THE

McGraw Publishing Company

James H. McGraw, Pres.; Curtis E. Whittlesey, Sec. and Treas.

MAIN OFFICES:

239 WEST 39TH STREET, NEW YORK.

BRANCH OFFICES:

CHICAGO: Old Colony Building.
PHILADELPHIA: Real Estate Trust Building.
CLEVELAND: Schofield Building.
SAN FRANCISCO: Atlas Building.
LONDON OFFICE: Hastings House, Norfolk St., Strand.

SUBSCRIPTION RATES.

United States, Cuba and Mexico	$3.00 a year
Canada	$4.50 a year
Foreign subscription	$6.00 a year
25 shillings. 25 marks.	31 francs.

Foreign subscriptions may be sent to our London office.

NOTICE TO ADVERTISERS.

Changes in advertisements intended for a particular issue should reach the office of THE ENGINEERING RECORD on Friday of the previous week. New advertisements can be received up to noon of Wednesday of the week of issue.

NOTICE TO SUBSCRIBERS.

REMITTANCES.—Remittances should be made by check, New York draft, or money order, in favor of THE ENGINEERING RECORD.

CHANGE OF ADDRESS.—The old address should be given as well as the new, and notice should be received a week in advance of the desired change.

BACK COPIES.—No copies of issues prior to July, 1906, are kept on sale, except in bound volumes.

DATE ON WRAPPER indicates the month at the end of which subscription expires. The sending of remittances for renewal prior to that date will be much appreciated by the publishers.

CLUB RATE.—In acknowledgment of assistance rendered by subscribers in the securing of new orders, a club rate of $2.50 per annum is quoted. This rate applies to subscriptions in clubs of two or more, at least half of the names in the club to be those of new subscribers.

Entered at the New York Post-Office as Second Class mail matter.

Of this issue of THE ENGINEERING RECORD 15,000 copies are printed. Total circulation for 1907 to date 748,000 copies, an average of 14,667 copies per week.

TABLE OF LEADING ARTICLES.

Cost Estimates in Hydro-Electric Transmission.

It is doubtful if any subject related to the production and sale of power for commercial purposes deserves more careful consideration at the hands of engineers than cost estimates in hydro-electric transmission. The reasons are not far to seek. Power distribution from steam plants is on the whole more restricted than transmission from hydraulic stations; the real question is narrowed down as a rule to securing the best location with respect to the market that is consistent with a given cost of land per square foot. The market itself lies within a smaller area, with rare exceptions; and the first cost, operating expenses and success of the selected equipment in service introduce few uncertainties unless standard types of apparatus are forsaken. There are, of course, notable exceptions to the prevalence of relatively narrow markets for coal-generated power in specific stations, such as the field of service of the Boston Edison Company's main station, or the distribution area of the Union Traction Company's central plant in Indiana. But in general there is little doubt that the commercial steam plant production is associated with more readily verifiable cost data than are available for hydro-electric estimates.

In the transmission of power from hydro-electric plants the competition of coal at distant markets, scattered over many counties, perhaps; the reliability of many miles of line operated at very high voltages; the fluctuations in the water supply at the generating station, the cost of flowage rights and of land for the transmission right-of-way, all complicate the estimated expenses and profits of the enterprise. Uncertain as these factors sometimes are they must be handled with the most unsparing frankness in preparing a sound estimate, and on top of all comes the vital question of development cost. To assume that a water-power project is a synonym for financial success simply because coal is eliminated from the generating process and fewer men are required at the plant per kilowatt of capacity, is the height of rashness. Recent observation of the commercial conditions in a number of hydro-electric plants confirms the conviction that the cost of development is second in importance to no other factor in the success of a modern transmission, on the monetary side.

Haphazard assumptions that the flow of a river as observed in one or two years can be counted upon indefinitely are likely to lead to serious expenditures for auxiliary steam equipment, especially in locations unfavorable to the storage of water in reservoirs. In proportion as records of flowage are in existence—and by records are not meant the stimulated recollections of the long bearded cross-roads grocery parliament—covering many years of extreme and average conditions, so will be the accuracy of the capacity estimate. So intimately is the development cost bound up with the available flow at different seasons in relation to head and storage, that long and painstaking checking and studying of the stream's discharge is amply justified, even though it increase the engineering cost by many hundred dollars.

Failure to utilize to the utmost every favorable natural condition in the hydraulic development exacts its tax in increased fixed charges. The estimate which overlooks the possibility of storage capacity for even 24 hours' operation falls short of the work. It costs money to keep a man on duty constantly and the boilers banked at an auxiliary steam plant, and where this is the practice, it is decidedly worth while to sit down and figure every possible scheme to secure one or two days' storage, at the least. It is not enough to make an estimate of the hydraulic development based on one or two hasty trips into the watershed to be utilized, and refreshed by hearsay data as to the flowage and drainage characteristics of the locality. Provision for the growth of the plant also receives scanty consideration in some reports. The cost of labor, of materials, expense of food supplies and of transportation may be lumped in a round figure of plant cost per kilowatt of capacity, but unless the local factors in these questions are known, uncertainty is given the chance to increase the fixed charges, which are as a rule the most important sum in the total cost of water power per unit of output.

Once the hydraulic development cost and probable average and minimum power available are carefully estimated, the way clears to a discussion of the rate problem. To a large extent rate consideration must be tentative in hydro-electric estimates, for under the stress of commercial operation and developing competition the rates may be obliged to change their shape if not their substance. Failure to estimate the minimum rate which, on the average, will pay the requisite operating expenses and investment charges, including depreciation of hydraulic as well as electric structures, invites disaster. There is little doubt that the charges of not a few hydro-electric power companies are too low, in consideration of the total cost of power production. Thus, to generate current in a hydraulic plant requiring the services of a steam auxiliary constantly as a reserve and often as a supplement, to transmit it 25 miles and sell it at from 3 to 1.5 cents per horse-power-hour even to consumers of moderate motor capacity, is a doubtful policy on the score of reasonable profit, even with coal at $6.00 per ton. In the particular system in mind which does this, it would be a difficult matter to raise the rates, for the present consumers never accurately figured the cost of their steam power before it was superseded by electricity, and were accustomed to paying power costs not in a single monthly bill, but in scattered items. If the original owners of the plant had made or purchased the necessary accurate cost estimates before embarking on the enterprise, the conditions to-day would be more favorable to securing the profit which could rightfully be expected in addition to the present divided rate.

The Policy of Secrecy.

An address by Dr. James Douglas, published on Dec. 7 in these columns, sets forth with admirable breadth of view the desirability of free interchange of ideas throughout the techincal world. Time was when, in all technical processes, profound secrecy was the order of the day. Patents were in ill odor, and the measure of protection secured by them was judged inadequate, so that when a valuable process was discovered it was worked behind closed doors so long as practicable and employees were muzzled as effectively as possible. The obvious difficulty of keeping many trade secrets against acute detective work and bribery has done more than anything else to check the practice, and while trade secrets still persist they are generally now of relatively minor moment, the really important advances being made the subject of patents.

Were the patent law more perfect and comprehensive, secrets would practically disappear and technical workers all the world over would live in a freer atmosphere. But the fact is that under the present rules of patent practice there are some things which are very difficult to protect adequately and others which can hardly be protected at all. One of the curious results of this is the not very infrequent use of a singular combination of patents and secrecy, a very generalized process being patented, *in terrorem* as it were, while the real process hidden behind it is practically a trade secret. In theory a patent must fully disclose to one skilled in the art the subject matter involved, so that the process could be actually worked or the apparatus successfully built on the basis of the published patent. As a matter of fact, and in the face of existing decisions, the nature of a technical disclosure is somewhat hazy and many patents are granted in which the disclosure is so incomplete that the real invention as practiced in very difficult to dig out of its environment. For example, if one looks up the patents on smokeless powder some very extraordinary misinformation can be se-

cured. Some of them are clear enough, but in others the list of alleged components and proportions is so vague that no one except the putative inventor could go ahead and make the supposed compound without a research quite equivalent to an independent invention. Some dye-stuff patents are almost equally bad, and it is reported that in the well-known case of the chemical final exhaustion of incandescent lamps one of the important defenses is incompleteness of disclosure. It is commonly said, too, that the data in some patents on photographic lenses are such as to require entirely independent redesign in order to produce anything of value.

In other cases, while the process of a patent may be technically fully disclosed, details necessary to commercial success are suppressed. All told, the number of commercial processes thus worked by practical secrecy although nominally patented, is very considerable. There are, besides, a good many instances of secret processes which, so far as anybody knows, are quite unpatented. Some few remain in the steel industry, in various metallurgical works, in the manufacture of special kinds of glass, and elsewhere. There is little doubt that in some cases secret details are important and valuable, and that the present patent system would not adequately protect them. Patents upon process are singularly hard to get in satisfactory shape, owing to various quantitative relations. In metallurgy, for instance, a particular reaction may give first-class yield only with particular proportions of ingredients or under peculiar temperature conditions. Infringement would be almost impossible to prove, even if the detail necessary to practical success could be patented, which is often difficult or impossible. The courts now distinctly recognize property in trade secrets and are disposed to protect it from theft or from improper use, as explained in previous issues of this journal.

Granting, then, that there may be wisdom in the preservation of trade secrets, one must admit that few technical manipulations really rise to that dignity. In most cases, the few little "wrinkles" held in a factory could be with great advantage swapped for others held somewhere else. It is one of the excellent functions of technical organizations to serve as a sort of clearing house for just these things. On the whole, and in the long run, a dog-in-the-manger policy does not pay either individuals or corporations. The engineer who freely and cheerfully gives helpful casual information on technical subjects to his colleagues makes more friends and gets more business than the solemn-faced chap who looks wise and hints grimly at important secrets when asked to lend a hand.

Of course an engineer, while developing a new apparatus or method, must in self-protection keep much to himself, lest some one with larger resources take the cue and push ahead of him. And yet stolen inventions are rare outside of novels—at least in the sense of inventions purloined prior to completion and developed for the benefit of the thief. There was a case of this sort a couple of years ago in which the inventor's mechanician queered an experiment and afterwards worked it out with some wicked partners and then sued the original inventor on the resulting patent. But the court arose and smote the offenders, and one can say generally that such larceny has very seldom been successful. In fact more inventors have suffered from failing to make disclosures of their work to their friends than have ever found disclosures misused. It is well, therefore, to take the optimistic view of human nature and to realize that one rarely meets a confrere who has nothing to give or is unwilling to impart what he has. One reason for the rapid progress of the arts and sciences in the last century was the growth of technical organizations and literature and the spread of a certain feeling of brotherhood among technical men.

At the present time there is more free and kindly interchange of information than ever before, and one has a right to expect still greater results in science and the arts. The technical papers read before various societies and the following discussions are rich in facts that a generation ago would have been jealously guarded, by which policy progress, which after all makes for general success, would have been checked. One kind of information, to venture a suggestion of improvement, ought, however, to be more freely given than is usual—and that is the results of failures. It takes a rather big man to own up to the futile things which he has attempted and yet such confession should be received with honor, for it is sometimes more valuable than the record of a success. Not only technologists but devotees of pure science are sometimes guilty of keeping very quiet about their failures. The result is a large amount of valuable human energy wasted in useless repetition of wearisome work. The best policy to-day is the broad-minded interchange of information, unless there are genuine and necessary trade secrets to be guarded, and these will steadily grow fewer.

Tests of Riveted Joints.

With the present requirements of large members for nearly every line of steel construction, it becomes of the utmost importance to reinvestigate the fundamental principles governing such construction before they are applied to members of much greater dimensions. The results obtained in the past by loading comparatively small members to failure, although in some cases few in number, have formed in reality the entire empirical basis of structural design. They have been of the highest value and, in general, it may be considered both rational and safe to reason from the tests of small members to the design of the largest now required, but that is not by any means the whole subject, even if the apprehensions created by the Quebec bridge failure be disregarded. The Engineering Record has already commented editorially upon the need of tests of the largest steel compression members which can be broken in any testing machine now existing, and all observations of that character applicable to compression members bear no less forcibly on riveted joints.

On the whole, a good many riveted joints which may be considered full-size have been tested to destruction, the most of such investigation having been done at the Watertown arsenal. This work, however, was performed a dozen or fifteen years ago before riveted joints had assumed anything like the magnitude in structural work which they now attain. A reference to the records of these and other similar tests will show at a glance the pressing need of an extension of that class of experimental work to joints of more nearly the proportions constantly employed in structural design of the present day. The plates then used were, in the main, much thinner than those now required, and the prevailing diameter of rivets now employed is seldom found in the older tests. Any one who has had occasion to test plates and shapes of light section will be impressed by the need of tests of joints built of much heavier plates than those of the old investigations and with the further need of using not only larger rivets to correspond with those now generally used in heavy work, but also greater numbers in the joints to be investigated. With joints of one or two rows of rivets, whether that joint be butt, lap or any other type, the distribution of the shearing stresses on the rivets or the tensile stresses in the net sections of the plates must be at least approximately uniform, eliminating any strong probability that the maximum intensity of either kind will be substantially different from the mean. That condition no longer holds, however, with three or four or more rows of rivets, which may easily be required in a structural tension joint, to say nothing of the excessive grouping of rivets found in compression joints, and allowing for the fact that the latter are usually supposedly of such a character as to permit the machined ends of plates and shapes to abut. Finally, the thicker plates produce a proportionately greater bending of the rivets. This latter is a most important consideration, for its influence in reducing the ultimate resistance of the joint is too complicated to permit its value to be computed with any sensible degree of accuracy.

The thinner plates not only leave the rolls at a sensibly lower temperature than thick plates, but they also generally have more work put upon them between the ingot and the final pass between the rolls, both of these effects tending to increase greatly the elastic limit and to some extent the ultimate resistance. A similar general observation, although of less force, may be applied to the smaller rivet in comparison with the larger. These and other material considerations go to show conclusively that while the values determined by the older tests of joints may not be, and probably are not, dangerously in error when applied to the heaviest connections now in use, there is sufficient reason to believe that either new values should be determined or the older confirmed by sufficient range of experimental work to include the full-size types now generally employed.

Public interest, at least that portion of it with industrial or technical affiliations, has been much stimulated during the past year or two by agitations designed to secure federal appropriations or funds from other quarters to be expended in full-size tests of structural members. No work of this character can be considered satisfactorily comprehensive without including the breaking of full-size riveted joints with such complete records of attendant phenomena as to solve all questions relating to the intensities and distribution of the tensile, shearing and bearing stresses developed in the various elements of the joints.

It is of special importance, among other things, to determine the effect of such unbalanced riveted connections as that of a group of rivets through the long leg of an unequal legged angle both with and without connecting lugs, and what may be taken as the real net section in such cases and others where the group of joint rivets is symmetrical about the centre line of the member, but with the outer rows of rivets diminishing in number nearly or quite to a point. In the case of the tension flange angles of a plate girder, when the rivets are staggered so as to make the net section the greatest practicable, no designer can be certain as to the value of that net section. Practice is by no means uniform in regard to these various questions of design of riveted connections, although they are of great importance as constituting the main features of the particular constructions in question. It is not possible to solve these questions of unsymmetrical arrangements of rivets or of real net sections except by full-size tests with the dimensions corresponding closely to those of actual work.

As already indicated, the apparent shear of rivets in joints, as determined by test would naturally be expected to be sensibly different from the ultimate shearing stress as determined for pure shear. The rivet has been upset to fill its hole in the process of heading, but, what is of more consequence, it is usually subjected to much bending unless the plate is thin. There are at

the present time not enough data to determine what may properly be taken as the working shear, with accuracy, in this branch of structural design. It is known well enough that when the rivet is subjected to heavy bending, its resistance to apparent shear is materially less than when such bending is absent, but a suitable allowance for thick plates has not yet been determined. Nor again can any engineer be confident of the value of rivets which bind three or four or more cover plates to the flange angles of a plate girder, supposing that the rivets fully fill their holes. Although riveted joints are constantly designed as if every element of any given case were completely known, few parts of a steel structure are in greater need of thorough experimental investigation.

Notes and Comments.

PASSENGER RATES between Pittsburg and Cincinnati on the boats of the Pittsburg & Cincinnati Packet Co. have been reduced to one cent a mile as a result of the two-cent fare on railroads required by recent legislation in Pennsylvania, Ohio and West Virginia. The loss of passenger business by the boats since the railroads reduced their fare was stated to be the cause of this cut in the rates. This does not look as if steamboats had such a tremendous influence as competitors of railways for passenger business as some inland navigation enthusiasts would have us believe.

THE CONNECTICUT RIVER BRIDGE at Hartford has been put in service, although it will not be formally dedicated until next spring. The design and construction of this imposing structure have been fully described in a number of articles in this journal, and it is therefore necessary to mention here only that it ranks among the finest masonry bridges of the world, which is only natural in view of the fact that Messrs. Alfred Boller and E. M. Wheelwright co-operated as consulting engineer and architect respectively in its design and Mr. Edwin D. Graves put so much of his ability and energy into his work as chief engineer that his health gave way under the strain about a year ago. The bridge has nine spans of lengths varying from 68 to 119 ft., its total length being 1,192½ ft. It is constructed of granite, and the simple grace of the spans and the strength of the piers make it a masonry structure well deserving a visit from those interested in bridge building.

THE ENGINEERS' CLUB of Philadelphia has recently shown good proof of its strong position by the purchase of a handsome house on Spruce St., which will be fitted up for a clubhouse. It is a four-story building, occupying a 25x170-ft. lot. Alterations will be made in it so that the second floor can be used as an assembly room for general meetings, and the first floor will have dining, smoking and meeting rooms. There will be a billiard room and other conveniences of a social nature in the building, and it is expected that with the greatly improved facilities the social side of the club will take an added importance. Attention is particularly called to this new home of the engineers of Philadelphia because it is an excellent example of what this journal considers the best thing for the engineering profession in any city. Engineering has so many branches, and those following them so rarely come together in a business way, that a club of this sort, combining both social and professional features, is highly desirable in any city large enough to have many engineers. What is wanted at the present time more than anything else in engineering circles is some centripetal tendency which will draw together all those who are engaged in designing or constructing works and machinery in any district. Until engineers get together socially and learn to know and respect each other personally there will be lacking that bond of good fellowship which has enabled physicians and lawyers to act unitedly whenever their interests required it. The Engineers' Club of Philadelphia is doing just this kind of good work, and its success should lead local engineering organizations elsewhere to strengthen their position in the same manner.

THE LIGHT MOTOR exhibited at the Paris Automobile Salon by M. Robert Esnault-Pelterie is interesting as bringing a little closer the practicability of aerial navigation. Few people realize that the distance between impossibility and possibility is almost reached, and that the engineer is the one who has the task of reaching and passing it. The successful construction of powerful motors of light weight, which has made the automobile a standard product, is an indication of what may be expected when more time and study have been spent on motors for aviation. The motor referred to weighs 2.86 lb. per horsepower, but its accessories and the propellor bring the total weight up to about 5.5 lb., and it is considered by some engineers who have looked into the subject that the greatest promise of successful reduction in weight is offered by a redesign of accessories and possibly by the use of some other source of power than gasoline. It is difficult to see how much more weight can be eliminated from the Esmault-Pelterie motor.

SOCIETY AFFAIRS are managed in some respects differently in Great Britain from the way they are here, as is evident from an announcement in the "Architect," of Dec. 6. It is given here in all its simplicity: "The Council of the Royal Institute of British Architects are prepared to receive applications for the appointment of secretary. Applicants, who need not necessarily be architects, should possess some literary capacity, a thorough knowledge of French and a working acquaintance with other languages. Age not less than about thirty or more than about forty-five years. The secretary will be required to devote his whole time to his official duties. Salary £500 per annum. Any canvassing will disqualify. Particulars may be obtained by writing to the Honorary Secretary, 9 Conduit St., W., not later than the 21st inst., and applications must be received by Dec. 31." It is worth while considering whether such a method of filling a vacant secretaryship of a great national professional organization may not have advantages when American societies have to appoint such officers, provided the constitutional requirements permit the procedure.

CENTRAL PARK, New York, is one of the city's most precious possessions. Visited during most of the days of the week it seems given over to wealthy drivers, riders and motorists, but on Saturday afternoon and Sunday it amply repays all the money spent on it. Children who otherwise would never know of birds and flowers, tired and worn men and women whose conditions of life have little enough sunshine and happiness to offset stern struggles, young people who see nothing attractive in Coney Island dance halls and the back rooms of saloons, fill the Park on such days. In the summer, particularly, this great open space for the people is a self-evident blessing to the city. It is therefore surprising that the municipal fathers pay no attention to the fact that the Park is wearing out. Five years ago, Mr. Samuel Parsons, who is the technical director of the Park Board's work, gave notice that the vegetation was dying out, but he was merely ridiculed then. Now anybody who knows about such things can see this for himself. Many of the trees and shrubs are past maturity and should be replaced. The thin layer of soil on the rocky bed of much of the Park needs mould and fertilizer, and a great amount of sodding must be done. The drives should be reconstructed and, as a matter of public health as well as public pleasure, the drainage of the land must be remodeled. These and other things will require about two and a half million dollars. It is a large sum, but it can be furnished in installments during a period of five years. It must be furnished before long or this chief pride of the city will deteriorate rapidly, and a place that has meant health as well as happiness to thousands of people of little means will lose much of its charm.

THE SETTING OF CEMENT has been discussed a great many times but it is safe to say that very rarely has a paper on the subject contained so much material for careful consideration as that by Messrs. Henry S. Spackman and Robert W. Lesley, printed in this issue. Mr. Lesley is not only a pioneer manufacturer of Portland cement in this country but he is also a student of the technology of the industry with which he is prominently identified. He is a firm believer in the obligation a successful manufacturer owes to the welfare of his industry, a belief that led him to endow the Lesley cement laboratory of the University of Pennsylvania. It has further led him to plan investigations into various aspects of cement and concrete that are still matters of dispute, and, with the co-operation of the Spackman Engineering Co., to carry on some most interesting research work, begun several years ago. The first fruits of this work was a paper on ancient Roman mortars read before the Association of American Portland Cement Manufacturers some time ago, and the second result is the paper printed on page 691. More studies are being made, and the results of all this work will form one of the most important contributions to our knowledge of structural materials ever made by an American manufacturer.

THE GRADE CROSSING PROBLEM was discussed very plainly by President Ralph Peters of the Long Island R. R. recently. He pointed out that notwithstanding the efforts of railroad companies to reduce the number of such crossings and the laws in many States providing for a joint expenditure of railroad and public funds for their elimination, there is a constant and persistent demand in every community for constructing more of them. The development of land schemes, of additions to towns and cities, the natural growth of communities in sections adjacent to railroads, have created new lines of travel and resulted in opening new streets and establishing new grade crossings. These crossings, when rightfully opposed by railroad companies, have been the cause of prejudice against corporations endeavoring to protect public interests as well as their own. The railroad is not so much responsible for the grade crossings as the public, for railroad managers are more than anxious to prevent more of them and to eliminate those in existence. They are ready to join in doing away with them, but feel that the work must be done with the co-operation of the communities and, in many cases, at joint expense. Mr. Peters urges that until all grade crossings have been eliminated, the public should not forget its joint responsibility for their existence and should use such crossings with great care. This opinion of the head of the Long Island R. R. is substantially that expressed in the laws of Massachusetts, the State where the respective rights of the public and of public-service corporations have received the most thorough study and the most equitable legislative treatment.

Appearance of Bridge on June 15th of this Year.

THE ERECTION OF THE ANCHOR ARMS OF THE BLACKWELL'S ISLAND BRIDGE.

The 630-ft. island span and the adjacent 591-ft. and 492-ft. cantilever arms of the 1,182-ft. west channel span and the 984-ft. east channel span have now been virtually completed, making a continuous structure 1,713 ft. long. This portion of the bridge has a total weight of about 48,700,000 lb. and is 135 ft. high above low water and about 320 ft. high to the tops of the main bents. Riveting, the construction of the upper floor, and other minor operations are now in progress on the cantilever arms, but the main travelers and steel falsework have been removed and are now in service for the erection of the anchor arms, 469½ ft. and 459 ft. long, on the Manhattan and Queens shores respectively.

Underneath each anchor arm a large storage yard has been enclosed by a high fence and in it a full length 85-ft. gauge track has been laid on which there is one of the two 65-ton gantries originally provided for the Blackwell's Island storage yard. Timber docks have been built near the piers at the water's edge, on both sides of the river, and equipped with 65-ton steel derricks with which the riveted members are unloaded from car floats and transferred on service tracks to the gantries, which pile and store them and finally deliver them to other service cars carrying them under the anchor arms within reach of the erection travelers, as they are needed. Shipments were commenced in January last, and since then about 11,000 tons of steel have been received at the Manhattan end and about 7,000 tons of it have been erected there. At the Queens end, about 8,000 tons of steel have been received since March, and about 4,700 tons were erected up to Oct 1. The construction of steel falsework for the Manhattan anchor arm was commenced in March, and erection was commenced in June and has since been carried on with a force of 75 to 150 men. For the Queens anchor arm the erection of falsework was commenced in April and of steel in July, and about 1,700 tons of steel were erected up to Oct. 1, with a corresponding number of men. The total weight of steel erected on Oct. 1 was about 68,000,000 lb.

The erection of the Manhattan anchor arm was commenced by a stiff leg wooden derrick with a 50-ft. 10-ton boom seated on top of pier 1, which built up the first two steel falsework towers and assembled on top of them the falsework traveler. This has a 33x57-ft. platform built up of stringers and floor-beams borrowed from the permanent structure, and carries one of the standard steel derricks with a 75-ft. boom of 65 tons capacity.

After several panels of the steel falsework had been erected and the falsework traveler advanced some distance beyond pier 1, the wooden derrick there commenced the erection of the No. 1 derrick used to assemble the permanent trusses. This traveler is of very simple construction, with a steel girder platform carrying two stiff-leg steel derricks with their masts braced together horizontally and diagonally, and having 65-ton booms, 85 ft. long. The traveler is operated by two special Lidgerwood engines and weighs about 300 tons with its rigging.

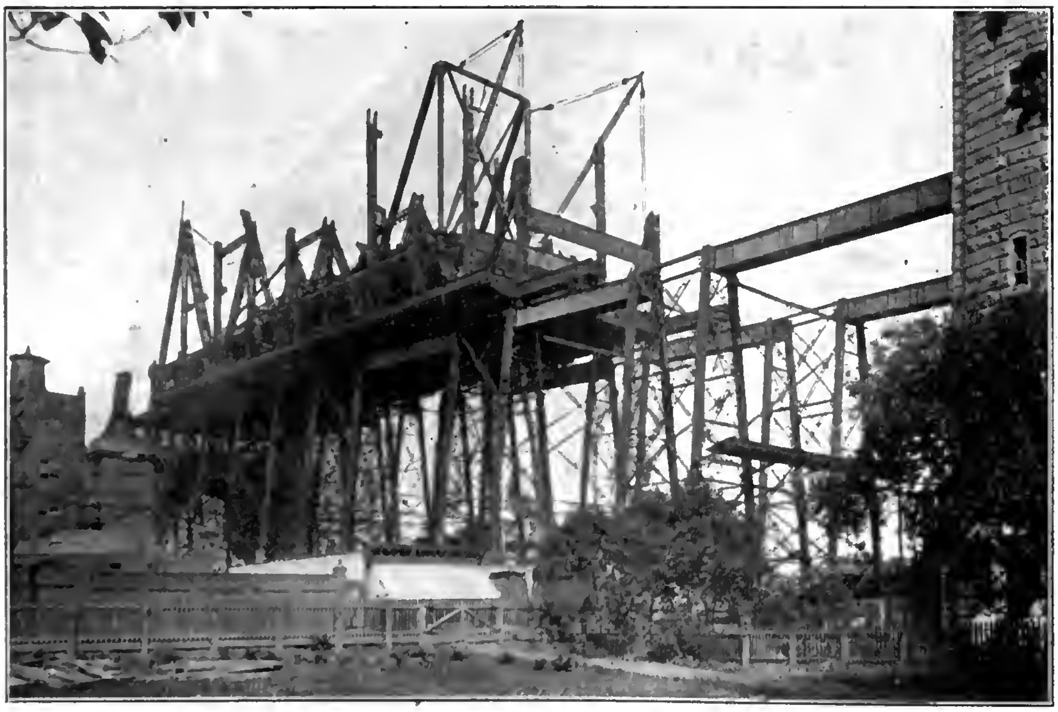
On the Queens anchor arm, traveler No. 1 has already progressed from pier No. 1 almost to the anchor pier, and has nearly completed the erection of the span up to the middle of the truss. On the Manhattan anchor arm, traveler No. 1 has now reached the anchor pier and completed the erection of the lower half of the truss, and the erection of the upper half has been commenced by traveler No. 2. This traveler has a Z-shaped side elevation and consists of a 36x40-ft. steel tower 124 ft. high, with an extended base and 63-ft. top overhang on the forward side to provide for the erection of panels of the truss in advance of the traveler for the cantilever arm. Although this function of the traveler is not necessary for the anchor arm erection, the large number of tackles are still suspended from it and it is equally serviceable in building the upper part of these trusses. This traveler, like No. 1, is operated by two special steam hoisting engines and, with its rigging and other equipment, weighs about 550 tons and requires a force of 60 men for its operation. No. 2 traveler is not yet entirely completed for the Queens anchor arm, but has been finished and in service for some time on the Manhattan arm, where its operations were at first supplemented by traveler No. 1, which for a time worked simultaneously with it erecting the upper parts of the trusses in the panels next the anchor pier as the traveler returned from that point toward the river.

The removal of the No. 2 travelers from the cantilever arms over the main channels was a work of some difficulty and was accomplished by means of the stiff-leg derricks seated on top of the travelers for use in erection operations and by a derrick and special falsework tower alongside. The first mentioned derrick was used for the removal of the overhang and part of the upper portion of the traveler. The remainder of the traveler was handled by a 10-ton 50-ft. derrick on top of a 29½x57-ft tower, 24 ft. high, seated adjacent to the traveler on the top lateral struts of the bridge. The tower was made with two transverse X-braced panels and a center post to carry the foot of the mast, which was supported on a small auxiliary tower, with bearing on the upper deck of the bridge.

Derrick No. 2 was re-erected on the Manhattan anchor arm, with a 13x18-ft. wooden tower, 70 ft. high, set at panel point 15. This tower was simply used as a support for the mast of the wooden stiff-leg derrick, with a 70-ft. boom of 10 tons capacity. The feet of the stiff-legs were anchored to the permanent trusses at panel point 16.

The booms for the large steel derricks were originally 75 ft. long, with a capacity of 65 tons. Since the completion of the island span and river cantilever arms they have been extended to a length of 85 ft. and reinforced to handle 75 tons. The rectangular cross section is now made up of two built channels, each with a 29x½-in. web plate and two 6x4-in. flange angles, latticed and connected by diaphragms 7½ ft. apart on centers. The links for connection with the topping lift tackle are six 6x¾-in. eye-bars 6 ft. 4 in. long, two of the center ones being bent to secure the proper spacing on the 3 and 5 in. pins. The bars are fixed in their relative positions with tie bolts and gas pipe separators. Similar links are provided for the hoisting tackle.

The plans and operations for the erection of the anchor arms correspond almost exactly with those for the island span and the cantilever arms,



Erection of Lower Part of Queens Anchor Arm with No. 1 Traveler.

described in previous issues of this journal. All of the principal web members of the trusses are erected in halves, spliced near the center of the height of the truss, the heaviest member being the 80-ton semi-diagonal nearest the main pier. As fast as the truss members are put in position temporary connections are made by inserting wooden pins 1 or 2 in. smaller in diameter than the holes, and later following them with the permanent pins preceded by ordinary sectional pilot nuts. The eye-bar members are assembled in complete panel groups in the storage yard, where they are accurately spaced and strongly clamped with steel and wooden yokes, after which they are handled like compression members as single units, the largest containing twenty separate bars and weighing about 65 tons. All truss pins are driven with an ordinary steel ram weighing about 2 tons. This has proved thoroughly efficient, so that it has not been necessary to use the hydro-pneumatic ram provided for this purpose. The 185-ft. vertical bents on piers 2 and 3, which weigh about 1,200,000 lb. each and were erected 8 in. out of plumb at the top, so as to provide for the reverse camber in the island spans, have gradually approached their final positions and are now exactly vertical and correspond to their calculated dimensions and locations.

Erection of Upper Part of Queens Anchor Arm with No. 2 Traveler,

There are in all about 752,000 field-driven rivets in the bridge, of which 125,300 are 1 in. in diameter, 426,850 are 7/8 in. and 199,860 are 3/4 in. Of these about 37,500 in the island span and adjacent cantilever arms are all driven. Field riveting on the Manhattan anchor arm is in progress in most of the vertical bents and includes pracically all of the rivets which can be driven without interfering with the possible adjustment of the members to take their share of the final stresses. All chord splices in the anchor arms are left entirely undriven, and no rivets are driven in the stringers at the main panel points. One end of each truss diagonal is left unriveted, and one end of each lateral diagonal or sway-brace member is also left unriveted.

On the island cantilevers a very large number of rivets in the bottom lateral system, floorbeams, stringers and lower chord splices were driven from a movable platform suspended underneath the lower deck of the bridge, which greatly facilitated the work and diminished the danger. The platform is 98 ft. long, transverse to the bridge axis and 26 ft. wide, and has a solid wooden floor protected by a hand rail and supported on a pair of wooden lattice girders 9 ft. deep and 98 ft. long. Long steel connection plates secured to the top chords of the girders are provided with a number of bolt holes to receive the lower ends of the suspenders. The latter are stiff vertical members made of angles and having hooked upper ends engaging the bulb angles which serve as guards on the outer flanges of two of the track stringers.

The platform was originally designed to have roller bearings on these angles, but after construction it was found easy to move it forward without the rollers, simply sliding on the angles by means of two small tackles anchored in advance and operated by hand. The roller bearings were therefore dispensed with, and the platform is rapidly moved back and forth by the men on it. Double sets of suspenders are provided, and when one set interferes with the floorbeams the other set is connected to the platform on the opposite side of the floorbeams, and afterwards the rear set is removed and the platform advanced. This arrangement saves time and expense otherwise necessary for placing numerous small riveting scaffolds and affords much greater convenience and safety for the riveters and painters.

On the lower deck of each of the anchor arm spans there is a small building, which contains an Ingersoll-Rand compressor of a capacity of 200 cu. ft. of free air per minute, driven by a Westinghouse 50-h.-p. electric motor. A special feature of the arrangement is the application to the motor of a pneumatic controller connected with the air in the receiver and adjusted to shut off the current in the motor when the pressure reaches 105 lb. per square inch and to turn it on when the pressure falls to 95 lb. The governor is of the standard type made by the Cutler-Hammer Manufacturing Co. The cooling water from the compressor is circulated through a Koven atmospheric cooler, where it falls in a thin sheet successively over a large number of horizontal steel discs arranged in a verical line, so as to cause a number of cascades. About thirty-two gangs of riveters are kept constantly at work, and the fitting-up for them is accomplished by four Philadelphia pneumatic reamers, which are also able to drill all the new holes required and frequently drill out bolts, rivets or drift pins that have to be removed. Compressed air at about 100 lb. is distributed parallel to the axis of the bridge through a screwed steel pipe 3 in. in diameter at the receiver, which gradually reduces and is provided with numerous valved outlets at convenient intervals.

There are about thirty pneumatic hammers used for general riveting, but for the rivets in the web splices of the bottom chords special pneumatic machines have been provided. These are designed to work in the 15-in. space between the webs, which could hardly be reached by ordinary methods. One machine has an X-shape framework, with two curved arms about 10 ft. long, intersecting on a common pivot like a pair of shear blades. The extremity of one long arm carries a pneumatic hammer, opposed to which is a holding-on die attached to the extremity of the other long arm. A pneumatic cylinder is placed at the opposite end of the machine, between the extremities of the short arms, to both of which it is connected. The long arms are set on opposite sides of the webs in which rivets are to be driven. The die is placed in engagement with the rivet head, and the pneumatic cylinder operated to separate the short arms and correspondingly converge the long arms, bringing the pneumatic hammer down close on the point of the rivet which is being held by the cap. The hammer is put in operation in the ordinary way and drives the rivets. Four of these machines are in service and are doing excellent work, having a capacity from 200 to 400 1-in. rivets daily.

Two other special riveting machines are so small and compact that they can be placed entirely within the chord in the 15-in. space between its webs. The cast-iron housing contains three horizontal pneumatic cylinders, transverse to the bridge axis. The center one, 4 in. in diameter, operates an ordinary pneumatic riveting hammer at one end of the machine, while the other two, 2 in. in diameter, operate cylinders at the opposite end on both sides of the machine, which, when pressure is admitted, are forced against one web of the chord and push the machine and pneumatic hammer against the opposite web, where the hammer engages the rivet to be driven. The latter is maintained in position by an ordinary pneumatic holder-on outside of the chords. This machine drives about the same number of rivets as the one previously mentioned, and both of them require four men to operate them. The rivets driven by them are 1 in. in diameter and about 6 in. grip. The painters follow the riveters and use the same suspended platforms.

The bridge was designed and its construction was executed under the direction of the Department of Bridges, of which Mr. J. W. Stevenson is now commissioner; Mr. C. M. Ingersoll, Jr., chief engineer; Messrs. O. F. Nichols and Albert Lord Bowman, consulting engineers; Mr. J. D. Wilkins, assistant engineer in charge of design, and Mr. J. B. Knighton, resident engineer. The Pennsylvania Steel Co. is the contractor for the fabrication and erection of the steel work.

AN ELECTRIC RAILWAY of considerable technical interest is operated by the Indianapolis & Louisville Traction Co. between Seymour and Sellersburg, Ind., a distance of 41 miles. The power-house is located at about the center of the route and direct current is transmitted from it at 1,200 volts, measured at the station between the single OOOO grooved trolley wire and the rails. There is an entire absence of high-tension feeder wiring and sub-stations. The station has two 26x48-in. Allis-Chalmers engines operating non-condensing at 120 r. p. m. These drive in pairs four 300-kw., 600-volt General Electric generators with their armatures mounted commutator to commutator on the engine shaft.

Retaining Walls on the Delaware, Lackawanna & Western R. R. at Buffalo.

The Delaware, Lackawanna & Western R. R. has just completed the reinforced concrete retaining walls for its track elevation work in the southeastern part of Buffalo, N. Y. Two general types of walls have been used, one for the sections below 12 ft. in height, and the other for sections from 12 to 24 ft., the last height being that of the maximum section. A buttressed wall is used for the higher sections, but because the saving effected by this type would not offset the extra cost of forming for the buttresses a plain L-section without buttresses was adopted for walls under 12 ft. in height. The forms for the latter are no more expensive than would be required for a plain concrete wall, while the saving of the L-section in concrete is evidently quite a material one. A wall with a toe projecting beyond the front face and under the sidewalk was first contemplated but objections by the authorities of the city of Buffalo prevented the adoption of such a design.

The tracks were placed near retaining walls only where the buttressed section was used, the distance from the center of the track to the back of the wall in no case being less than 7 ft. 6 in. No tracks whatever were close to the section without buttresses, the retained fill having a long slope up to the roadbed level. The earth pressure against the walls, which are 2 ft. thick, was figured according to the formulas in Church's Mechanics, the weight of earth being taken at 100 lb. per cubic foot. The weight of concrete was taken as 150 lb. The pressures due to the moving loads on the tracks were figured for Cooper's E 50 loading. The width of the base for the buttressed type was taken as half the height of the wall above the top of the base plus 2 ft., and for the L-section as half the distance from the top of the base to a point where a vertical line through the inner edge of the base intersects the slope line, the slope being 1½:1. The base is 2 ft. 6 in. thick. The stresses in the steel were kept under 16,000 lb. per square inch and in the concrete under 500 lb.

The reinforcement of the buttressed section consists of both horizontal and vertical bars near the face of the wall, horizontal bars in the base and inclined bars in the buttresses, square mild steel being used in all cases. Those laid horizontally in the face of the wall are ⅝-in. material spaced on different centers, farther apart at the top and closer at the bottom, to take care of the increasing pressures toward the bottom of the wall. The vertical bars in the front face are of ½-in. material spaced throughout on 2-ft. centers. In the back face five ½-in. bars have been placed on 18-in. centers. Tie rods run from the wall into each buttress, two of them being looped over every third of the horizontal face bars. They are 6 ft. long and ½ in. square. The heaviest bars used on the work, 1¼ in. square, are used for the diagonals in the buttresses. There are eight of these, but only four run the entire distance from the top of the wall to the outer end of the base, the others starting at intermediate points. At the bottom of the buttresses, four of the diagonal bars are bent back toward the wall and are embedded near the under side of the base. Running longitudinally in the top of the latter are 1-in. square bars, in the outer half of the footings. The rods in the face do not come closer than 2½ in. to the surface of the concrete, and those in the buttresses and in the base not closer than 3½ in.

In order to preserve the proper spacing for the horizontal bars in the face a 2 x 2 x 3-16-in. angle is placed in the face at each buttress, holes being punched in one leg to hold the bars in their proper positions. They are left in place and form part of the permanent reinforcement of the wall. The horizontal bars are on 18-in. centers for the first 6 ft. down from the top, on 12-in. centers for the next 6 ft., on 9-in. centers for the next 5 ft. 3 in., and on 6-in. centers for the remainder of the distance to the bottom of the wall.

The reinforcement for the sections below 24 ft. and above 12 ft. in height is substantially the same for all sections, except that the base would be moved upward cutting off the lower part of the reinforcement shown in the diagram, so that from the top down for any given distance the steel will be the same in walls of all heights.

The buttresses are 2 ft. wide and 12 ft. 6 in. on centers. In the original design it was intended to place an expansion joint every 25 ft., or on the center line of every second buttress. When construction was started, however, it was found that the wall could be more economically placed in 50-ft. than in 25-ft. sections and it was therefore decided to place the expansion joints every 50 ft., so that the day's work could be made to terminate at an expansion joint.

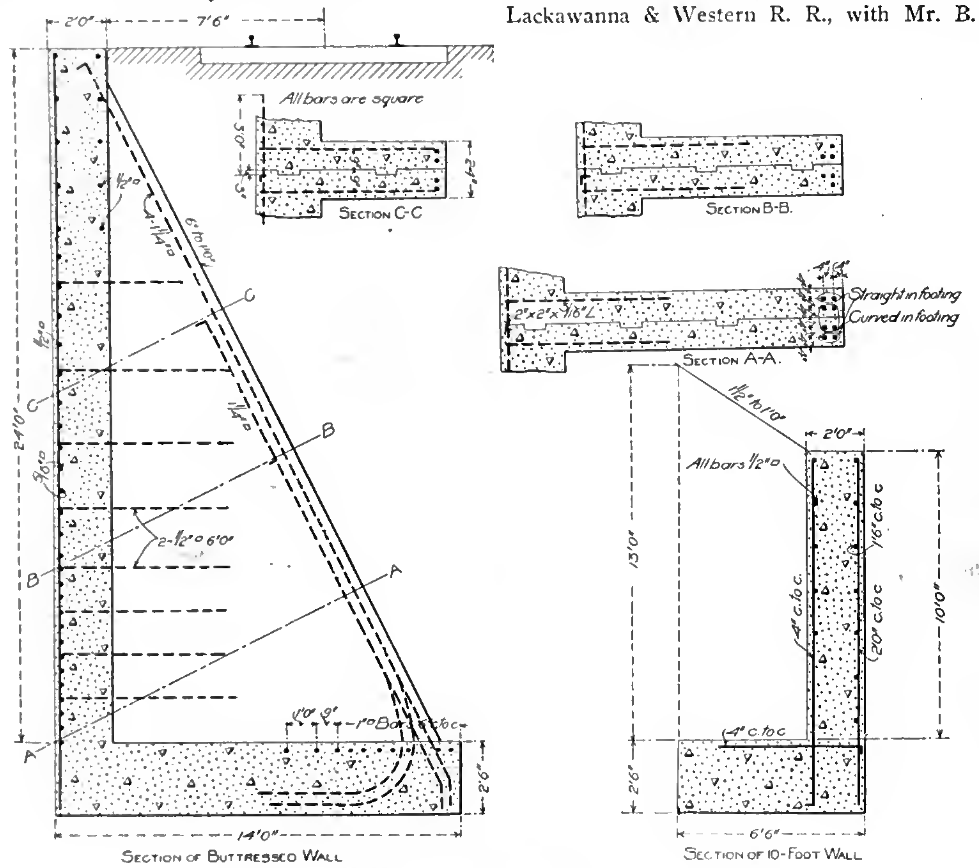
All of the horizontal bars are 28 ft. long, while the others, necessarily, are cut to shorter lengths in accordance with their positions. The concrete was a 1:3:6 mixture made with gravel.

For the lower walls without buttresses the reinforcement is similar to that of the 10-ft. wall in the diagram. For this particular height it consists of ½-in. square bars in the base and in both faces of the wall. The vertical bars in the front face are on 2-ft. centers, and the horizontal bars on 18-in. centers, while in the back face the vertical bars are on 4-in. centers and the horizontal ones on 18-in. centers. The bars in the base are placed horizontally on 4-in. centers and run from the front of the wall back into the footing.

An accompanying photograph shows clearly the placing of part of the reinforcement before the concrete was cast. As will be noted, great care was exercised in holding the steel in its proper place. A board notched on both sides with the proper spacing for the diagonal bars was used to prevent the displacement of the steel. Similar notched boards were placed in the base to hold the bars in proper position, and at the upper ends of the diagonal bars in the buttresses. For the latter purpose the notched piece was nailed to a bracket attached to the front form for the wall. The vertical and horizontal bars, in addition to these precautions, were wired at intersections so as to insure against displacement. The concrete was placed very wet and on this account long ½-in. rods threaded at both ends were used to tie the forms together.

The walls are now completed and although on account of the soft nature of the ground along the right of way, all of them rest upon piles, no cracks have occurred. Of the maximum section, 24 ft. high, there is a total length of 1,700 ft., and of this length 1,000 ft. are in one continuous wall.

The wall was designed under the direction of Mr. L. Bush, chief engineer of the Delaware, Lackawanna & Western R. R., with Mr. B. H. Davis in immediate charge of the work. The field construction was in charge of Mr. R. M. White, resident engineer.



Reinforcement in Buttressed and L-Sections.

COMPETITIVE DESIGNS for the proposed municipal office building for Greater New York have been invited by the city from thirteen architectural firms. The building, which is to cost about $8,000,000, is to stand near the Manhattan end of the Brooklyn Bridge and its lower floors will be used as the Bridge terminal for surface, subway loop and elevated trains. The floor space for offices, exclusive of halls, shafts and courts, is 600,000 sq. ft., necessitating a building 20 stories high, which will accommodate all but two of the municipal departments. The firms invited to compete are J. Stewart Barney, Carrère & Hastings, Clinton & Russell, J. H. Freedlander, Cass Gilbert, Heins & La Farge, Helmle & Huberty, Hoppin & Koen, Howells & Stokes, H. R. Marshall, McKim, Mead & White, Trowbridge & Livingston and Warren & Wetmore. It is understood that Mr. Cass Gilbert will not compete. Each firm will receive $1,000, and the winner will receive $5,000 for his design if the city does not accept it. The judges agreed upon are Frank Miles Day, president, American Institute of Architects; William A. Boring, vice-president, American Institute of Architects, and Francis C. Kimball, designer of many large New York office buildings. The designs are to be submitted April 15, and the decision announced on May 14, 1908.

Pipe Lines for Hydraulic Power Plants.

The technical staff of the Telluride Power Co. have organized the Telluride Institute, and at its meetings papers of an engineering character are presented for discussion. One of these, by Mr. Arthur Jobson, was on pipe lines for hydraulic power plants, and an abstract of it follows:

The determination of the most economical diameter for the penstocks of high-head hydraulic power plants is often a troublesome problem to the engineer. The principal factors on which the solution of this question depends are quantity of flow, static head, probable total cost of development per horse-power, and cost per pound of the pipe or penstock erected. Its proper solution is particularly important should the proposed plant be one of high head, in which case the cost of the penstock will be a large percentage of the total cost of the installation.

Methods of Holding Reinforcement in Place.

Long Stretch of 24-Foot Retaining Wall on Lackawanna Track Elevation, Buffalo.

The power lost in a pipe line per unit of length for a fixed quantity of flow varies inversely as the fifth power of its diameter. On the other hand, its cost per unit of length for a fixed static head will vary as the square of the diameter. Hence it follows that should a pipe of very large diameter be selected for the purpose of increasing the efficiency of the pipe line, the value of the extra amount of power obtained due to this higher efficiency may not merit the increased investment required. It also follows that should a very small size be selected for the purpose of reducing the annual charges on the investment, the resulting loss due to the lower efficiency of the pipe line may more than offset this reduction in annual cost. As a result it is important in fixing the diameter of penstocks to consider both the cost of the pipe installed and the loss of power in the pipe during the operation of the plant. These losses should be balanced, one against the other, in such a manner that the resultant due to each factor acting in coincidence, shall be as small as possible, consistent with the total first cost of the plant and its operating expenses.

In deriving an expression for the most economical diameter of penstocks, two methods of procedure may be adopted: (1) The yearly interest and depreciation on the first cost of the pipe may be obtained in terms of its diameter, and also the value of the power lost in the pipe line per year in terms of the diameter. Evidently the sum of these two expressions will be the total loss per year due to each factor acting in coincidence, and if this sum is derived with respect to the diameter, a diameter will be obtained such that the sum of these losses will be a minimum. (2) The sum of two ratios may be obtained in terms of the diameter; one ratio being that of the total cost per unit of length of the pipe installed to the total cost of the proposed installation, and the other, the ratio of the power lost in the pipe to the total rated capacity of the plant. If this sum be derived with respect to the diameter of the pipe, a diameter will be obtained such that the sum of these ratios will be a minimum.

Either one of these two methods will result, theoretically, in the most economical size of pipe. In developing this expression the second method will be adopted, the values of the letters and symbols used being represented as follows: Q = quantity of flow in cubic feet per second; V = velocity of water in feet per second; D = diameter of pipe in feet; t = thickness of pipe in feet: S = safe tensile stress of metal in pounds per square foot; P = internal pipe pressure in pounds per square foot; A = internal cross-sectional area of pipe in square feet; h = static head in feet; h' = loss of head in feet due to pipe friction; f = coefficient of pipe friction; c = cost in dollars per pound of installed pipe; k = weight of metal used in pounds per square foot; N = total cost of proposed installation in dollars; C = cost of pipe installed per unit length; H = total cost of installation per horse-power.

The following well-known formula represents the loss of head per unit of length in a circular pipe flowing full of water:

$$h' = 2 f V^2 \div Dg \ldots\ldots (1)$$

Since $V = Q \div A = 4Q \div \pi D^2$, by substituting this value for V in (1), $h' = 32 f Q^2 \div \pi^2 g D^5$. Assuming the combined efficiency of a water wheel and generator to be 75 per cent. for large units, the following is the expression for the horse-power developed from a water-power installation: Horse-power = 0.0851 $Q h''$, where h'' is the effective head. Hence the loss of power per unit length of pipe due to friction will be given by:

$$\text{Horse-power lost} = 0.0851\ Q\ h' \ldots\ldots (3).$$

Substituting the value already derived for h' in (3):

$$\text{Horse-power lost} = 2.723\ f\ Q^3 \div \pi^2\ g\ D^5 \ldots (4).$$

Let $H.\ P.$ equal total horse-power of plant, and r' equal ratio of horse-power lost to $H.\ P.$ Then,

$$r' = 2.723\ f\ Q^3 \div \pi^2\ g\ D^5\ H.\ P. \ldots\ldots (5)$$

The volume of the pipe per unit of length will be given by $t\ \pi\ D$, and its weight per unit of length by $k\ t\ \pi\ D$. Hence,

$$C = c\ k\ \pi\ D\ t \ldots\ldots (6).$$

But, $t = P\ D \div 2\ S$, and, $P = 62.4\ h$. Therefore, $t = 31.2\ h\ D \div S$. Substituting this value for t in (6), gives,

$$C = 31.2\ c\ k\ \pi\ D^2\ h \div S \ldots\ldots (7).$$

Let r'' = ratio of C to N.

$$r'' = 31.2\ c\ k\ \pi\ D^2\ h \div S\ N \ldots\ldots (8).$$

Hence,

$$r'' + r' = 31.2\ c\ k\ \pi\ D^2\ h \div S\ N + 2.723\ f\ Q^3 \div \pi^2\ g\ D^3\ H.\ P. \ldots\ldots (9)$$

This last expression is the one sought for, namely, the sum of the ratios of the cost of the pipe per unit length to the total cost of the installation, and the power lost per unit length of the pipe to the available power, in terms of the diameter, D. If this expression is derived with respect to D and equated to zero, the resulting value of D will be that for which the sum of these ratios will be a minimum. Let $R = r'' + r'$.

$$\frac{dR}{dD} = \frac{62.4\ c\ k\ \pi\ D\ h}{S\ N} - \frac{13.615\ f\ Q^3}{\pi^2\ g\ D^6\ H.\ P.}$$

Equating this expression to zero and solving for the power of D, we get:

$$D^7 = 0.218\ f\ S\ N\ Q^3 \div c\ k\ \pi^3\ h\ g\ H.\ P. \ldots (10).$$

Let H equal total cost of installation per horse-power.

$D^7 = 0.218\ f\ S\ H\ Q^3 \div c\ k\ \pi\ h\ g$.....(11).

The safe tensile stress of ordinary steel may be taken at 8,000 to 10,000 lb. per square inch and its weight 490 lb. per cubic foot. Assuming 8,000 lb. per square inch as the value of the safe tensile stress, and its weight per cubic foot as given above; also reducing π and g to their proper numerical values,

$D = \sqrt[7]{(0.5145\ f\ H\ Q^3 \div c\ h)}$.......(12).

Allowing S to remain in the formula, we get:

$D = \sqrt[7]{(0.0000004466\ f\ S\ H\ Q^3 \div c\ h)}$..(13).

Several objections will no doubt arise as to the value of the above derived formula in actual practice. Foreseeing a few of these possible objections and questions, they will now be discussed before attempting to make an application of the formula.

The first question which may arise is: Does the value of D as given in this equation represent a fixed value for the total length of the pipe to be installed, or is it a variable quantity depending upon the static head impressed upon each unit of the pipe? It will be remembered that h is the total, or static head under which the proposed plant is to operate. It will also be seen that the cost of the pipe installed was computed on the basis of unit length, and furthermore, that in making this computation the diameter and thickness of this unit length was assumed constant. But in the final cost formula, $C = 31.2\ c\ k\ \pi\ D^2\ h \div s$, t is eliminated, its value being replaced in terms of h. Hence it follows that the cost of the pipe per unit of length is a direct function of the static head impressed upon that particular unit length, and from this it follows that the value of D as given by equation (13) is the most economical size of pipe for that unit length and the static head impressed upon it. Evidently then D is not fixed for any particular installation, but varies as the static head upon the different parts of the pipe varies. In computing the most economical size of pipe at the power station, h represents the actual or static head of the installation, but in computing the most economical size of pipe for the same installation under half the static head of the station, then the value of h to be substituted in the final formula will be represented by one-half the actual head. Hence the interpretation of h will have to be changed. Instead of defining it as the actual head of the installation in feet, it will now be defined as the static head impressed upon a unit length of pipe for which the most economical size is being computed.

No serious questions can arise regarding the values of S and Q in the final formula. The tensile strength of the metal to be used in the pipe may be determined very closely, and when once determined, the value of S then depends upon the allowable factor of safety. The quantity of flow is usually one of the first factors to be definitely fixed in a proposed hydraulic power development, as this and the effective head are the two factors which determine the rated horse-power capacity of the plant. However, some allowance should be made for load factor in fixing the value of Q, as it is the average quantity of flow which should be used to determine the proper size of pipe rather than the maximum.

The most serious questions which may arise in making a practical application of this formula are those which will be suggested in making substitutions for f and H; the coefficient of pipe friction, and the cost per horse-power of the proposed installation in dollars. Each of these quantities are functions of D. Rankine gives $f = 0.005\ (1 + 1/12\ D)$. This, however, is not strictly true. Experiments show that the value of f depends not only upon the diameter of the pipe, but also upon the velocity of flow. J. T. Fanning gives in "Hydraulic and Water Supply Engineering," p. 233, several tables showing the value of f for various pipe diameters and velocities of flow. These values were determined by experiments with smooth iron pipes, and are probably correct, within a reasonable degree of accuracy. In these tables it is shown that for a pipe 18 in. in diameter, f varies from 0.00559 to 0.00451 at velocities of flow ranging from 1 to 20 ft. per second; a decrease of approximately 20 per cent. If the velocity of flow is fixed at 20 ft. per second, then f varies from 0.00481 to 0.00381 for pipes varying in diameter from 12 in. to 36 in., a reduction again of approximately 20 per cent. In any case the value of f should easily be fixed within 10 per cent. of its true value, since for a fixed quantity of flow a variation in velocity of flow of from 1 to 20 ft. per second would result in a decrease of diameter in the ratio of 4.5 to 1. Assuming that it is possible to select the value of f within 10 per cent. of its true value for the most economical size of pipe, then the resulting error in computing the diameter of the pipe from equation (13) will be the seventh root of 10 per cent., or approximately 1.4 per cent. From this diameter of pipe which is in error 1.4 per cent., the velocity of flow may be easily determined, which will be in error approximately 2 per cent. But for these slight errors in both D and the velocity of flow, the resultant error in the selection of f from the tables will be almost inappreciable, and in substituting this new value for f in equation (13) for recomputing D, evidently this error will be inappreciable in the diameter since the seventh root of the error will be taken. Hence one computation of D, with an assumed value of f, is all that is necessary to determine the true value of f within reasonable limits.

As has already been mentioned, the cost of a hydraulic power plant is a function of the high-pressure pipe used in the installation. Also, in the substitution for the value of H in equation (13), the objection may be made that the value of H cannot be definitely determined before the proposed plant is completed. However, after all preliminary investigations have been made in regard to such a plant, experience has shown that the cost of the plant completed and ready for operation can be predetermined very closely. At least the permissible investment should be known within reasonable limits after all the factors affecting the sale and generation of power have been investigated. If it is impossible to estimate even approximately the actual cost of the plant, then the value of the permissible investment should be used for H.

Let it now be assumed that all the factors entering into the cost of a proposed plant are known with the exception of the cost of the high-pressure pipe. This may be roughly estimated at first, to be determined more definitely after a computation of the diameter has been made, using the above rough estimate. For instance, let it be assumed that the estimated cost of a plant is \$90 per horse-power, \$15 of which is the estimated cost of the pipe line. However, upon computing D on this basis, and then computing the cost of the pipe for this value of D, it is found that the cost of the pipe will be \$7.50 per horse-power, instead of \$15 as first estimated. Hence in using \$90 per horse-power instead of \$82.50, which is very near the true value, an error of about 1.3 per cent. was made in the computation of D. Since the cost of the pipe varies as the square of the diameter, an error of approximately 1.7 per cent. was made in computing its cost on basis of \$90 per horse-power, instead of \$82.50. But a variation of 1.7 per cent. in the computed cost of the pipe (D being determined on a basis of \$15 per horse-power), when taken in connection with the total cost of the installation per horse-power, is scarcely appreciable, and is inappreciable when substituted in equation (13) for computing D. Hence, as in determining the proper value for f, two computations are all that are necessary. First, estimate as near as possible the cost of the pipe. Use this value in connection with the other factors entering into the total cost of the proposed installation for H. Determine the value of D on this basis; knowing D determine the cost of the pipe. If this computed cost is reasonably close to the estimated cost, no change need be made in the value of H. If it is not, then change H to correspond to this new value of the pipe cost and recompute the value of D.

For the purpose of making an application of this formula the following hypothetical case will now be assumed: Let $h = 1800$; $Q = 30$; $f = 0.005$ (for first computation); $H = 100$; $c = 0.11$. Two different forms of pipe will be assumed, lap-welded for the high pressure, and riveted pipe for the lower pressures. Let safe tensile stress for lap-welded pipe equal 8,000 lb. per square inch, $= s'$, and, safe tensile stress for riveted pipe equal 10,000 lb. per square inch, $= s''$. The efficiency of the riveted joints will be taken at 70 per cent.

With the above assumed static head and quantity of flow the capacity of the plant will be approximately 4,500 h.-p., and its total cost \$450,000 at \$100 per horse-power. The total length of the pipe line will be assumed to be 5,000 ft., and its cost, erected, \$45,000; one-tenth of the cost of the plant. In making this computation the method of procedure will be as follows: The length of pipe subtended between the static heads of 1,800 and 1,500 ft. will be given a constant diameter and definite length; between the static heads of 1,500 and 1,250 ft., also a constant diameter and definite length, and so forth; decreasing the difference of elevation between the terminals of pipe lengths having fixed diameters as the elevation increases. In computing D by equation (13), the mean static head upon sections of fixed diameters will be taken, and also in computing the cost of these different sections the mean static head will be used. This will result in no error in cost computation, since the thickness of the pipe is a direct function of h where D is constant.

TABLE I. VALUES OF DIFFERENT FUNCTIONS FOR VARIOUS HEADS.

h	l	D'	V	C	f	D'
1,800 to 1,500	450	1.68	13.5	\$9,500	.00453	1.66
1,500 to 1,250	500	1.73	12.7	\$9,300	.00450	1.698
1,250 to 1,000	300	1.78	12.0	\$4,850	.00449	1.75
1,000 to 800	400	1.84	11.2	\$5,550	.00447	1.807
800 to 600	400	1.90	10.6	\$4,600	.00445	1.872
600 to 400	600	2.00	9.5	\$5,500	.00440	1.96
400 to 250	500	2.08	8.8	\$3,730	.00437	2.042
250 to 150	700	2.23	7.7	\$3,700	.00431	2.174
150 to 50	950	2.47	6.3	\$3,070	.00424	2.41
50 to 0	200	3.00	4.3	\$ 240	.00406	2.917

The diameter of the pipe will first be computed on a basis of f equals 0.005, and pipe cost equals \$45,000. This will be designated D'. Having D', the true value of f may be obtained closely from the tables, and also very near the true pipe cost may be computed. Using these values of f and of pipe cost, D will be recomputed.

Substituting in equation (13) the values assumed for this hypothetical case: $D' = \sqrt[7]{(63{,}100 \div h)}$, for the lap-welded pipe, and $D' = \sqrt[7]{(55{,}400 \div h)}$ for the riveted pipe. Also from equation (7) $C = 0.00455\ D^2\ h\ l$, for the lap-welded pipe and $C = 0.0053\ D^2\ h\ l$, for the riveted pipe.

In the accompanying Table I the computations are tabulated in the order in which they were made. The first six sets of values are for lap-welded pipe and the remainder are for riveted pipe. The total cost of the pipe as given in the first computation is \$50,040. This value is so near the estimated cost of the pipe that no change need be made in H for the second computation of the diameter. Hence in recomputing D the original expression was changed only by the values of f as given in the above table, instead of the constant value 0.005, as first assumed.

The Stone Crushing Plant at the Menard, Ill., Penitentiary.

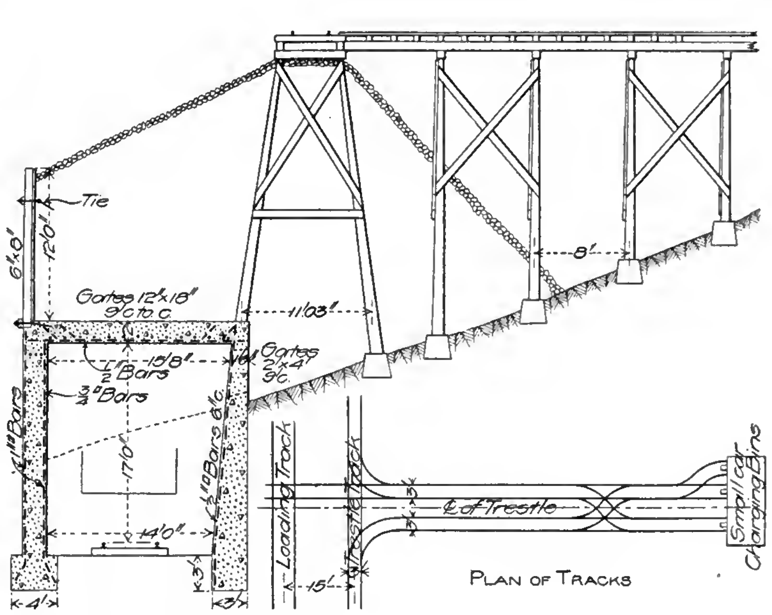
The Illinois State Highway Commission has, as one of its functions, the regulation of the distribution of crushed stone produced by convict labor at the State penitentiaries. Under regulations formulated by the Commission, this stone is supplied free to township or county highway officials for use on the public highways, the local officials paying the freight charges. It is also used by the Highway Commission in the construction of experimental roads.

When the act creating the Highway Commission was passed, in May, 1905, there was, at the Southern Illinois Penitentiary, at Menard, on the Mississippi River, about 70 miles below St. Louis, a stone crushing plant consisting of a No. 6 old-style Allis-Chalmers crusher, run with a 90-h.p. Westinghouse engine and an O'Brien boiler. This plant, which is operated entirely by convicts, is within the prison stockade and has a capacity of about 350 cu. yd. per 8-hr. day. As soon as the provisions of the State Highway Commission act became widely known, "free macadam" was in such demand that this plant became entirely inadequate. Accordingly, in the crusher like that already installed and, as will be seen later, the storage capacity can be greatly increased with very little difficulty.

A new quarry at Menard has been opened up in the rocky bluff, which is characteristic of the east bank of the Mississippi River from St. Louis to Cairo. Just north of the prison yard this bluff rises on an angle of nearly 45 deg., from the river bank to a general height of about 250 ft. above the water. The rock formation, which is a fairly good limestone, is overlaid on top of the bluff with considerable clay soil, a great quantity of which has been gradually washed down over the bluff, reducing the steepness of the incline and necessitating some difficult excavation before solid foundations can be secured. At the foot of the bluff, near the water's edge and parallel to it, a bench about 50 ft. wide is maintained, on which are the tracks of the Missouri Pacific Ry. and the Illinois Southern Ry., the latter being on the river side. Just inside the railroad tracks and about 15 ft. above them, is a county highway, the east fence of which is the west boundary of the State property available for the crusher site and quarry.

The crusher, which is an Allis-Chalmers, rotary No. 7½ machine, is located on the side storage pile and under which the railroad cars are run to be loaded. Small dump cars, operated by hand on the trestle tracks, deliver the stone from the three small receiving bins to the storage pile under the high single-track trestle.

The wall on the east or quarry side of the loading track supports one side of the floor of the storage bins; it also acts as a braced retaining wall, supporting the material on the hillside. It is 22 ft. high, 3 ft. wide at the base, and 16 in. wide at the top and is reinforced near its free face with ½-in. vertical twisted bars spaced 6 in. center to center. On the river side of the loading track the weight of the stored material is carried by series of 15x24-in. reinforced concrete columns. These columns are spaced 6 ft. on centers and each rests on a concrete pedestal 4 ft. square and 3 ft. deep. Each column is reinforced with four 1-in. twisted bars, one in each corner, and these are hooped at 18-in. intervals with No. 8 steel wire. The columns carry a reinforced concrete girder 24 in. wide and 37 in. deep, including the 20-in. floor slab of the storage bins. The girder is reinforced with four ¾-in. bars placed in a plane just above the crowns of the soffits of the arches. No arching effect was considered in the preparation of the



Stone Crushing Plant at the Southern Illinois Penitentiary, Menard, Ill.

spring of 1906, the Commission, in accordance with its powers as defined in the convict labor act, called on the Board of Prison Industries to install additional crushing plants at the Menard and Joliet penitentiaries. The Joliet plant, which has no unusual features, was put in operation in a few months. At Menard, a side-hill installation was required and it was decided to construct storage and car-loading pockets in connection with the crushing plant. This plant has been completed and put in operation only recently. The combined capacity of the plants at the two prisons amounts to about 1,350 cu. yd. per day.

Among the considerations that influenced the design of the Menard plant was the fact that it is desirable to employ convicts as steadily as possible. The preparation of crushed stone for road construction, at a plant without storage facilities, can be carried on economically only during the summer and fall when the crushed stone can be loaded directly from the crusher bins into cars and shipped to the work. Even during the working season it seemed likely that the men would often be idle because of lack of cars or delays on the construction work. With storage facilities, however, the crusher can be run more steadily and better advantage can be taken of empty cars when they are available. It is thought that the present storage pockets at Menard will be practically equivalent to another hill with its head at the elevation of the quarry floor, which was placed at El. 167 on the advice of Dr. H. Foster Bain, State Geologist, whose examinations indicated that the stone below this elevation is of a poor quality. The crusher has a capacity of 500 cu. yd. per 8-hr. day and is driven by a 100-h.p. Chandler & Taylor engine supplied with steam by a 150-h.p. Allis-Chalmers boiler. The engine and boiler rooms are placed on the north side of the crusher building, the engine-room floor being at El. 149.3 and the boiler-room floor at El. 134.8.

The skip cars loaded with uncrushed rock are run downgrade to the crusher and their contents delivered by gravity. The crushed stone passes by gravity from the crusher to the screen and from the latter falls into three small bins, built over two 3-ft. tracks which extend on a slight down-grade on a timber trestle nearly perpendicular to the general north and south direction of the quarry face. About 50 ft. from the crusher house the two tracks on the outgoing trestle diverge and turn off on a single-track trestle whose general direction is parallel to the quarry face. The rails of the single-track or storage trestle are about 27 ft. above the surface of the hill directly beneath them. The trestle legs on the up-hill side rest on concrete pedestals, while those on the down-hill side rest on a reinforced concrete structure, which partially supports the designs, the arches being introduced solely for their appearance. The 20-in. floor slab is reinforced transversely with 1-in. bars, 4-in. center to center, and longitudinally with ½-in. bars, 8-in. center to center.

The outside walls of the storage bins are made of 2-in. planks nailed to 6x8-in. posts, the feet of which are placed in niches along the edge of the floor slab, where they are secured by rag bolts and a continuous waling piece. A second waling strip is secured to the posts near the top of the bins, and provision has been made for securely anchoring the posts against the outward pressure of the retained material by ties running to deadmen buried in the hillside. The crushed stone is dumped from both sides of the longitudinal trestle track, and the pile rests partly on the concrete floor and partly on the hillside. The different sizes are kept in separate piles by light plank partitions. Most of the stone is admitted to the railroad cars through 12x18-in. gates in the floor of the bins over the center line of the loading track, spaced 9 ft. on centers. When the supply of stone is so low that it does not run freely through these gates it can still be delivered to the cars by gravity and without shoveling, through 2x4 ft. gates in the side wall, spaced 9 ft. on centers.

The switch track to the storage pocket leaves the Missouri Pacific Ry. about 1,300 ft. south of

the crusher. It crosses the tracks of the Illinois Southern Ry. and, continuing northward on a rising grade, crosses the county highway at grade and runs along the bluff in a bench cut through the storage plant and several hundred feet beyond. Empty cars are stored on the track north of the crusher and are run under and away from the storage packets by gravity. At present only 125 lin. ft. of concrete structure has been built, 62½ ft. north and 62½ ft. south of the center line of the double-track trestle from the crusher. The length of the storage pockets can be increased readily whenever this seems desirable. It is estimated that the storage pile will contain about 3,500 cu. yd. per 100 lin. ft.

The excavations for the crusher plant foundations and for the loading track amounted to about 1,300 and 8,000 cu. yd., respectively. Though the excavated material was mainly earth, the work was very difficult owing to the great number of buried boulders which from time to time had broken off from the outcrop at the top of the bluff, and rolled down the side hill. Many of these necessitated blasting. All the work was done with convicts, three of whom in general are equal to two ordinary men, and with mules and wheel scrapers. Some of the earth was wasted and the rest was used in forming an embankment for the switch track near its junction with the main line.

The material excavated at the crusher site was delivered to wagons in the switch-track cut through an open chute 2 ft. wide and 2 ft. deep. As the chute could not be placed at a grade steep enough to cause the earth to slide freely, the latter was scraped down with a specially designed scraper made to fit the chute. This was drawn by a mule which walked on a path at right angles to the chute, lines and pulleys being arranged so that the scraper was pulled down as the mule walked one way and up as he walked in the opposite direction. The earth was delivered to the chute in wheelbarrows, and boulders too large to be handled in this manner were rolled down the hill. The crusher machinery was brought to the site from the main line of the railroad in wagons over a road built along the side of the bluff. Coal and other supplies are now hauled to the plant over the same road.

The reinforced concrete structure was built entirely by convict labor and the construction presented no unusual features. The concrete was hand-mixed.

The plans and specifications for the entire installation were prepared by Mr. A. N. Johnson, State Engineer. The plant was built under the direction of the Board of Prison Industries, whose general representative on the work was Gen. J. B. Smith, warden of the Southern Illinois Penitentiary. The storage pockets and the foundations and houses for the crusher, boiler and engine were built by convict labor. Mr. W. S. Gearhart was resident engineer for the Board of Prison Industries during the early part of the work, and Mr. W. T. Beckelhimer during the later part.

A 55-Ton Traveling Tower Crane of unusual working radius has been placed in service on the docks at the harbor of Santa Cruz, on the island of Teneriffe. The tower section, about 20 ft. in height, is carried on six legs, each traveling on a four-wheel truck. The crane member pivoted to the tower is a double-truss structure, 138 ft. long, overhanging 105 ft. from the pivot to the hoisting end and 33 ft. in length from the pivot to the counterbalance. It is designed for a capacity of 55 tons at a radius of 58 ft. from the pivot. The crane is operated electrically, a 54-h.-p. motor being used, both for hoisting and for moving the tower, a 15-h.-p. motor for revolving the crane and a 30-h.-p. for the trolley.

Experiments on Wind Pressure.

About five years ago Dr. T. E. Stanton began a series of investigations to determine the distribution and intensity of the pressure of the wind on structures. This research work was proposed by the Committee of the National Physical Laboratory of Great Britain as the first investigation to be undertaken in the Engineering Department of the Laboratory. The first part of this research was communicated to the Institution of Civil Engineers in December, 1903, and related to the resultant pressure and distribution of pressure on flat plates normal to and inclined to the direction of a uniform current of air.

As those experiments were made in a channel 24 in. in diameter, the dimensions of the plates were necessarily small, but between the range in dimensions obtained, which for circular plates was from ¼ in. to 2½ in. in diameter, the results indicated that the resistance of geometrically similar plates was proportional to the area of the plates. In the case of dissimilar plates, however, such as square plates and long rectangles, the resistances per unit area differed considerably.

The value of the resistance so found in these experiments on small plates was somewhat smaller than that determined by Dines, Frowde and Langley for plates of the order of 1 square foot in area. For comparison, the values of the constant, K, in the pressure velocity relation, $P = KV^2$ are given in the following table:

Experimenter	Method	Value of K
Dines	Whirling Table	0.0029
Frowde	Moving Carriage	0.0037
Langley	Whirling Table	0.0033
Author	Plate in uniform current	0.0027

On the completion of this part of the work, it was decided to make observations on flat surfaces of areas ranging up to 100 sq. ft. when exposed to the wind, since general experience tended to show that in actual winds whose velocity was not uniform over time or space, the mean pressure per square foot on a large surface was considerably less than that on a small one. As a knowledge of this variation in resistance with the dimensions of the structure, if it exists, is all-important in design, the investigation of this problem was made the chief feature of the new experiments. This work was described by Dr. Stanton in a paper read before the Institution of Civil Engineers on Dec. 3, of which an abstract follows.

For the purpose of the work a steel windmill tower was erected in the grounds of the National Physical Laboratory at Teddington. The experimental boards and models of structures were attached to a light framework carried by the cap of the tower, the height of the center of the boards from the ground being 50 ft.

After some preliminary experiments, the method of observation finally adopted was the determination of the constant in the pressure-velocity relation for pressure-boards of varying dimensions and for the models of structures. It was found, as anticipated from a knowledge of the variable character of the velocity of the wind, that single observations were quite worthless for the purpose in view, but that, if for any pressure-board or model about 200 observations of the velocity of the wind and the corresponding pressure on the board were taken, it was possible to obtain a fairly accurate value of the constant. In these observations the velocity of the wind was estimated from a pair of pressure-tubes, similar to those used by Mr. Dines in his anemometer, placed about 15 ft. above the center of the board. These tubes were connected by lead pipes to a sensitive water-gauge, of the type used in the author's previous experiments, placed at the foot of the tower. The resultant pressure of the wind on the board was estimated from a measurement of the pressure produced in a closed cylinder of air by the deformation of a thin steel diaphragm forming its cover which was in contact with the center of the pressure-board. This pressure was also transmitted through lead pipes to the foot of the tower, and there measured by a similar tilting gauge to the one used for the velocity estimations. The simultaneous observations of pressure and velocity were only possible in the short periods of time in which the velocity of the wind was fairly constant. Such periods, lasting from 2 to 5 seconds, were found to occur about once a minute in a fairly steady breeze.

The results of these observations on three pressure-boards, one 5 x 5 ft., one 5 x 10 ft., and one 10 x 10 ft., gave practically identical values of the constant in the pressure-velocity relation. In units of pounds per square foot and miles per hour, the mean value of this constant for the three boards was 0.0032. As this value agreed so well with the average of those obtained by previous experimenters when using plates of the order of 1 sq ft. in area, it was not considered necessary to make experiments on plates smaller than the one 5 x 5 ft. in the present case.

Further observations on the intensity of the pressure at the front and back of the boards appeared to show that the cause of the higher value of the constant compared with that obtained in the case of the small plates in the 24-in. experimental channel, was the relatively greater intensity of the negative pressure at the back of the boards compared to that at the back of the small plates.

Experiments were also made on a model of a braced-girder 29 ft. long by 3 ft. 7 in. deep, and on a roof model whose sides were 8 x 7 ft. The ratio of the resistance per unit of area of the model girder to that of a square board in the wind was found to be precisely the same as the ratio of the resistance per unit of area of a small model of the girder made to a linear scale of 1 in 42 to a square plate in the experimental channel and uniform current used in the previous experiments.

The resultant pressures on the roof were obtained, for both windward and leeward sides, at angles of 30, 45 and 60 deg. inclination to the horizontal, and indicated the considerable suction effects on the leeward side of a roof when the pressure inside the building is augmented from the windward side by open doors or windows.

These results lead to the conclusion that the resistance of a complicated structure in the wind can be accurately predicted from a determination of the resistance of a small model of the structure in an experimental channel.

The Motor Boat for naval service appears, from discussions at the recent meeting of the Society of Naval Architects and Marine Engineers, to have some advantages over the steam launch. The question of reliability of the gasoline engine as a prime mover, which has heretofore deterred its more general adoption for naval service, has been practically settled by elaboration of design and refinements in construction, so that the general opinion is that when a well-built engine is placed in the hands of a man trained for the work, it is sufficiently reliable for naval use. It was pointed out in the discussion that the launch engine is not subjected to the jar and vibration that attend the operation of the automobile motor, and that the latter engines have now been made so flexible and reliable that 100-mile sealed-bonnet tests are possible. The saving of space required for the machinery over that of the steam launch is 20 to 25 per cent., according to the design of the engine.

The Gatun Dam.

The annual report of the Isthmian Canal Commission for the past year, and the issue of the "Canal Record" for Dec. 4, together give some instructive information concerning the Gatun dam, which is the crucial feature of the Panama Canal design. In one of the appendices to the Commission's report, Mr. Ernest Howe, geologist, furnishes a detailed account of the geology of the site of this great structure. According to his statements, the sides of the broad lower valley of the Chagres at Gatun converge and the stream passes through a gap in the mountains which is a little over one mile wide. The geological conditions at the site of the dam are the result of many changes. At some time after the Gatun beds had been deposited, the central and southern portions of the present isthmus were subjected to volcanic disturbances and the whole region underwent considerable deformation. The geology of the central portion of the isthmus indicates that a vast amount of erosion took place following the elevation of the land, and that the sedimentary and later volcanic rock now exposed represent but a very small part of the bed that originally covered the region. There were three great uplifts which threw these beds out of position and the third resulted in the streams intrenching themselves in deep canyons in the material left by the second uplift. When the Chagres River had succeeded in cutting somesomething more than 200 ft. below the second level, the land began to sink and the gorges were gradually filled with gravel, sand, silt and clay. It is believed that this sinking continued until a large part of the Colon level now represented by swamps, was submerged and covered by sea water. Finally there was a slight elevation of the whole region, which raised these deposits a few feet above tide level.

During the periods of maximum uplifts, when streams were flowing in canyons like those of the Chagres, the rivers were heavily charged with detritus. All of the finer part of this material was swept down to the sea, the coarsest was deposited along the upper portions of the stream, but gravels and small boulders filled the stream beds to the mouths of the rivers. Where subsidence took place before the period of canyon cutting has ceased, as in the case of the Chagres, the velocity of the streams was checked and they were capable of carrying only fine material, which was deposited far back from the mouths. As a result, in the bottom of such a gorge as that of the Chagres at Gatun, there is a comparatively thin deposit of coarse gravel, sand and a few boulders, while the greater part of the alluvium is of the finest clay and silt, with a certain amount of fine gravel and sand mixed with it.

The boring records indicate considerable sand and gravel at points comparatively near the present surface; Mr. Howe considers that it is unlikely, however, that any sand or gravel, unmixed with clay, occurs in the deposits except at or very near the bottom. The reason that the boring records specify "Sand and Gravel" is that when the samples are taken from time to time during the process of sinking the hole, only the coarsest material is collected, the finer clay being held in suspension and carried off with the water flowing from the hole. In certain of the holes temporary flows of water were encountered, but after a few hours these invariably ceased. They are believed to occur when, in the course of making a boring, the casing is introduced into a lenticular deposit of sand or water-bearing gravel under pressure from the overlying bed. The sands, being surrounded by much less pervious material, are in the nature of reservoirs in which water is stored under pressure, and when this pressure is released at the point where the casing enters the sand, water may rise to the surface if under sufficient pressure and flow from the top of the casing until the pressures are readjusted. Professor Howe believes that far from indicating porous materials underlying the site for the dam, the occurrence of such flows of water only proves the extremely impervious character of the materials lying between the surface and the water-bearing beds. As a foundation for an earth dam, he considers that the geological facts show that the alluvium filling the valley of the Chagres at Gatun will be entirely satisfactory.

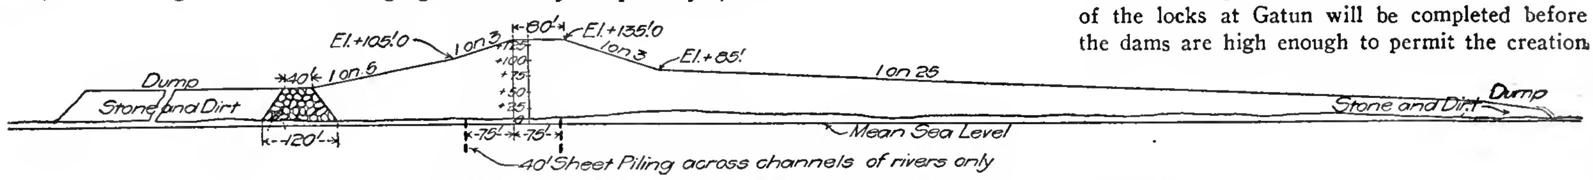
The great locks will be at the northeast end of this dam. They will be almost entirely in fine-grained argillaceous sandstone, except at the lowest point to be reached at the extreme southern end, where conglomerate occurs beneath the sandstone. The sand of which these rocks are composed was derived from the older igneous rocks of the region. The debris resulting from the breaking down of these rocks was transported by the streams to the sea and deposited, layer upon layer, until some 200 ft. had accumulated. Considerable clay was mixed with the sand, and this, together with the lime derived from the sea water, acted as a cement and bound the grains of sand together, forming a massive rock.

The rocks from which the sands were derived were almost, if not entirely, destitute of quartz, and the sandstones lacking this mineral are more subject to decomposition than rocks consisting principally of quartz sand. As a whole the rocks are stated to make excellent cores with the diamond drill. When taken out and exposed on the surface they remain firm and hard; in rare instances they have been found to crumble and break down into a sandy clay. The rocks are well compacted and capable of supporting heavy loads when confined, but being poorly cemented are unable to withstand erosion, and should be fully protected where such action is anticipated. On account of the very considerable amount of clay present in all of the rocks, it is believed by Mr. Howe that they will prove to be almost entirely impervious to water, except in the case of the conglomerate. Wherever the latter is encountered, it may be expected to be water-bearing at all times. This rock stands in vertical walls without timbering in a test pit sunk into it, and so long as it is confined it will support heavy loads.

The section of the Gatun dam has recently been slightly changed, and the accompanying diagram shows the revised form. The method of building the dam and filling the lake is explained in the "Canal Record" substantially as follows:

The total length of the dam is about 7,700 ft. from the locks on the northeast to the hills on the southwest. At about its middle point there is rising ground, now known as Spillway Hill, where the regulating works are to be built. It is proposed first to dig a channel about 300 ft. wide through Spillway Hill, the bottom of it to be at sea level or thereabouts. The Chagres River will be passed through this channel during the construction of the dam across the valleys on either side of the hill. As soon as the portions of the dam abutting on Spillway Hill are high enough to hold from 50 to 55 ft. of water in the lake it is proposed to build across the channel through Spillway Hill a concrete dam high enough to hold the lake at this level. This will be done to facilitate the work of dredging in the Chagres Division. During the dry season following the completion of this dredging the dam across the channel through Spillway Hill will be brought to its full height, and a permanent spillway constructed, which will include the necessary regulating works, by means of which the surplus water of the lake will be passed down to the level of the sea.

Preparations will be made for closing the channel through Spillway Hill before the Chagres is turned into it, and all closures will be accomplished during the dry season, thus enabling the Chagres to form a lake to the height of the dam across the spillway channel during the following wet season. It is considered probable that Gatun Lake will not be allowed to fill to the height of 50 or 55 ft. until the upper end of the lock at Gatun has been completed and the upper gates have been erected. If this plan of procedure is carried out and the progress of the work comes up to anticipation, the upper portion of the locks at Gatun will be completed before the dams are high enough to permit the creation of the lake at 50 to 55 ft. elevation. This lake will make water transportation available for handling large quantities of timber that will be submerged by the lake, and contracts may be let for cutting this timber, or it may be sold standing to the highest bidder. The exact capacity of Gatun Lake has not yet been known. The total amount of excavation at the Gatun lock, dam and spillway up to Dec. 1 has been 1,136,000 cu. yd.



The Revised Cross-Section of the Gatun Dam of the Panama Canal.

A BRICK CHIMNEY under construction for the 59th St. station of the New York Steam Co. lost a small section of its top in a hurricane on Dec. 14. The chimney is being built of perforated radial brick by the M. W. Kellogg Co. and will be 264 ft. high and 17 ft. in diameter at the top. The condition of the chimney at the time of the accident is stated by Mr. M. W. Kellogg, president of the M. W. Kellogg Company, to have been as follows: "On Friday, the day before the storm, the brickwork of the chimney had been completed to within about 12 in. of the cap at the top, the chimney wall having been carried up about 2½ ft. on that day. Practically no work was done on Saturday morning, owing to the snow, which later turned to rain. Upon increase of the wind in the afternoon to a gale of 70 miles velocity, the brickwork freshly laid at the top on the afternoon before was dislodged and fell. A careful investigation indicates that none of the brickwork but that laid on Friday and which was still green was affected. The height of wall dislodged was from 2 to 2½ ft., but, owing to the circumference of the chimney at the top of about 55 ft., the quantity of material that fell was large, probably 20 tons." When the top of the stack fell it crashed through the roof of an adjoining building, killing one person.

Accuracy of Slide Rule Computations.

By John Berg.

When preliminary estimates on engineering works are of such a nature that the slide rule can be used in their computation, then this little instrument ought to be employed. It not only saves considerable time, but it saves much mental effort; and the final results are more apt to be free from large errors than when all the work is done the long, tedious way. To sit day after day for seven or eight hours, with only a short intermission at noon, multiplying and dividing, and not doing much else, is very tiresome work. I have also found that I am more liable to errors during the latter part of the afternoon after such a day's work.

I have known the average end-area formula to be used in finding the volume of a prismoid; the unit weight per cubic foot assumed to the nearest tenth of a pound; the stress in full members computed to the nearest pound and better. More consistent would it have been to have used the prismoidal formula in finding the volume; assume unit weight per cubic foot to the nearest pound; compute stresses to the nearest hundred pounds, and do all the work of multiplication and division on a slide rule—i. e., by graphic logarithms. There is much less chance for a large error in the latter result, and it should be obtained with less fatigue and greater speed.

Practical opportunity has recently been afforded me to test the accuracy of slide rule computation, especially in the reduction of cubic feet to cubic yards, and, though having already had a good deal of respect for the efficiency of the slide rule for accuracy on computations, I was more than satisfied with the results obtained in the investigation. Omitting one large error, apparently due to a slipping of the slide and reading before re-setting, and instantly discovered on a rapid and rougher check of the work, the following results in division were obtained:

Of 28 three-figure quotients, ranging in magnitude from 391 to 999, inclusive, 23 were correct to the nearest unit; the remaining 5 were each 1 unit too small. However, the maximum "unit" error in the case of the 5 quotients was really only ⅔ and not 1; or, reduced to a percentage basis, the maximum error was 0.11 of 1 per cent. The sum of the 28 numbers representing cubic feet was 510,349; the sum of the 28 quotients as obtained by the slide rule was 18,900 cu. yd., a sum that is too small by 1.8 cu. yds.; i. e., the sum as obtained from slide rule results is in error by less than 0.01 of 1 per cent.

A similar study was made of 116 quotients ranging in magnitude from 1,007 to 8,590, inclusive, the numbers being pretty well distributed under the respective groups given in the accompanying table.

With the exception of group 9, maximum and total errors had to be added to the corresponding slide rule result to give the correct amount.

Of the 144 quotients only 2 were in error by as much as 0.1 of 1 per cent., and these were 0.110 per cent. and 0.101 per cent. respectively. From the table it will be seen that in no case is the average error in the sum of even a comparatively few numbers one-half of this maximum. The average error for the 144 quotients was 0.024 of 1 per cent., or, expressed as a ratio, 1 in 4,200, a result quite comparable with that obtained with a steel tape over moderately rough ground. By a comparison with the results of the thorough investigation of the relative accuracy of planimeters by Prof. Lorber, of Loeben, Austria, quoted in J. B. Johnson's "Surveying," it will be seen that the slide rule is far more accurate than the polar planimeter, and that it compares very favorably with the suspended and rolling planimeters, even though the latter of these is considered an "instrument of precision."

Assuming the possibility of absolutely accurate horizontal measurements, it will not be very difficult to find a field engineer who will admit the possibility and even the probability of errors of 0.1 of a foot in the differences of level elevations in a cut or fill. If the cut is of an average depth of 10 ft. the above error is 1 per cent. of the quantity. Cut the probable error down to 0.01 of a foot and the chances are 70 to 1 that the slide rule is more accurate still. Allowing, further, for errors in plotting up the field notes; errors in the transfer to a tracing; errors due to shrinkage of tracing cloth and blue-print paper; "personal equation" errors in following contour lines with the tracing arm of the planimeter; errors inherent in the planimeter measurement itself, allowing for all these and other probable errors, not more than due credit will be given if we say that the slide rule is at least as accurate for the conversion of field data into office estimates as are the methods used in obtaining these data by the average assistant in the field and in the drafting-room.

TABLE OF ERRORS IN 116 QUOTIENTS.

Group.	Number and Range of Quotients. Correct.	Small.	Large.	Total.	From.	To.	Numerical Error. Max.	Total.	Per Cent. Error. Max.	Average.
1	23	5	0	28	391	999	0.7	1.8	0.110	0.010
2	25	14	5	44	1007	1980	1.4	12.5	0.095	0.020
3	11	8	5	24	2000	2944	1.9	3.7	0.068	0.007
4	4	5	2	11	3027	3934	3.9	9.1	0.101	0.024
5	0	9	1	10	4033	4991	4.4	20.0	0.088	0.044
6	2	6	0	8	5105	5945	2.5	9.5	0.042	0.021
7	2	6	0	8	6070	6991	4.8	14.6	0.075	0.028
8	0	6	1	7	7131	7989	6.7	25.5	0.091	0.047
9	0	2	2	4	8137	8590	3.3	0.6	0.040	0.002
Total..	67	61	16	144	391	8590	6.7	96.1	0.110	0.024

Should it be desirable to approximate to greater accuracy than is possible with a direct reading of the rule, then the first figure may be obtained mentally when a series of numbers is to be divided by the same small number as, in this case, 27. In such a series of 21 quotients, also taken from practical work, only one was in four figures, all the others having five figures and ranging in magnitude from 11,324 to 69,493. Of the 21 quotients 5 were correct to the nearest unit; 1 was too large by 1 unit; 1 was too large by 2 units; 7 were too small by 1 unit; 3 were too small by 3 units; and 4 were too small by 4, 5, 6 and 7 units each. Reduced to a percentage basis the maximum error in this series was 0.022 of 1 per cent., and the average error for the 21 quotients was less than 0.004 of 1 per cent., 1 in 25,000! If these errors are larger than first expected it can be explained by the fact that the maximum was obtained from a quotient beginning with 2, which was followed by a 7. The four largest errors of 4, 5, 6 and 7 were all found in quotients whose first digits were smaller than the following digit. But for this fact we might have expected even a better ratio for the average error than 1 in 25,000. Though the observations are not numerous enough to warrant enunciation of a proposition to the effect that the percentage of error is independent of the size of the first digit, yet this seems to obtain, as might be expected, though it appears somewhat erratic.

As in the case of straight division on the rule, its use in getting the remaining figures, after the first has been obtained mentally, has yet the advantage of speed and accuracy with less liability to large error. The probable percentage of error in this method depends mainly on the relative numerical values of the first two figures: e. g., if the first figure is 1, obtained mentally, and the second 9, obtained on the scale, then the maximum error on direct reading of, say, 0.1 per cent. may be reduced to 0.05 per cent. If, on the other hand, the first figure is 9, and the second figure is 1, the above maximum of 0.1 per cent. on direct reading will approach 0.001 per cent., a total range in the ratio of probable maximum error from 1 in 2,000 to 1 in 100,000, accepting an ordinary maximum error of 0.1 per cent. for direct reading on the scale.

Since accuracy in reading depends primarily on the accuracy of the graduations and secondarily on close interpolation, we should expect as small errors in multiplication as in division. This is well illustrated by the following example: Of 27 two-factor, four-figure products, ranging in magnitude from 3,321 to 8,046, inclusive, none ending in 0, 7 were correct to the nearest unit; 2 were too large by 1 unit; 12 were too small by 1 unit; 2 were too small by 2 units; 1 was too small by 3 units; and 3 were too small by 4 units. Reduced to a percentage basis, the maximum error was 0.079 per cent., and the average error was 0.019 per cent., both of which results compare favorably with the maximum and average errors for quotients.

For most engineering computations with the pocket-and-office rule it is a useless waste of time to attempt reading all results to four significant figures; but if the greatest possible accuracy is desired, result to four figures, beginning with the figure 1, may be read to the nearest unit; and those beginning with 2 and 3 may be read to the nearest 5 units; but in the remaining numbers the fourth figure may as well be 0. Even with these limitations average errors ought to be well within the ratio of 1 in 2,000, while the chances appear very favorable for much better results, unless several settings have been made as in a continued multiplication or division.

Engineering students can never begin too early getting acquainted with a slide rule. Its study can with much profit be begun in the freshman year, or as soon as the study of logarithms is well under way. The two studies are more than supplementary; they are identical. A proper understanding of the one is a thorough knowledge of the other. A slide rule is a whole set of logarithm tables in itself, in which, as in the tables, the characteristic is absent; a fractional part of the scale unit of which is an equal fractional part, the mantissa, of the unit exponent whose base is 10; and on which the engraved figures and intermediate graduations are the numbers corresponding to the fractional exponent, or mantissa, above mentioned.

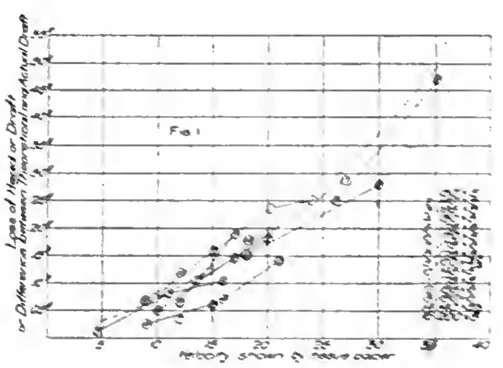
For evident reasons it is not always best to require students to purchase slide rules early in their college course, yet students have been known to be sorry afterwards that they had not been compelled to get the rule much earlier. Unless one has had a rule in use a little so he can himself test it for accuracy, he ought to intrust its purchase to someone better acquainted with its use. For lack of something else which may be better, I have been substituting this test for accuracy in the graduations on the scale most used: Find the reciprocals of several numbers along the whole length of the scale, say all the prime numbers from 11 to 97, inclusive, and as many more similar three-figure numbers, reading their reciprocals to four significant figures. Compare with a table of reciprocals found in most any handbook. With the usual pocket rule the reciprocals will not all be correct to the nearest unit; but the maximum error, with careful reading, ought not to be over 0.1 per cent., and the average at least not more than one-half, and preferably not much over one-fourth, of this maximum, the average being obtained by adding all errors numerically and not algebraically. If these limits are considerably exceeded another rule should be tried, for there is a great difference in the accuracy of slide rules on the market.

The Design of Power Plant Chimneys.

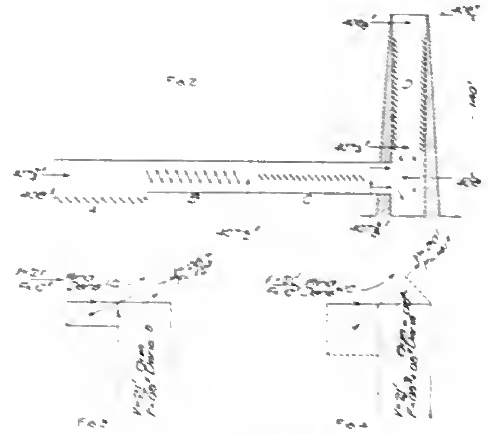
By Frank Kingsley.

The design of a power plant chimney is a problem which is usually solved by rule-of-thumb methods. The common practice is to look over the vague generalities expressed in engineering hand-books and then lay out a structure vastly in excess of the requirements. We say that a chimney 150 ft. in height and 6 ft. in diameter will serve 1,000 h.-p. of boilers, or carry off gas from the combustion of 5,000 lb. of coal per hour, but what is the result if the diameter is made only 5 ft.? What if the height is made 100 ft.? What if 500 h.-p. is added to the plant? What if forced draft is introduced? Answers to these questions cannot be obtained from any of the formulas in common use.

Considering Kent's formula, $H = (0.3 \text{ h.-p.} \div E)^2$, which is the best known of any of the empirical formulæ, it is manifest that if it gave a satisfactory stack for a battery of Babcock & Wilcox boilers (where the gases make three passes through 10 or 12 rows of staggered tubes) it would give, for a battery of Manning upright boilers, a structure vastly in excess of the requirements. This is because the resistance to the passage of gases through the former type of boiler is much greater than through the latter, and more draft is needed to pass the gases through it. It is also evident that with a stack designed from this formula the proper grate area and rate of combustion will have to be determined by experiment after the plant is in operation. In fact, Mr. Kent, in his hand-book, admits that this is necessary.



Draft Measurements.



Draft Diagrams.

The Stirling Company, in its book on steam boilers, offered a method of stack design by which the resistance of the boiler, of the bed of coal and of the flue are approximated from past experience, added together, and from this total the necessary height of stack is obtained on the assumption that the effective draft is 80 per cent. of the theoretical draft. The area is found from the formula, $A = 4.92 \text{ h.-p}^{2/5}$.

Both of the foregoing methods of stack design are incomplete, because they do not consider the fact that a stack has two duties to perform; first, to produce draft at its base; second, to carry off gas.

Now, if any stack is considered from the standpoint of the quantity of gas carried off, the problem becomes solely one of velocities, because the relative density of stack gas does not vary, at any certain temperature, over 1 per cent, and the variations from the absolute temperature of 1,000° F. found in fairly good practice are negligible. Hence, the weight of gas passed up any stack depends simply upon the speed at which it travels, and it would appear that, if high velocities could be obtained, stacks of extremely small diameter could be used.

However, the resistances within the stack become greater as the velocity of gas increases, and, while diameter may be decreased by high velocity, the effective draft at the stack base will be decreased so that height will have to be added to make up for it, or else grate area increased to make up for the decreased draft.

A question might be asked here as to how the high velocities may be obtained, and it will be necessary to bear in mind that the velocity of gas in any stack depends simply upon the amount of gas delivered to the stack. As more coal is burned, and more gas is produced, the velocity rises; as less coal is burned, the velocity falls. The stack height is absolutely immaterial, except in that it establishes as a limit the point where the entire theoretical draft is devoted to producing velocity, and this condition is, of course, never reached. A stack 200 ft. high with dampers closed tight will give no velocity to the gas in it, notwithstanding the height; while the gas in a 50-ft. stack over an upright boiler with under grate forced draft may nearly reach the maximum velocity of 29 ft. per second.

In order to throw some light on this subject, the writer made a series of observations, at the instance of the Parson Manufacturing Co., upon a number of average-size power plant chimneys. These consisted of stack draft and temperature readings on each stack; and, after each reading, obtaining the velocity of the gas in the stack by timing a handful of tissue paper, introduced into the stack, from the base to the top.

The temperatures of stack gas and external air were obtained with 800° thermometers, and the draft was obtained with a spiral draft gauge reading to 0.01 in. The paper was introduced into the stack by springing the breeching slightly away from the brickwork where it entered the stack. Its velocity was timed with a stop-watch. The paper was found to fall in stationary air at the rate of, roughly, 2 ft. per second for the average stack; and, consequently, it was assumed, on account of the less dense medium, to show a velocity of 3 ft. per second less than the real velocity of the stream of gas.

Barometer and weather conditions were noted daily, but as the average barometric variation only affected the draft 0.01 in., it was neglected eventually. As all the plants visited had either a damper regulator or ash pit blower regulator, a number of readings were taken with this on and with it off. Each set of readings was averaged; and the variation from the mean noted. This was for the purpose of obtaining an idea of the efficacy of the apparatus, and to detect the presence of unconsidered factors. At the lower velocities of stack gas, or where the stack was under-loaded, the variations were large; but at high velocities they were inconsiderable. Unfortunately the importance of the pressure created by a wind blowing into an open fire-room door was not considered when the readings were taken, and this introduced an error in several instances.

The aspirating effect of wind in blowing across the top of the stack was found to be negligible; in fact, when it is considered that the ordinary "brisk wind" has no greater velocity than the gas in the average stack—namely, 20 ft. per second—it becomes evident that this very common assumption is not based on sound reasoning. It is also evident that no appreciable change of temperature can take place in a properly loaded stack, because the gas travels to the top in 5 to 10 seconds.

It was found that the pyrometer was very slow in action, in comparison with the draft gauge; and, as the conditions were subject to continual slight changes, a certain amount of error was introduced from this source also.

With the above readings, and a knowledge of the stack height, it became possible to calculate the draft which the stack should give at its base; and by subtracting from this the actual reading shown by the draft-gauge, the loss of head for certain velocities in the stack were obtained. The results obtained are given in Fig. 1, being platted with vertical measurements, indicating loss of head, or draft, in inches of water, and horizontal measurements indicating velocities (not corrected for the action of gravity on the tissue paper).

It will be observed that the platted results take the form of a roughly defined curve, regardless of the size of the stack, showing that resistance is not due to friction alone, which is determined by the well-established formula:

$$\text{Loss of head} = CV^2H/D.$$

In view of this fact it might be well to analyze the forces and resistances acting on stack gases, with the help of Fig. 2. Assume a stack about 140 ft. in height, with an atmospheric pressure at its base of 408 in. of water, or 14.75 lb. per square inch. Call A the grate, B the tubes and C the breeching. Let D represent the rough sides, giving a skin friction. Now, with air at about 50° F. and stack gases at 560° F., we may expect that the air between the top and the bottom of the stack will exert a pressure of 2 in. of water, and the gas in the stack (being of half the density) will exert 1 in. pressure. Then at the top of the stack there will be 406 in. pressure, and at the base inside 1 in. more, or 407 in., if the gas is stationary. However, assume the gas is moving, and assume that, just before exit, the gas has ⅜ in. of pressure above the atmospheric pressure (this will be considered later). Then, if the skin friction, D, is ⅜ in., the pressure just above the breeching connection will be 406¾ in. + 1 in. = 407¾ in. Now, to turn the gases from their horizontal direction as they leave the breeching requires a certain force. Calling this ⅛ in. the pressure at the point where the observations of draft were made would be 407⅞ in., and a draft gauge would show ⅝ in. of draft at this point, whereas if the gas were stationary the pressure would be 407 in. and the gauge would read 1 in. From this it will be seen that each loss of draft or head shown on Fig. 1 was composed of three separate resistances: (1) exit velocity, (2) skin friction, (3) change of direction.

To consider each of these separately: When air at a small pressure flows through a frictionless tube into the atmosphere it obtains velocity as it enters the tube and loses pressure. In other words, its potential energy of pressure changes to the kinetic energy of motion. At the exit the kinetic energy or "velocity head" is dissipated in eddies and friction as each particle gives up its velocity to other particles, and if a draft gauge were placed at the exit no reading would be shown. In the case of a chimney, however, the condition is one where a stream of gas of, roughly, half the density of air, is made to issue from the top of the stack, and in so doing it displaces its own volume of the

heavier medium. Assume a frictionless, weightless piston, introduced momentarily just below the top of the stack; on its under side it will have the force due to velocity of the gas, and equal to $h = v^2/64.4$, and on its upper side it has air, to move which at the same velocity requires a force $H = v^2/64.4$; but since the density of air is twice that of gas, the force or column, H (although the same height), weighs twice as much as h; consequently, twice the force, which the velocity of gas exerts alone, is needed to move the piston at the velocity of the stack gas.

Another method of explaining this would be to consider a stack 1 ft. square, as shown on Fig. 3. Assume the velocity of the gas in the stack, as shown, to be 21 ft. per second, which gives it velocity head of 0.05 in. Then assume a wind blowing across the top of the stack at the same velocity, which would give it (due to greater density) a velocity head of 0.10 in. By completing the parallelogram of forces, it is seen that the two forces will combine and proceed at an angle of 26° 30′ from the horizontal; and, as the mean density, upon which the resultant force of 0.112 in. acts, is .75, the velocity in that direction will be 26.7 ft. per second. But since the sine of 26° 30′ is 0.446, it will be necessary to have the same amount of gas that passes through an opening 1 ft. square at 21 ft. per second velocity pass across an area of 0.446 sq. ft. at a velocity of 26.7 ft. per second. This is manifestly impossible, and the pressure in the stack must be increased or the stack velocity decreased.

If the same conditions occur with 0.05 in. excess pressure in the stack, Fig. 4, the two forces combine to produce 0.141 in., which acts at 45 deg. from the horizontal and gives a velocity to the combined gases of 30 ft. per second, as they have a mean density of 0.75. Now, the sine of 45 deg. is 0.70; so that we have to pass gas at 30 ft. per second across an area of 0.70 sq. ft., which makes a discharge of 21 cu. ft. This is the exact amount of gas that the stack is carrying.

Hence a pressure must be exerted at the top of the stack equal to the difference between that which will move the gas and that which will move the air at the same velocity, or, roughly, $R_1 = \frac{1}{2} CV^2 \div 64$, C being the factor for changing feet of air at 60° to inches of water; or, corrected for gas at 500°, this amounts to $R = 0.00011V^2$. The second of the resistances, or the skin friction of the stack, is unquestionably expressed by the formula $R_2 = CV^2H \div D$, C being a constant depending on the nature of the substances in contact and the density of the gas. Sturtevant's factor, which is very commonly used for the friction of the air in iron pipe, would give, allowing for the decreased density, $C = 0.0000285$; and since it is generally conceded that this is 75 per cent. of the factor for brick ducts, the resistance to skin friction would become $R_2 = 0.0000038V^2H \div D$.

Now, the value of $H \div D$ varies from 15 to 35 for average stacks, with a mean of about 25; and by substituting:

Maximum	$R_2 = 0.000133V^2$
Mean	$R_2 = .000095V^2$
Minimum	$R_2 = .000057V^2$

The third resistance, or that caused by the bend at the base of the stack, is one to which it is difficult to ascribe an exact value. It would seem from Fig. 2 that the velocity head should be neutralized by eddies due to impingement of the gas upon the perpendicular stack walls. The resistance of the bend would then be the head necessary to again impart velocity to the gas, or $R_3 = 0.000115v^2$.

In several cases this resistance has been found to agree with the formula $R_3 = 0.00015v^2$; and this, at 18 ft. velocity, amounts to 0.05 in., or the amount allowed by Stirling for any bend, the velocities given by their formula being about 18 ft. per second. If for want of a better established formula this be taken, the total resistances are as follows:

Maximum	$R = .000393V^2$
Mean	$R = .000355V^2$
Minimum	$R = .000317V^2$

Now, even with the high velocity of 30 ft. per second, the variation from the mean is only 0.034 in., and this, when compared to the draft of the stack, or, say, 1 in., is negligible. Therefore, $0.000355v^2$, or, say, $0.00036v^2$ can be taken as a close approximation of the loss of head in any stack, where V equals velocity of stack gas in feet per second.

Stirling uses $\Delta D \; fW^2VH \div A^2$ as a formula showing the loss of head or draft in stacks "due to inertia and friction." While this formula is incorrect in form, the constant used has been undoubtedly determined by the average of a large number of experiments, and for average conditions it may be used as a check. By substituting for A its equivalent, $\frac{1}{4}\pi D^2$, and for C its equivalent, πD, and by using the mean value for f, or 0.0017, the formula becomes:

$$\Delta D = 0.0018H \; (W/A)^2(4\pi D/\pi D^2).$$

But the weight of any sample of flue gas, or W, at average temperature varies but little from (volume $\div$ 23), and volume divided by area equals velocity. Substituting and cancelling:

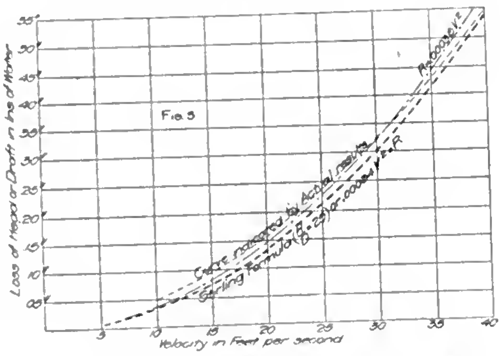
$$\Delta D = 0.0000136v^2H \div D;$$

Then calling $H \div D = 25$, as before:

$$AD = 0.00034v^2.$$

This checks closely with the previous formula:

$$R = 0.00036v^2.$$



Velocity and Loss of Head Curves.

The curves in Fig. 5 are platted from these two formulæ, and from the average of the results indicated by Fig. 1 and corrected for action of gravity on the tissue paper used to determine velocities.

Now having established the approximate relation between velocity and loss of draft by experiment and by theory, and having checked the result from past practice, it is possible to make use of the curve, as follows:

The curves in Fig. 6 are based on the principle that if a 100-ft. stack will give a draft of 0.61 in., with no velocity when the outer air is at the temperature of 70° Fahrenheit, and the stack gas is at the temperature of 500° F., the draft at a velocity of 10 ft. per second will be 0.036 in. less [$R = .00036 \times (10)^2$], as shown by Fig. 5.; at 20 ft. velocity it will be 0.144 in. less.; at 30 ft. velocity it will be 0.324 in. less, and so on. These results, shown in the form of a curve for a 100-ft. stack, give the drafts which may be expected at various velocities. Curves for stacks of other heights are laid off in the same manner.

Since these curves are based on a stack temperature of 500° F., and since this temperature may sometimes be as high as 600° F., it is necessary to consider the effect of this variation. With 600° F. temperature an 88-ft. stack produces about the same draft as a 100-ft. stack with 500° F. temperature. Therefore, if a temperature of 600° F. is expected (from overrating boilers or other causes), and a draft of 1 in. is required, the stack which gives 88 per cent. of this, or 0.88 in., is the one to be taken from the curves of Fig. 6.

To consider now the ability of a stack to carry off gas: The volume of stack gas produced in any power plant is primarily dependent upon the weight of coal burned. It is also dependent upon the temperature of the gas and upon the amount of excess air used in the combustion of the coal. The extreme variation of temperature, with fair practice, is to 600° F., which makes an increase in volume of 10 per cent. The factor of excess air is, however, a large one. One pound of coal when completely burned requires, under very good conditions, 200 cu. ft. of air; under good conditions, 250 cu. ft. of air; under poor conditions, 300 cu. ft. of air.

Thin fires, irregular stoking and excessive drafts are conditions which should not occur in a modern boiler room, and so need not be considered.

Now, 250 cu. ft. of air, after burning 1 lb. of coal and being reduced in temperature to 500° F., makes a volume of about 450 cu. ft. of flue gas; and if the stack velocity is 1 ft. per second, or 3,600 ft. per hour, the area of stack necessary to carry off gas from the combustion of 1 lb. of coal per hour is, under the above conditions, $450 \div 3{,}600 = 0.125$ sq. ft. Therefore, by dividing the area of any stack by 0.125 the number of pounds of coal that the stack will handle at a velocity of 1 ft. per second is obtained; or, multiplying the required weight of coal in pounds per hour by 0.125, gives the necessary stack area for a velocity of 1 ft. per second.

The actual area of a stack, however, is not all effective. There is a layer of gas at the sides which is stationary or nearly so. The thickness of this probably varies with the velocity, but Kent assumes it as 2 in. thick for all stacks, and following this principle as one of long established use, a 4-ft. stack would have an effective area of 10.44 sq. ft., and at 1 ft. per second velocity would carry off gas from 84 lb. of coal per hour. At 5 ft. per second velocity it would handle 418 lb., and at 10 ft. per second, 836 lb.

By applying this method to various sizes of stacks, the table under Fig. 6 was prepared, and with the combined curve and table it is possible to give the necessary height and diameter of a stack which will maintain a given draft at the base while carrying off the gas produced by the combustion of a given weight of coal per hour.

The object of maintaining draft at the base of a stack is to overcome the resistances of flue and boiler and to produce sufficient vacuum over the fire to give the necessary rate of combustion. The relation of vacuum over fire, or furnace draft, to the number of pounds of coal burned per square foot of grate per hour is a subject which is hardly within the scope of this article. It is affected largely by the care with which the firing is done and, with the coking coals of the Eastern States, depends on how often and how well the lumps of coke are broken up. It is also affected by the class of fuel, but as anthracite is no longer a commercial steam fuel, soft coal need only be considered. Owing to the wide use of stokers, soft coal slack will soon be about as high priced as run of mine coal. In fact, at the prevailing prices, run of mine coal is by far the better fuel commercially in almost all parts of the country; hence slack coal need not be considered under ordinary conditions, and with

average firemen the following rates may be expected for run of mine coal:

Eastern Coal. Draft.	Coal per sq. ft. of grate.	Western Coal. Draft.	Coal per sq. ft. of grate.
0.20 in.	14 lb.	0.20 in.	18 lb.
0.30 "	19 "	0.30 "	24 "
0.40 "	24 "	0.40 "	30 "
0.50 "	28 "	0.50 "	35 "

These figures may be greatly exceeded under favorable conditions.

Stirling gives a curve showing a rate of 50 lb. coal per square foot of grate, with a draft of 0.40 in., and Whitham records a test where 0.30 in. gave a rate of 32 lb. of coal per square foot, but such results could not be expected in every day practice. In fact, dirty or uneven fires, holes or large lumps of coke may easily reduce the figures in the table 50 per cent. In one plant examined by the writer a draft of 0.70 in. only produced a rate of 20 lb, with good Pennsylvania coal mixed with 40 per cent. of yard screenings, because the firemen spoiled the fires by excessive slashing and did not keep the surface well broken up and even.

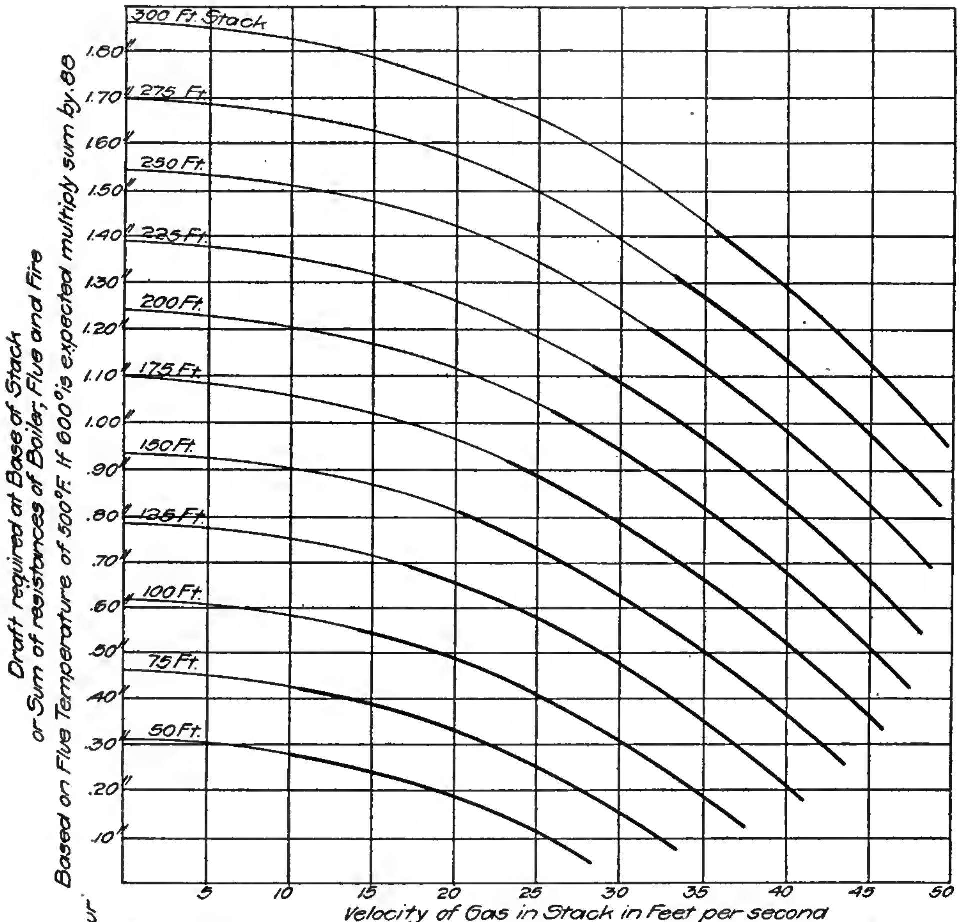
The resistances of the various types of boilers have been found to be, roughly, as follows, when delivering rated capacity under ordinary conditions of operation:

RESISTANCES OF BOILERS.

Babcock & Wilcox, double deck	0.40 in.
Babcock & Wilcox, standard	0.30 "
Stirling	0.20 "
Heine	0.20 "
Return tubular	0.10 "
Upright	0.00 "

(For 25 per cent. over-rate multiplied by 1.5.)

The resistance of each 100 ft. of straight flue may be considered as 0.05 in., and the resistance of each bend as 0.05 in. These values are, of course, dependent upon the size of the flue and the velocity of the gas in it, which should be about 20 ft. per second under ordinary conditions. This velocity gives very large flue areas, compared with past practice, but it is nearly always cheaper to build large flues than high stacks.



Lbs of coal to be burned per hour

Stack Dia.	Eff. Area	10	15	20	25	30	35	40	45

Based on 500° Stack Temperature — If 600° is expected multiply lbs. of coal to be burned by 1.10

Based on 250 cu.ft. Air per 1 lb. coal — If 300 cu.ft. is expected multiply lbs. of coal to be burned by 1.20

Chart Giving Dimensions of Chimneys for Different Services.

To take a concrete example: Assume a battery of Babcock & Wilcox boilers, which are to run at rating. They are connected to a horizontal flue 100 ft. long, which makes one bend before entering the stack. The uptake from each boiler enters the main flue at right angles. The boilers are to furnish 3,000 h.-p. by burning a fair grade of Eastern coking coal, giving 1 h.-p. for each 4 lb. of coal burned, and hence 12,000 lb. of coal are to be burned per hour. Assume the total grate area of all boilers to be 500 sq. ft., then 24 lb. of coal must be burned on each square foot per hour, and from the table of rates of combustion it is seen that 0.40 in. of draft must be given over the fire.

Now, there will be needed 0.4 in. draft for the furnace, 0.3 in. to overcome boiler resistance, 0.05 in. to overcome the bend at each uptake, 0.05 in. for the 100 ft. of main flue, and 0.05 in. for the bend in the main flue. This gives a total of 0.85 in. needed at the stack base.

Referring to the vertical division marked "draft" on Fig. 6 and selecting the point corresponding to 0.85 in., it is seen that a horizontal line, drawn from this point, crosses the curve marked "150-ft. stack" directly above the velocity of 15 ft., meaning that a 150-ft. stack will give 0.85 in. draft when the velocity is 15 ft. per second. Extending the horizontal line to the curve of the 175-ft stack, it is seen that the velocity nearest to being below the intersection is 25 ft., meaning a 175-ft. stack will maintain 0.85 in. of draft and a velocity of 25 ft. per second. In the same way a 200-ft. stack is shown to give 0.85 in. of draft and 35 ft. velocity.

Now referring to the table of Fig. 6, it is seen that if 12,000 lb. of coal are to be burned with a stack velocity at 15 ft., or that given by a 150-ft. stack maintaining 0.85 in. of draft, the stack must be nearly 12 ft. in diameter (which diameter will handle 12,800 lb. of coal at this velocity). But if the stack is 175 ft. high and the velocity is 25 ft., the diameter need only be 9 ft., or if the stack is 200 ft. high it need be only 8 ft. in diameter.

The horizontal line showing 0.85 in. of draft crosses the curve of the 150-ft. stack outside of the heavily marked part of the curve, and this indicates a velocity too low to be economical. Except under extraordinary conditions, the 175-ft. by 9-ft. stack will be cheaper than and preferable to the 150 x 12-ft. It will undoubtedly contain less brick and will be less liable to the effect of outside conditions.

Suppose that it is desired to get the same horse-power by reducing the number of boilers or by over-rating the boilers 25 per cent., and say that the grate area is proportionately larger and the fireman careless. Then it may be expected that the flue temperature will go up to 600° F. and that uneven fires will bring up the volume of air per pound of coal to 300 cu. ft. Then if the total grate area again is 500 sq. ft. the sum of resistances will be $0.30'' \times 1\frac{1}{2} + 0.05 + 0.05 + 0.05 = 1.00$ in.; but as the temperature is 600° F., it is necessary to figure on only 88 per cent. of this, or 0.88 in.

The coal actually to be burned will be 12,000 lb. per hour, but since temperature is 600° F., its equivalent, or $12{,}000 \times 1.10 = 13{,}200$ lb., must be allowed for. Also, since excess air is to be increased, the equivalent of coal properly burned is $13{,}200 \times 1.20 = 15{,}800$ lb.

The table shows that a 10-ft. stack handles at 25 ft. velocity 14,650 lb. of coal, and at 30 ft. velocity 17,500 lb. of coal; and as the horizontal line of 0.88 in. of draft crosses the 175-ft stack curve at about 27 ft. velocity, it may be expected that a 175 x 10-ft. stack will handle 16,100 lb. of coal, which is just above the required amount of 15,800 lb., so that the necessary stack is 175 x 10 ft.

To consider another problem which often arises, namely, that of determining the height of stack to be added in case of an increase of horse-power in an old boiler plant: Assume that the foregoing plant has a stack 175 x 9 ft. and that it becomes necessary to add 1,000 boiler horse-power to the plant, the new boilers to be similar to the old ones in every way, and led into the stack by a separate connection or by a properly enlarged breeching. Then the amount of draft at the stack base will not have to be increased, but the velocity of the stack gas must be increased to take care of the extra 4,000 lb. of coal burned per hour.

Referring to the table of pounds of coal burned, Fig. 6, it is seen that if 16,000 lb. are to be burned and the stack is 9 ft. in diameter, the velocity will have to be nearly 35 ft. per second, because this velocity in a 9-ft. stack carries off gas from 10,500 lb. of coal per hour. A vertical line drawn from the point showing 35 ft. velocity intersects the horizontal line of 0.85 in. draft just above the curve for the 200-ft. stack, or where the curve for a 205-ft. stack would be; or, in other words, it is necessary to "top out" the old stack 30 ft. This will undoubtedly be cheaper than building a new stack and foundation for the new boilers.

The proper areas for breechings which will give a velocity of 20 ft. per second may be obtained from the column showing effective areas corresponding to the various weights of coal burned per hour in the column under 20-ft. velocity.

Now by comparing the figures given in the first of the foregoing examples and Kent's table of chimney capacity, it is seen that in Kent's table a stack 175 x 8½ ft. will serve 2,300 h.-p. or burn about 12,000 lb. of coal. This is a smaller stack than is indicated in the example, but if the draft over the fire is set at 0.30 in. instead of 0.40 in., and the draft at the stack base reduced to 0.75 in., the table in Fig. 6 shows that about 12000 lb. can be handled by a 175 x 8-ft. stack. If in the same example tubular boilers are used instead of Babcock & Wilcox, and the necessary draft reduced to 0.55 in., the stack may be reduced to 133 ft. in height, if the diameter is kept at 9 ft.; or if the dimensions are kept at 175 x 8½ ft it will burn 16,500 lb. of coal.

Referring again to the formula $H = (0.3\ \text{h.-p}/E)^2$, with regard to the velocity it gives and the drafts exerted at stack bases, it is evident that, since the height is made a function of horse-power divided by area, the velocity for any height is constant. These velocities, drafts and percentages of total drafts are shown below in a table:

Height.	Velocity.	Effective draft at base.	Per cent. of total draft exerted.
300 ft.	37 ft	1.38 in.	75 per cent.
250 "	33 "	1.17 "	75 "
200 "	30 "	.93 "	76 "
150 "	25 "	.72 "	78 "
100 "	20 "	.48 "	79 "

From this it is easily seen why stacks designed from this formula give good results if the correct height is chosen. It also accounts for the common saying that for the taller stacks Kent's formula gives excessive diameters, because it is seldom that the draft at the base of a stack has to be over 1.00 in., and consequently there would be 0.17 to 0.38 in. wasted which could have been applied to increasing the velocity and decreasing the diameter.

To return to the questions in the opening paragraph: Reducing a 150 x 6-ft. stack, burning 5,000 lb. of coal, to a diameter of 5 ft. will decrease the draft 0.30 in. Reducing the height to 100 ft. will also decrease the draft 0.30 in. If we add 500 h.-p. to the plant, without increasing the grate area under each boiler, the stack must be increased to 200 ft. in height. Introducing forced draft will allow the furnace draft to be applied to increasing velocity; if this be 0.40 in. it will enable the stack to carry 1,600 h.-p., or burn 8,000 lb. coal per hour.

This article refers in a number of places to the well-known chimney formula originated by Prof. William Kent, dean of the College of Applied Science at Syracuse University. Proofs of the article were accordingly submitted to him and he has furnished the following comments:

"There is one statement by the author that I do not think quite fair to my formula. He says, 'It is manifest that if it gave a satisfactory stack for a battery of Babcock & Wilcox boilers, it would give for a battery of Manning upright boilers a structure vastly in excess of the requirements.' I tried to make it clear in my book that the formula was to be used after the height had been assumed, see pages 734-6.

"I have looked into Mr. Kingsley's paper to see how he would solve a practical problem of burning 12,000 lb. of coal per hour under B. & W. boilers. He says that for a 175-ft. stack, the diameter need only be 9 ft. My table shows that for a 175-ft. stack, 102 in. diameter will give 11,500 lb. of coal per hour, and if, as is generally believed, my table errs on the safe side, then 102 in. diameter may be considered enough for 12,000 lb. of coal, instead of 108 in. that Mr. Kingsley's formula would give. Mr. Kingsley, however, states that if the chimney is 200 ft. high, it need only be 8 ft. in diameter. My figure for a chimney of that size is 2,167 × 5, or only 10,835 lb. of coal, so there is a considerable lack of harmony between Mr. Kingsley's method and my own. For a 175-ft. stack he would give a larger diameter than I would and for a 250-ft. stack he would give a smaller diameter. In the absence of experimental proof I should prefer to use my method.

"Mr. Kingsley's method of proportioning a stack seems to be a rather roundabout one, involving a knowledge of what drafts are required to burn different kinds of coal at different rates of combustion, what velocities are needed in chimneys to carry off the gases, and what resistances to draft there are in different kinds of boilers and in flues and bends. Many of these data are imperfectly known, and one of them, the resistance on the bed of coal on the grate may vary from minute to minute through a wide range. It would seem to be just as well to have a purely empirical method of selecting the height of the chimney; that is, to find out from boiler manufacturers or others what height of chimney they have found suitable for different rates of combustion with different kinds of coal, and then, using that height, take the diameter from my table. In the more than twenty years that my table has been before the public, I have never heard objection to it on the ground that it gave too small an area of chimney. It has often been objected to for giving a chimney larger than was necessary, but that is a good fault, and I have never had sufficient evidence of the fault being large enough to warrant the figures or the formula being changed."

The Mississippi River Bridge, at St. Louis, of the Illinois Traction System, commonly known as the McKinley syndicate, was started on Dec. 8 by launching the foundation caisson for one of the channel piers on the Illinois side of the river. The bridge will span the river from the town of Venice, just north of East St. Louis, on the Illinois side, to the northern part of St. Louis, on the Missouri side, the location being about 8 miles south of the Merchants Bridge. The structure will consist of three channel spans, the middle one 523 ft. long, and the other two 521 ft. long, with three short approach truss spans on the Missouri side and two on the Illinois side. The piers will be of concrete with stone facing and granite coping. Those for the main spans will be carried down 60 to 65 ft. to bed rock, while the approach piers will rest on piles. The bridge has been designed for two 120-ton electric locomotives, and will be heavier than either of the other St. Louis bridges. In general outlines it is similar to the Merchants Bridge, but differs in details. The wagon ways will probably be located in the center at first, but as traffic increases will be placed outside the trusses on cantilever supports. Mr. Ralph Modjeski, Chicago, as consulting engineer for the St. Louis Electric Bridge Co., designed the structure.

Mechanical Plant of the Brooklyn Institute Building.—II.

Ventilation.—The building of the Brooklyn Institute of Arts and Sciences is devoted to a variety of museum and educational purposes, including extensive museums of natural history, archaeology, anthropology and ethnology, a large gallery and sculpture hall, an auditorium seating 1,500 persons and laboratories, studies and work-rooms, all of which are largely public in character, so that it is desirable to provide for thorough ventilation. Mechanical ventilation had been provided for in the original west wing of the building, including both fresh air supply and exhaust ventilation in capacity sufficient to clear the air in all departments when crowded with visitors, and this provision has also been made a feature of the second and third sections of the building, recently completed. Ventilation has been provided for in practically all rooms above the cellar, in capacities sufficient for maximum normal occupancy while in the auditorium special provisions were made for ventilation along the lines of the best practice in theatre and lecture hall ventilation.

The ventilation systems were, owing chiefly to the construction of the building in sections at different times, laid out independently for each section. Each division requires, on account of the size of the building, an equipment of large capacity and extensive duct systems for air distribution and gathering systems, the central section having an additional system independent of that for general ventilation which is intended to serve the auditorium only. There is to be noticed a lack of uniformity in capacities between the ventilating equipment in the different sections which is due largely to the varying purposes for which the different portions of the building are used. The systems vary in capacities from 30,000 to over 50,000 cu. ft. per minute of fresh air supply and from 26,000 to 50,000 cu. ft. of exhaust, the capacity of supply generally exceeding that of exhaust ventilation to create a plenum within the building. The fresh air supplies are all cleansed by cheese-cloth filters of the usual construction and the systems are fitted with tempering coils and moistening pans for the control of the temperature and the humidity of the air delivery.

The ventilation is planned throughout the entire building for downward circulation of air, the fresh air supply being admitted through registers in the upper side walls near the ceiling line, except in special cases where the outlets are located in the ceiling, while the exhaust register openings are almost all located at or near the floor level; in toilets and where heat removal was deemed of importance, there are top exhaust openings. Thorough distribution of the supply is provided by well-studied arrangements of registers in all rooms, which, in their relation to the exhaust registers, direct currents of air into all corners. In all of the larger rooms there are two or more sets of supply and exhaust registers, there being in some of the larger museum and laboratory rooms, of a maximum size of 38 x 108 ft. in plan, as many as six and eight registers each for supply and exhaust. In the smaller rooms such as used for offices and auxiliary work rooms which range in size from 12 x 20 ft. to 15 x 40 ft., there are uniformly two each for supply and exhaust, but the locations chosen are so separated as to render the circulation general and positive. Exceptions to this are to be noted only in the auditorium, where a special system has been installed and in the toilet rooms, which, of course, have exhaust ventilation connections only, with fresh air supply connections omitted other than in the form of louvres in the panels of the doors connecting with the

outside or the corridors through which air may enter to replace that exhausted. The general arrangement of register openings was affected somewhat by the desire to confine the duct risers connecting with them to certain rows of inside partition walls in which they may be concealed with the least amount of interference with the interior arrangement and the daylight lighting from side windows. As may be noticed from the general first floor plan of the building, in the original west wing, all of the duct risers are arranged in the cross-wise partition walls with none in the side walls, but in the new easterly wing ducts have been placed in the side walls to a limited extent where found desirable for better distribution connections. In the central section of the building the duct risers are very generally distributed, being carried up for the greater part in furred enclosures which were provided for the interior decorative construction.

As there were no definite ventilation requirements imposed in the various parts of the building, as the conditions of occupancy are in all portions except the auditorium irregular and indefinite, the design of the ventilating equipments was merely based on the desirable ventilation rates of from three to four changes of air per hour in all rooms which it is thought will be ample for all ordinary conditions. In the auditorium in the basement of the central portion, however, the conditions were more definite, ventilation being required at the rate of 30 cu. ft. per person for the average audience expected in attendance. The sizes and arrangements of the fan equipment were decided by the construction of the different sections of the building at detached intervals, a single unit each for both fresh air supply and exhaust being installed in each section of sufficient capacity to handle that general division of the building, while basement or cellar locations for the fresh air supply blowers, with convenient filtered air intakes, were chosen with exhaust fans in the attic. In the original west wing, the fresh air blower was located in the west end of the basement, the greater part of which floor is utilized for museum purposes, and the distribution duct line concealed in furred ceiling construction, but in the central portion and the new east wing, the sharp descent in the grade at that portion of the site facilitated the provision of sub-floors which are used solely for the mechanical equipment and thus without waste of valuable space above ground level. In the two latter cases the distribution duct lines are carried on the cellar ceiling exposed, the trunk duct and branches being covered with asbestos block and canvas. For the fresh air supply, fans of the centrifugal type were selected in all cases, while for exhaust, disc fans were installed in attic locations where convenient to the gathering duct systems and roof discharge outlets, excepting in the case of the auditorium system, where owing to concentrated space ventilated it was thought desirable to locate this fan in the basement alongside of that for fresh air supply. The fans are all motor driven with the exception of that for fresh air supply in the old west wing, in which case the direct connected steam engine drive which was originally installed, has been retained. In the case of the auditorium systems where both fresh air supply and exhaust fans are both located in the basement, they have been arranged side by side with a tandem drive from a single large motor.

The principal details of the fan equipments, their drives and tempering coils are presented in an accompanying table. The fans of the centrifugal type are all three-quarter housed steel plate blowers supplied with the tempering coils by the B. F. Sturtevant Co., and are for the greater part installed with top horizontal discharge casings. They have single direct connected drives with the exception of the systems supplying fresh air to the central portion of the building where, on account of the large volume of supply required, and also of lack of space for a very large unit, two smaller units were installed which are coupled in tandem to a single motor drive and have connections in multiple for both intake and delivery. The motors installed are all C. & C. direct-current, slow-speed motors which are operated on separate power circuits from the local power plant supply, their control being in the local distributing switchboards in each section of the building; they are fitted with Cutler-Hammer starting boxes fitted with both overload and underload release to permit of their being operated with a minimum of attention. The fresh air blower in the west wing is driven by a 10x12-in. Sturtevant horizontal automatic steam engine which, as stated in the preceding article, receives steam from the high pressure system from the power plant and exhausts locally into the low pressure heating main which centers in that wing.

The fresh air fans have short direct intake connections made in the most convenient manner to the outside air, at low levels, the intake air being cleansed by cheesecloth filters. The west wing fan intake is through a grilled window opening in the west end of the basement, that for the east wing fan through a window and area way at the front, while that for the two fans in the central portion is through a masonry enclosure outside of the building wall which is connected with a 3x24-ft. galvanized iron enclosure that is carried up to a hooded opening about 12 ft. above grade level at the rear of the building.

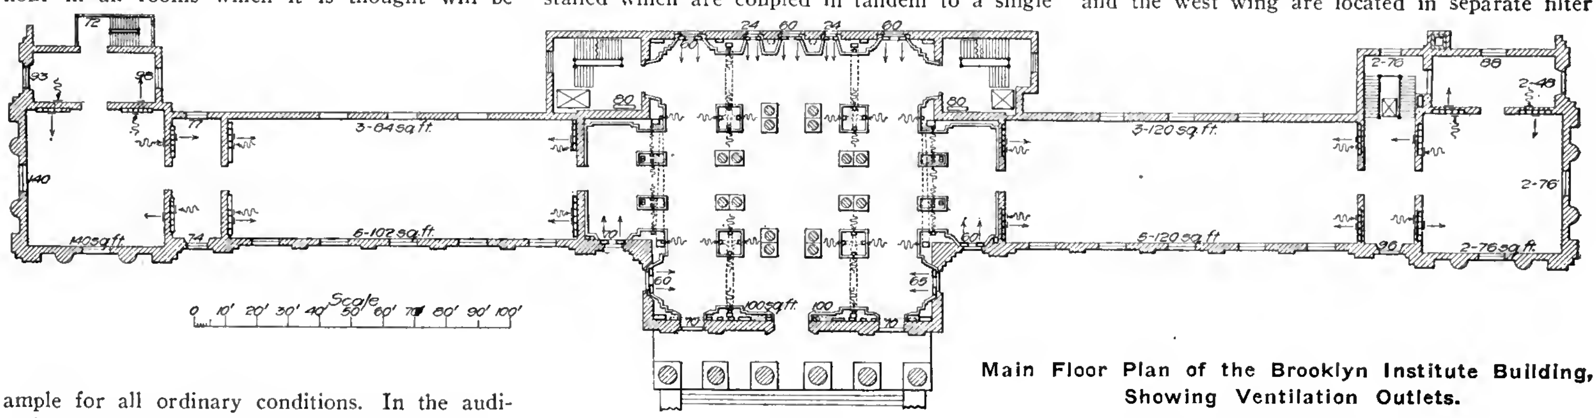
Each of the intakes is fitted with a filter of the usual zigzag frame construction with cheese-cloth as the filtering medium, the areas of which cloth are proportioned in relation to the maximum fan capacities as to secure low rates of filtering velocities, which range from 50 to 70 ft. per minute in the various filters. The higher filter velocity of approximately 70 ft. per minute, is to be found in the filter for the central portion which supplies the two fans, one for general ventilation and the other that for the auditorium; as the auditorium is to be used only occasionally and presumably at such times as the remainder of the building will be closed, an area of filtering medium was chosen which, while causing a rather high rate of flow if for both systems should happen to be operated to maximum capacity simultaneously, will in all probability be rarely if ever operated under this condition of maximum capacity. The filters are of the usual construction consisting of light wooden frames carrying wire netting over which the cloth is tightly stretched, which are mounted in light galvanized iron framework with fittings for clamping them in place air-tight; duplicate filter screens are provided to enable replacements of those in service for cleaning. The filters for the central portion and the west wing are located in separate filter chambers of ample size which open directly to the outside and from which the fans draw through short duct connections; in the west wing system the fan is itself located directly within the filter chamber enclosure, thus avoiding the intake duct connections. In the two former cases, however, the tempering coils are conveniently located in the intake duct connections between the filter chamber and the fan intake, permitting direct connections from the fan delivery openings to the delivery duct lines, while in the west wing system it was necessary to provide space in the fan delivery ducts for the coils. The tempering coils are of the Sturtevant mitre pattern of 1-in. pipes, which are installed in two row sections throughout in numbers of sections and in capacities of surface indicated in the accompanying table. The steam supply and vapor and condensation return connections to these coils were referred to in the description of the heating system of the building in the preceding article. These coils are like the direct radiation fitted for automatic temperature regulation, each system having two control thermostats, one in the outside air operating the supply and return valves of the two outside pipe sections only when the exterior temperature drops below freezing and the other inserted within the delivery ducts for the close adjustment of the air delivery to the temperature required.

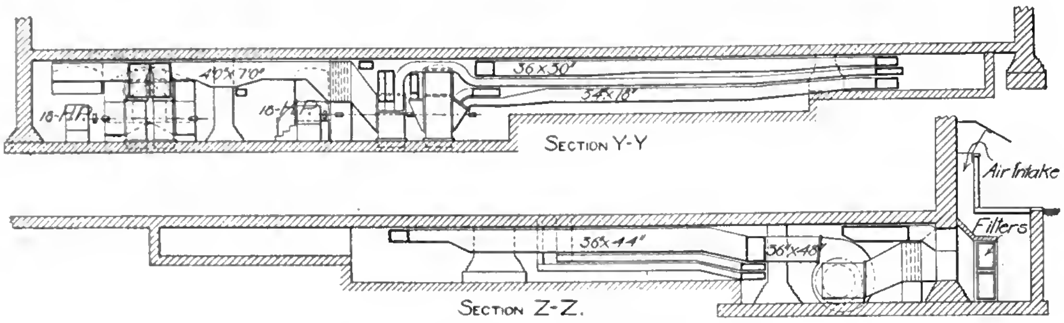
The duct systems have been liberally proportioned for low velocities of flow, rates of from 1,800 to 2,000 ft. per minute being prevalent in trunk duct lines which are decreased to lower values in the branches and finally to velocities of outflow not to exceed 350 ft. per minute through the outlet registers. The duct systems in the side wings are comparatively simple, consisting of a single longitudinal trunk duct through the



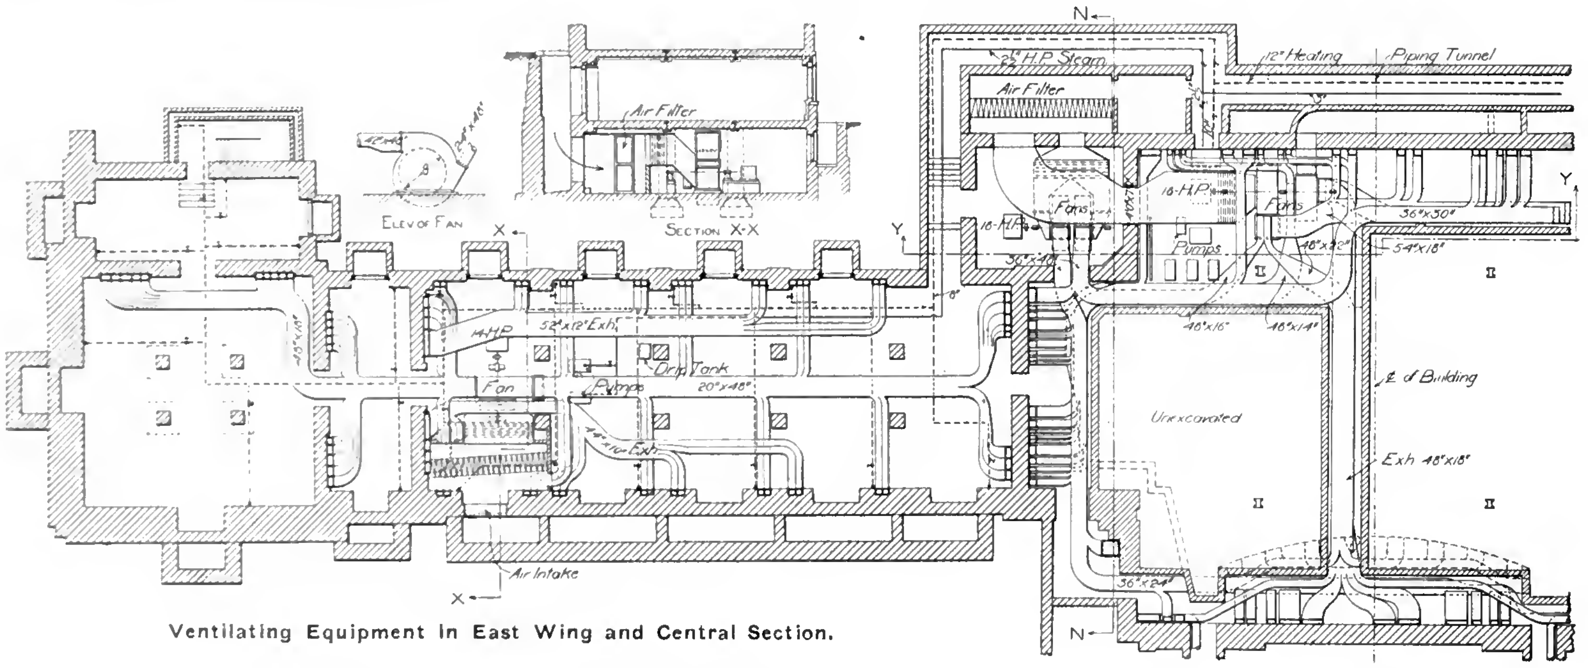
Main Floor Plan of the Brooklyn Institute Building, Showing Ventilation Outlets.

center of the cellar or basement with branches to the banks of partition risers to the upper floors; these risers of which there are one to practically every floor in each group, are made uniformly 12 in. in depth and vary in width, provisions being made for them in the furred wall construction in the various cross-wise partitions of the side wings. In the central portion of the building the arrangement differs somewhat, trunk duct lines extending from each of the two fans for general ventilation around the four side walls of the basement with branches to the duct risers that are carried up in the furred side wall faces. The general arrangement of the supply duct work, as well as also that for exhaust ventilation, are well shown in the accompanying drawings. The exhaust ducts and connections follow in fact the general arrangement of those for fresh air supply, duct risers being carried up also in the cross-wise partitions of the wings and in the furred side wall construction of the central portion to gathering duct lines in the attic which connect with the disc exhaust fans. The supply and exhaust duct risers are in fact alternated, the exhaust connections to the upper floors occupying spaces directly above those for supply to the lower floors with consequent economy of space. It was necessary to arrange the gathering duct lines in the side wing attics in two divided lines on either side owing to the provision of the extensive skylights in the middle portion of the roofs for the art gallery lighting. These lines and only on starting. These fans all draw from spacious exhaust chambers into which the branch gathering ducts connect and deliver direct to the outside through exhaust hoods in the roof with openings of the full size of the fan in each case. These roof discharge hoods are of heavy copper construction, well braced and are specially designed to protect the fan and motor from the weather, while not restricting the outflow.

Auditorium System.—The ventilation of the auditorium has, as above stated, been provided for in accordance with approved public hall practice, air being circulated on the downward system and capacity provided for approximately 30 cu. ft. per minute per person for an average audience of a little over two-thirds of the seating capacity. The seating capacity of the hall is about 1,500, of which there are about 1,000 seats on the main exhaust are, as above stated, located in the sub-basement space under the rear of the main floor where convenient for short connections to the outside air. The fans are both Sturtevant centrifugal blowers, of sizes and capacities indicated in the accompanying table, and as they are intended only for simultaneous operation when the hall is occupied, they were located side by side and fitted with tandem drive from a single large motor. They both have three-quarter housed casings, the exhaust blower with top horizontal discharge outlets, while the fresh air fan, being connected to the same drive, is necessarily of the 45-deg. upward discharge type. The arrangements of duct work connections are shown in the accompanying drawings. The fresh air supply fan has intake in common with that for general ventilation of the central portion, connection from



Sections Showing Fans and Ducts in Central Section.



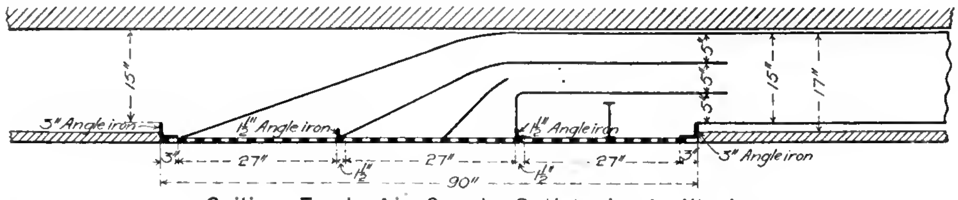
Ventilating Equipment in East Wing and Central Section.

the branch lines from the end sections of the wings lead in both cases to exhaust chambers near the central portion of the wing from which disc exhaust fans discharge through roof outlets. In the case of the central portion of the building the exhaust fan is located in the attic space in the rear of the base of the dome and draws through two gathering ducts that extend on all four sides of this section. The exhaust duct lines are similarly designed for low velocities of flow, averaging but little over 1,000 ft. per minute, and the ducts are without insulation covering throughout.

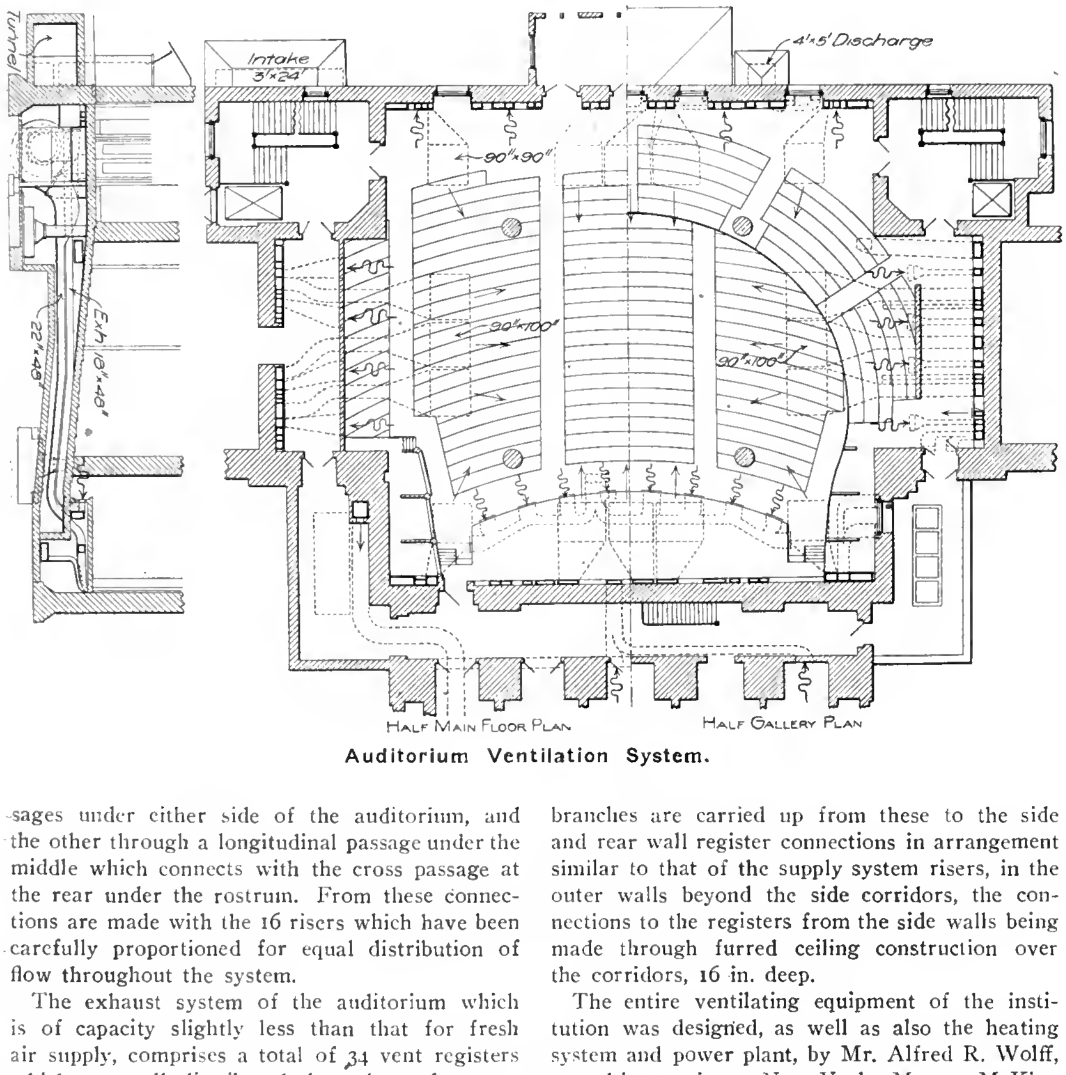
The exhaust fans are Howard & Morse disc exhaust fans of the sizes and capacities indicated in the table and are of the vertical type in the central portion and east wing systems while that for the original west wing was installed horizontally. They are all direct connected to C. & C. direct current electric motors, special vertical shaft motors being used for the two former units. These motors all have separate feeder circuits from the distributing switchboard in the basement to permit of being shut down directly from the latter board and requiring attention floor arranged in five rows and about 500 seats in six groups in a balcony that surrounds the hall on three sides, with in all, 12 boxes, six on either level. The main floor slopes downward to the front towards the rostrum, to a point 4 ft. below the level of the rostrum, the latter and the rear floor and corridors being on the level of the basement floor of the building. The rostrum is 16 ft. in width by 58 ft. long, and the hall itself 104 ft. in maximum length, parallel to the rostrum, and 86 ft. in width, with a ceiling height of 26 ft., giving thus a total cubical content of approximately 235,000 cu. ft. With this arrangement of the gallery and the seating, it was thought preferable to admit the fresh air supply through distributed points in the ceiling, around the outer edges, and to withdraw the foul air in the main hall through openings under the rostrum, and in part through ceiling registers at the extreme rear edges and sides of the room both under and over the gallery. In this way it was felt that by designing for low velocities of register flow the most effective distribution could be secured without noticeable draft.

The fan equipments both fresh air supply and the filter chamber to the fan being made through an intake duct of some length located on the ceiling of the sub-basement above the other supply fan. The exhaust fan has its discharge at the rear of the building through a short stack of height similar to that for the central portion fresh air intake, but for purposes of separation of the intake and discharge, the latter stack, which is 4 x 5 ft. in section, is located some 75 ft. to the west of the intake stack, connection being made to the fan discharge through a 4x4-ft. underground masonry duct immediately outside of the building wall. Fresh air is delivered to the auditorium through 16 ceiling outlet registers which are well distributed over the ceiling area. Twelve of them are registers with 90x100-in. faces which are arranged in groups of three over the center of each of the four sides of the room, while the remaining four registers have 90x90-in. faces and are distributed in the corners of the ceiling. Each of the outlet registers is, as may be noted from the accompanying detail, divided into three sections with distributing baffles in the connection to the ducts in order to spread the outflow evenly over the register face and prevent

any tendency toward draft. The delivery velocities for which this system was designed are exceptionally low, the flow velocities averaging from 1,500 to 1,700 ft. per minute in the trunk duct lines from the blower which are successively decreased in the risers and branches to about 800 ft. per minute at the connections to the registers in which the discharge velocities are reduced to only about 50 ft. per minute, thus precluding the possibility of a draft being felt in any part of the room. These ceiling registers are supplied through three main duct lines from the fan in the basement, one of which extends through pas-



Ceiling Fresh Air Supply Outlets in Auditorium.



Auditorium Ventilation System.

sages under either side of the auditorium, and the other through a longitudinal passage under the middle which connects with the cross passage at the rear under the rostrum. From these connections are made with the 16 risers which have been carefully proportioned for equal distribution of flow throughout the system.

The exhaust system of the auditorium which is of capacity slightly less than that for fresh air supply, comprises a total of 34 vent registers which are well distributed throughout the room in relation to the fresh air supply openings for the purpose of creating a thorough and positive circulation. Of these vent registers, there are 10, each with 14x36-in. faces and comprising together about one-third of the total exhaust ventilation capacity of the system, which are located in the front portion of the rostrum. Of the remainder 12 are located in the side and rear walls of the room under the balcony, and the other 12 similarly in the side walls above, all of these registers being located at the ceiling line with the exception of the four at the rear under the balcony; at this portion of the main floor there are doorways leading out into the area way at the rear for purposes of fire exits, and here the register openings were located near the floor line. This arrangement divides the remaining two-thirds of the vent register capacity between the spaces at the rear both above and below the balcony, obtaining thereby the most complete distribution of register openings. Similar low velocities of flow are also provided for in this system, the duct lines being proportioned for maximum velocities of less than 1,500 ft. per minute, while the connections to the registers are proportioned for velocities of inflow of less than 250 ft. per minute. The arrangement of the exhaust duct work is also similar to that for fresh air supply, there being three main trunk lines leading to the fan intake, one through each of the side passages, and the other through the central passage to the rostrum intake openings at the rear. Riser branches are carried up from these to the side and rear wall register connections in arrangement similar to that of the supply system risers, in the outer walls beyond the side corridors, the connections to the registers from the side walls being made through furred ceiling construction over the corridors, 16 in. deep.

The entire ventilating equipment of the institution was designed, as well as also the heating system and power plant, by Mr. Alfred R. Wolff, consulting engineer, New York. Messrs. McKim, Mead & White, New York, are architects for the institute buildings.

THE LIMIT OF SUPERHEATING desirable for Corliss engines was stated in a discussion of papers on superheated steam at the recent New York meeting of the American Society of Mechanical Engineers, to be to a temperature of 500° Fahr. With steam used at higher temperatures, the valves give trouble by warping and binding, due to their unsymmetrical form, and also in certain cases cylinders have been known to change shape sufficiently to give trouble. In engines fitted with slide and gridiron valves, however, no difficulty is experienced except with lubrication and that has in certain cases been overcome by special direct oil connections to the valve seats.

Some Main Line Revisions on the Baltimore & Ohio R. R.

The Baltimore & Ohio R. R. has completed a revision of its main line between Hollafield and Davis, Md. This is a continuation of work that has been going on for the past seven years in straightening the alignment and making a low-grade freight line from Relay to Washington Junction, the former place being its junction point with the Washington branch, and the latter its junction point with the Metropolitan branch; these two branches forming its line via Washington, by which route its through passenger trains are run. That part of the main line between Relay and Mt. Airy follows the Patapsco River, the valley being narrow and crooked, with hills rising from the water's edge and spurs from the hills projecting across the bends at intervals which have made it necessary in the reconstruction to build a number of tunnels and bridges, as the original location followed closely the windings of the stream resulting in heavy grades and curves.

T. A. Shoemaker & Co., contractors, of Philadelphia, began work on the revision of the line between Hollafield and Davis, in September, 1905, and completed it in October, 1907, during which time they excavated 400,000 cu. yd. of material, 70 per cent. of which was solid granite, the balance being sand, loam, and clay; 10,000 cu. yd. of bridge masonry of Pennsylvania sand stone; 5,000 cu. yd. of concrete in foundation; two tunnels having a combined length of 1,523 ft.; three undergrade crossings; reconstructed a highway 5,000 ft. in length, and changed the channel of the river in two places.

The grading averaged 100,000 cu. yd. per mile, 187,000 cu. yd. being in the Alberton cut, which was 2,000 ft. in length and 75 ft. high, and practically all the earth on the entire work was in this cut, between the original surface and a point about 25 ft. above subgrade. All the material was removed with a 70-ton Bucyrus shovel working in lifts from the surface to subgrade, bringing it down full-width, and wasting the top material on tracks on the same grade with the shovel, running around the contours of the hill.

The material in the east end on the south side was found to be a conglomerate, there being pockets of mica sand, red clay, and ledges of limestone alternating, which caused the south slope to break and pockets of this material to slide out at the seams. These slips were removed with the shovel. The balance of the excavation was all granite, which was removed with steam drills, and shovel. Dorsey tunnel, one mile west of Alberton and on the opposite side of the river from the old line, with a length of 1,025 ft. face to face of portals, was bored through solid granite, and only 96 ft. at the west end had to be timbered, on account of seams in the roof. A top heading, 7x10 ft., was first driven from both ends, the balance of the material being taken out in two benches. The amount of excavation in this tunnel was 36,500 cu. yd.

The material in Davis tunnel, one-half mile east of Davis and on the same side of the river as the old line, proved to be a mixture of mica sand, soft granite which disintegrated when exposed to the air, and a hard rock which followed the subgrade closely, at times reaching as high as the wall plate grade 14 ft. above subgrade. The length of this tunnel is 498 ft., face to face of portals, and it had to be timbered for its entire length. Seven segments of 12x12-in. timbers were used for the centers, and plumb posts 3 ft. center to center, also 12x12-in. for two-thirds of its length. Where hard rock was encountered at wall-plate grade the segments rested on wall plates on the rock bench.

The method used in driving this tunnel was

varied from that at the Dorsey tunnel, to the extent that the first heading was excavated from the roof to the wall-plate grade and was taken out full width, the bottom bench being taken out later, the excavation amounting to 17,000 cu. yd. On Oct. 22, 1906, while this tunnel was being lined, 98 ft. of lining having been completed in the east end, a fall occurred 140 ft. from the east end, 30 ft. in diameter almost on the center line, and extending to the original surface of ground 92 ft. above subgrade. This fall was almost plumb and had the appearance of being a shaft, the north side overhanging slightly, having a well-defined rock seam, and from that point south the material was soft granite and mica sand. The contractors began to line the tunnel from the west end and finally got to within 104 ft. of the lining from the east end. They tried several times to get under the fall by using crown bars, and on four different occasions were within a few feet of getting through when the southwest corner would give away and crush their timber centers. They finally gave this method up, and in June, 1907, when the size of the fall had increased to 53 ft. at the roof of the tunnel and 140 ft. at the surface of the ground, they began the use of a Model A Marion shovel and had the fall removed, which consisted of 36,000 cu. yd. and formed a natural slope to original grade. The tunnel was completed Sept. 25, 1907.

Both tunnels are standard section for double track, and lined with shale and vitrified brick and have sandstone portals. Both were driven by compressed air, the compressor plant being located midway between them, and the air conveyed to them by a [illegible] pipe. The excavation was unclassified.

The old roadbed [illegible] abandoned except for one-half mile [illegible] of [illegible]ollafield, which was raised 5 ft. above the old grade. East of Alberton the new line [illegible] north of the old line through a rock cut [illegible] from Alberton to just east of Davis tunnel [illegible] line runs on the opposite side of the river [illegible] the old line, crossing it at this point [illegible] the old grade and again crossing to the north side of the old line at the west end of Davis tunnel 8.2 ft. above the old grade, where it continues on this side until Davis is reached, where it connects with the old line.

The revision eliminates 542° 02′ of central angle, and reduces the maximum curve from 12° to 7°, all curves being spiraled. The double-track roadbed is 30 ft. in cuts, and 33 ft. on fills, with 85-lb. rails and stone ballast. The west-bound grade has been reduced from 0.9 to 0.5 per cent. and the east-bound from 0.8 to 0.5, all grades being compensated.

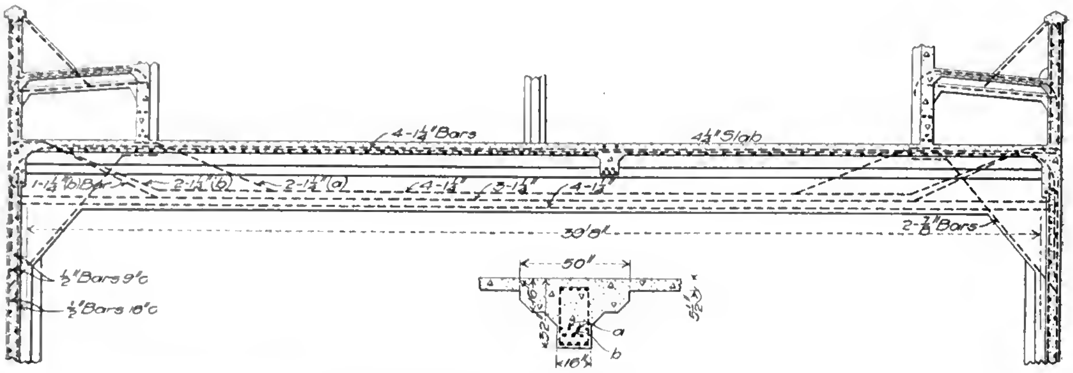
The cost of the improvement has been $750,000 and the work has been done under the direction of Mr. D. D. Carothers, chief engineer; Mr. A. M. Kinsman, engineer of construction, and Mr. J. T. Wilson, assistant engineer.

THE BAY SHORE CUT-OFF of the Southern Pacific Railroad in San Francisco was put into service last week. The new line eliminates the disadvantages of the old coast line route in entering the city, and cuts out about five miles of distance, several hundred degrees of curvature and some heavy grades. The ranges of hills to the south of the city are pierced by the new line, necessitating about two miles of tunnels, two miles of trestle and a cut 95 ft. deep, all within 10 miles.

A Reinforced Concrete Hotel Building in Oakland, Cal.

By Edw. L. Soulé, Assistant Engineer with John B. Leonard, San Francisco.

An interesting example of the use of reinforced concrete is furnished by the Hotel St. Mark, now nearing completion at the corner of Twelfth and Franklin Sts., Oakland, Cal. A view of the finished structural framework, as recently completed, is shown in an accompanying picture. The building consists of two rectangular structures, with a connecting portion, the whole having a shape resembling somewhat that of the letter H. The building rises to a height of 108 ft. above the street level and includes nine floors, a mezzanine floor and a basement. On the outside the concrete skeleton is covered with cement plaster and provided with moulded ornamental trimmings and galvanized iron cornice. The interior finish and partitions conceal the beam and girder construction. The present description will treat of the reinforced concrete work. The main entrance on Twelfth St. leads through the arched lobby to the hotel office in the central portion. The entire Franklin St. portion will be elaborately fitted for a cafe and banquet hall, while the hotel lobby, parlor, organ loft, kitchen and bar occupy the remaining space of the first floor. The upper floors will furnish about 250 rooms equipped for hotel accommodations. The ninth, or sample room floor, will afford commodious display rooms for commercial men.



Design of Ninth or Sample-Room Girders.

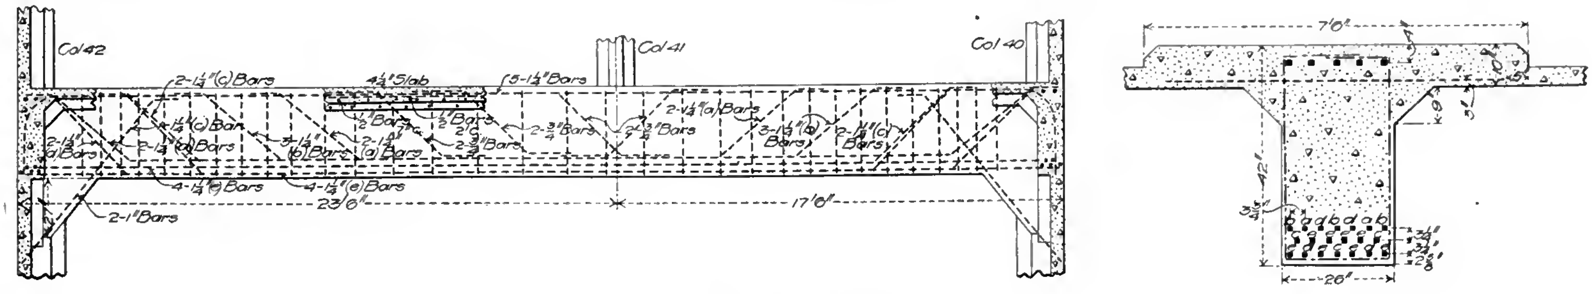
The Hotel St. Mark in Oakland.

The plan of the foundation, shown in one of the diagrams, consists of simple, spread and continuous footings, which bring a load of about three and one-half tons per square foot upon a firm clay soil. The lot line footings are carried partly on continuous and partly on cantilever footings. The eccentric moment of the continuous wall footing is overcome by reinforcing the basement wall vertically and by placing tension on the main slab bars of the first floor. Cast-iron plates were used in the majority of the footings to distribute the load carried by the column bars. Lapping bars were also provided, thereby securely anchoring the columns to the foundation and affording sufficient rigidity to move with it.

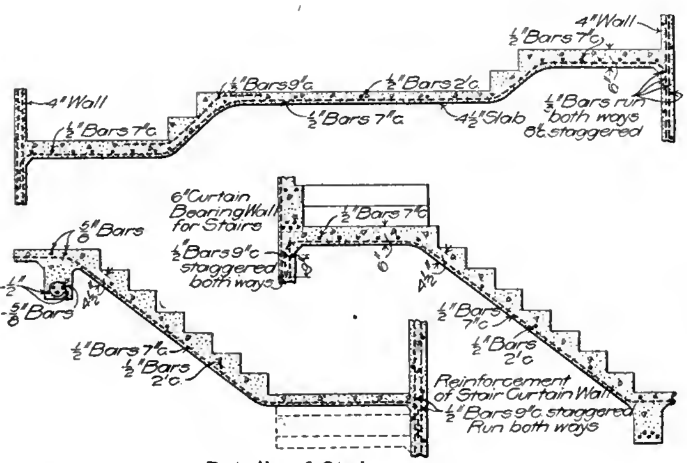
In the basement the columns have an octagonal cross-section. The vertical reinforcement varies according to the load, and is wrapped spirally with soft iron wire. In the majority of cases light reinforcing bars were used, and in some places a double core of eight bars each was provided. The outer bars form the basis for wrapping. The inner core, composed of large-sized bars, was strapped with ¼-in. soft wire at 12-in. intervals. The interior columns above the first floor are square, except two columns between the first and second floors, which were made round for architectural reasons. The corners of all square columns and beams were chamfered by nailing small triangular strips in the molds.

Half plans of the typical and second floors are

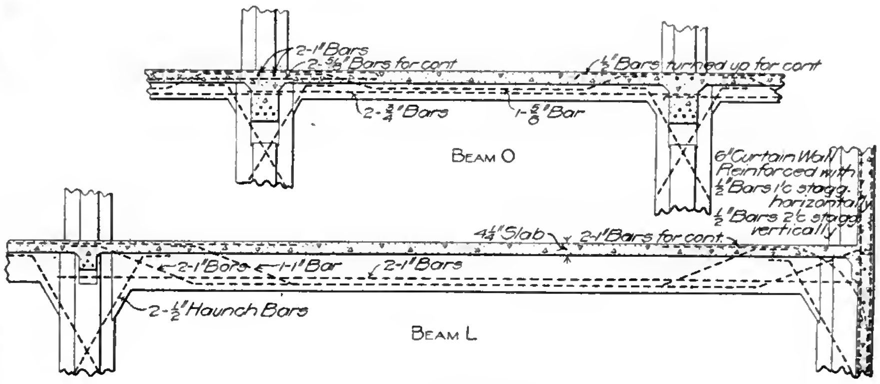
shown in one of the diagrams. In order to afford facility for rapid construction, the design adopted was that of a flat slab type with supporting beams between columns. The transverse beams L between the columns in the interior row are 10 in. wide and have a total depth of 18 in.



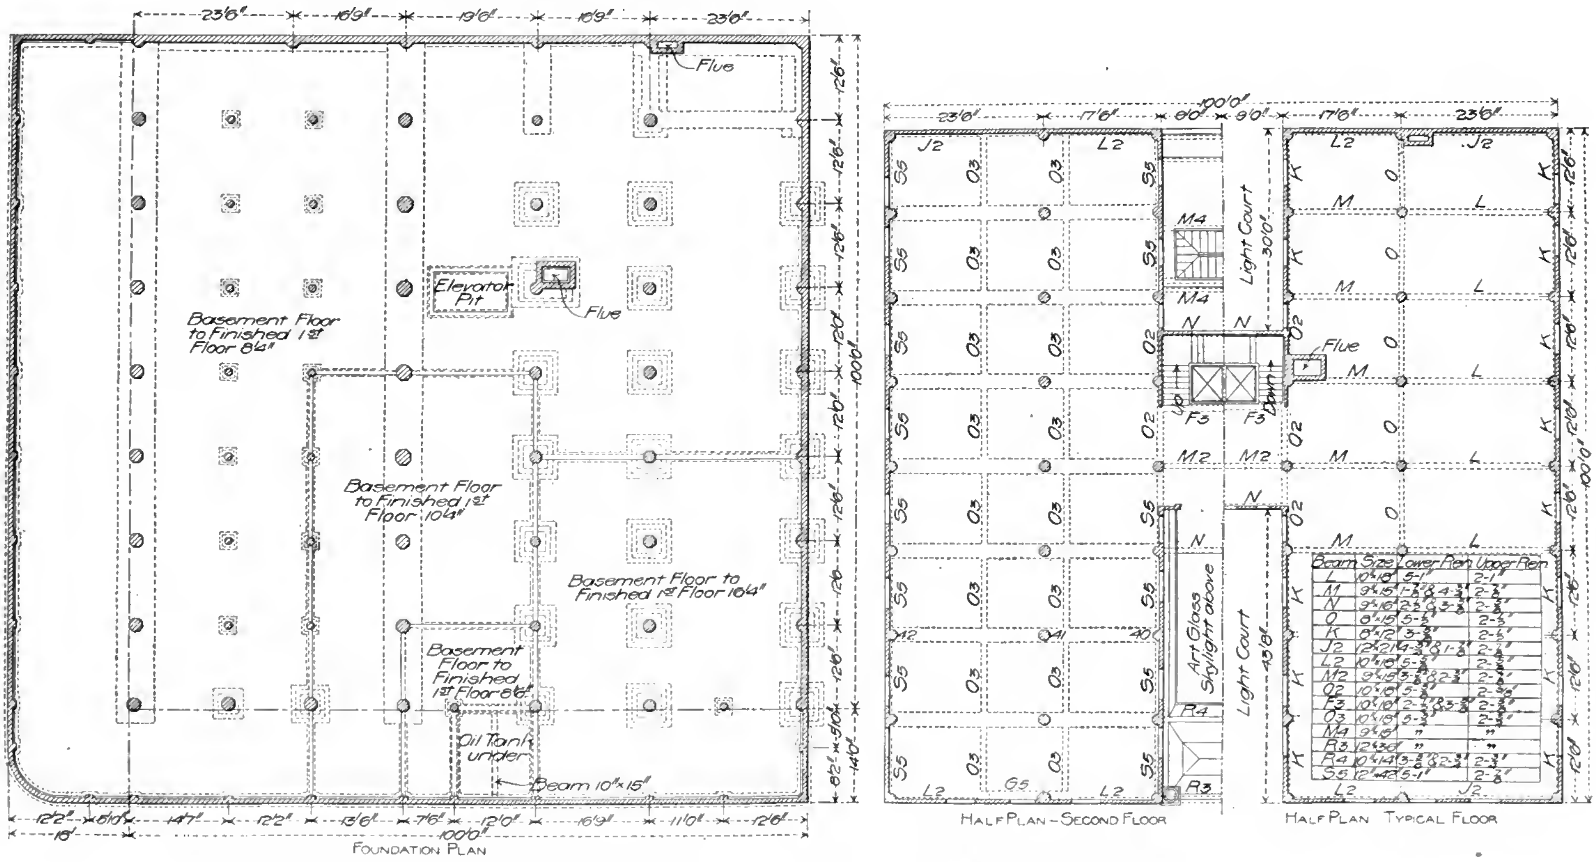
Design of Girders over the Banquet Hall.



Details of Stairs.



Details of Typical Beams.



Foundation and Floor Plans of the Hotel St. Mark, Oakland, Cal.

They are each reinforced with five 1-in. corrugated bars. The M beams are 9 in. wide and 15 in. deep, reinforced with one ⅞-in. and four ¾-in. corrugated bars. The O longitudinal beams are the same size as the M beams, with five ½-in. reinforcing bars each. In the details of a typical five-bar beam it will be seen that one bar turns up at the quarter point of the clear span, two bars at the eighth point and two bars continue over the supports. Due consideration has been given to the action of continuity by affording about four-tenths of the main reinforcement in the upper side of the beam at points of support. These continuity bars extend from the quarter point of the clear span to the corresponding quarter point of the adjacent span.

In order to maintain the clear space in the banquet hall, it was found necessary to terminate the intermediate columns on girders extending from wall to wall, affording a clear span of 37 ft. 8 in. This was accomplished by means of the tee girders shown in one of the detail diagrams. The architect's plans limited their size to 26 in. width and 32 in. depth to the underside of the slab, on account of the panel depth and finish of the cafe ceiling. Accordingly, the section consisted of five 1¼-in. bars placed in the compression area and twenty 1¼-in. bars to resist the tensional stress. The bars were obtained in special lengths and required no splicing.

Because of the limitation of size of the second-story girders and to reduce the load on the columns, there were also constructed suitable girders of the same span at the eighth floor and at the ninth, or sample room floor. The eighth floor girders are 16 in. wide by 25 in. total depth, and are each reinforced with seven 1¼-in. bars in the lower flange and two 1¼-in. bars in the compression flange. The ninth, or sample room, girders carry the roof loads concentrated on the columns and their own floor loads. One of the diagrams shows the details of sizes and reinforcement.

The first floor was designed for a live load of 120 lb. and the typical floor for a live load of

60 lb. per square foot. Intermediate beams were used on the first floor, thereby reducing the slab to $3\frac{1}{2}$ in. in thickness. The typical floors consist of a $4\frac{1}{4}$-in. slab. Over the rough slab is laid a $\frac{3}{4}$-in. finishing coat of cement grout, making a floor with a total depth of 5 in.

A large number of small openings for vents, electric wiring and pipes were required in the floors at various places. These areas were, however, reinforced with additional bars and enclosed by the partition framing.

All walls were built monolithic with the rest of the building and were usually 6 in. thick above the first floor. The reinforcement consisted of one-quarter of one per cent. of the sectional area, one-third of which was placed vertically and the remainder horizontally, all bars being staggered between the outer and inner surface of the concrete. The basement walls serve as retaining walls and are reinforced vertically on the lot line sides. The sidewalk retaining wall varies from 9 in. at the top to 12 in. at the bottom, and is reinforced horizontally between pilasters, which serve as vertical beams.

An interesting portion of the construction is presented in the various stairways, which illustrate the adaptability of concrete to special details. Attention is directed to the diagram giving plan and detail of typical stairways. The flat soffit allowed of uniform form work and proved an easy type for erection. Near the entrance there is a spiral stairway winding to the basement; also, in the central portion a circular stairway rises to the orchestra balcony.

For the columns, [illegible] the concrete used consisted of one part of cement and six parts of a sand and gravel mixture; for the foundation the proportions were one part cement and seven and one-half parts of aggregates. Golden Gate cement, manufactured at Cement, Cal., about forty miles from the building, was used almost exclusively.

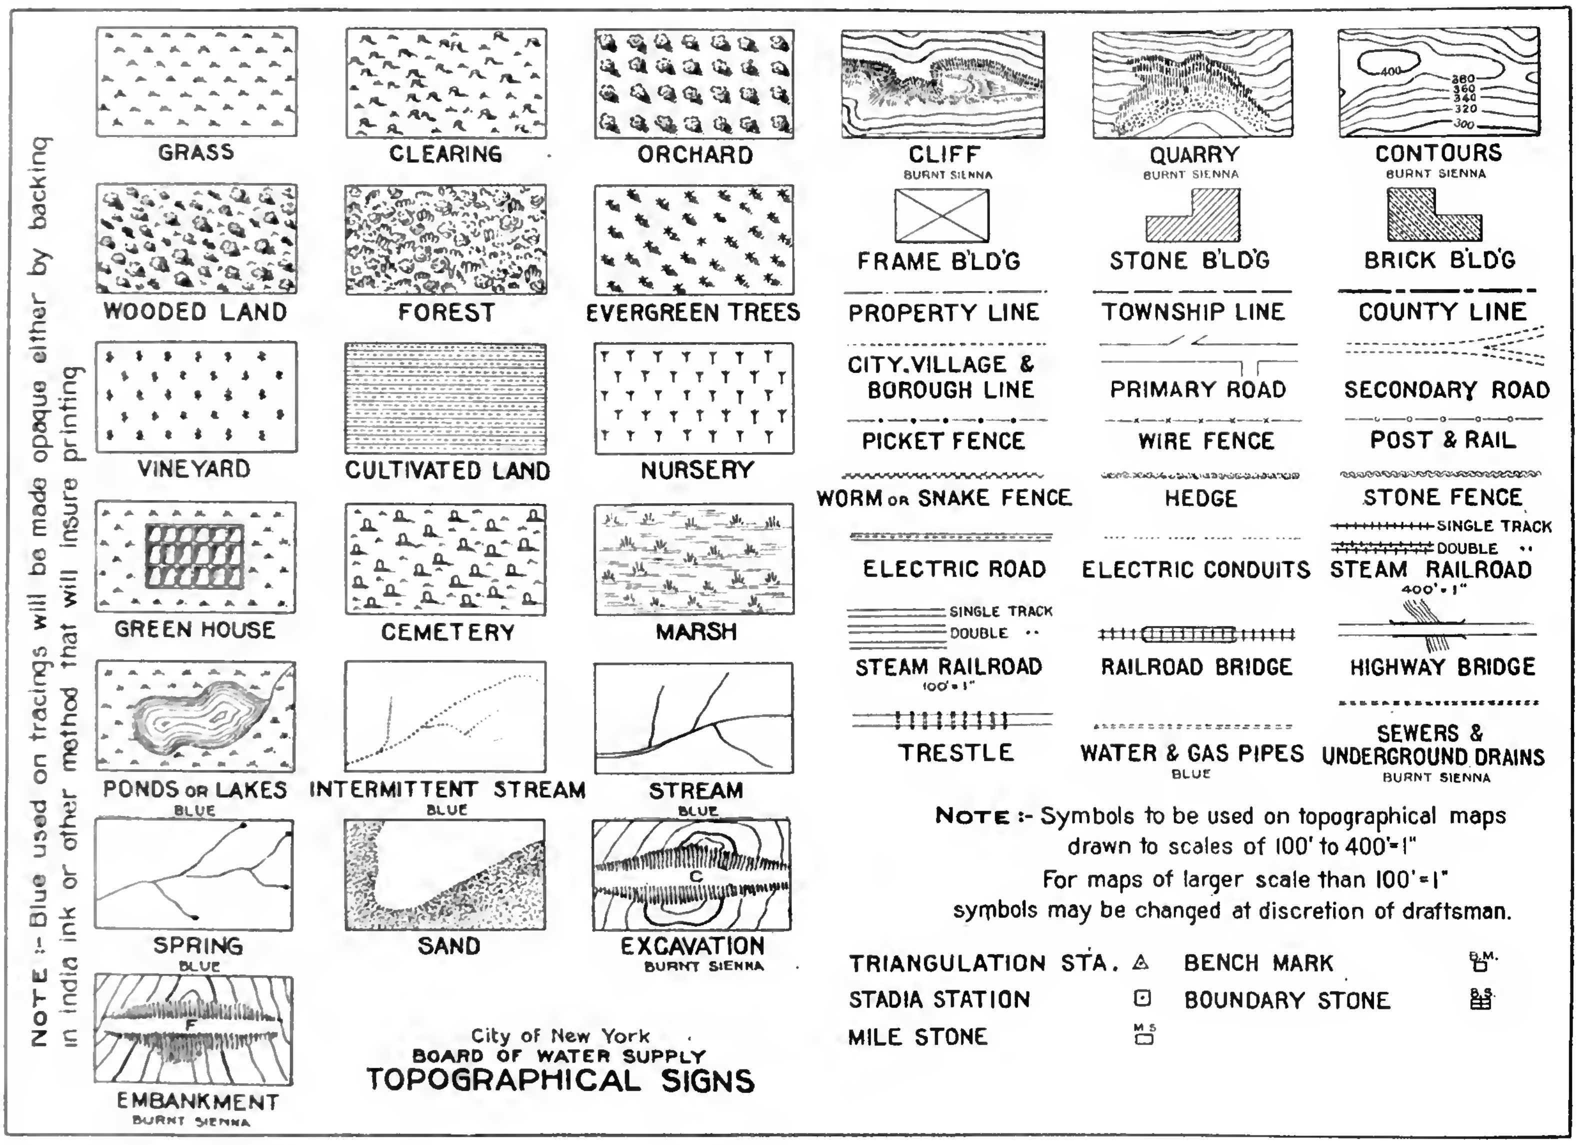
The natural mixture of sand and gravel were of such proportions as to be suitable for direct use. Two adjoining storage bins, one for the cement and one for the sand and gravel, were installed in the basement, near a Smith mixer that discharged the concrete into a hoist. This hoist was situated in the front light well, near the connecting portion of the two rectangular wings, and elevated the concrete to a dumping bin at the required height, from which carts were filled, wheeled over the forms and dumped as required. The concrete was mixed very wet.

Heavy rains considerably impeded the progress of excavation during the month of January, 1907. However, by March 1, the concreting of the foundation was commenced, and after the second story was passed an average progress of a floor per week was made, the fourth story being poured in five and one-half days. Ninety-nine yards were deposited in one day during the fabrication of the second story girders, and 65 yd. were recorded in four hours during the pouring of the eighth floor girders. By July 3 the building was completed structurally except the ceiling beams of the entrance lobby, which were omitted because of the hoist. The concrete was practically completed in 98 working days. On the work there were employed an average of 90 workmen, exclusive of plumbers and electricians, for about 130 days. About 2,520 yd. of concrete and 200 tons of reinforcing bars were used in the structural framework. All reinforcements were made with Johnson corrugated bars, proportioned for a unit stress of 16,000 lb. per square inch. In general, concrete is figured to carry a compressive stress of 600 lb. per square inch.

The architect of the building is Mr. Benjamin G. McDougall, who placed all the structural details of the building in the hands of Mr. John B. Leonard, consulting engineer, of San Francisco. The Lindgren-Hicks Co. is the contractor.

Standard Topographical Signs.

The Board of Water Supply of New York has to make a great many topographical maps for copying by blue-printing. This drafting is done in a number of offices widely separated, and to insure uniformity in the work the symbols shown in the accompanying chart have been adopted for all maps on scales of 100 to 400 ft. to 1 in. For



maps on a larger scale than 100 ft. to the inch, the symbols may be changed at the discretion of the draftsman. It will be noticed that these symbols are somewhat less detailed in some respects than those in most text books on topographical drawing. But two colors are used in addition to black, burnt sienna and blue; burnt sienna gives fairly good lines on blue prints, but blue gives poor lines, and for this reason blue used on tracings must be made opaque by backing with India ink or some other method that will insure printing. In reproducing the symbols by photo engraving, it has been necessary to reduce them from the original chart about three-tenths. So many inquiries for these symbols have been received by the Board that they are published here, by the consent of the Board, in order to be generally available for engineers interested in such work.

The Ratio of Heating Surface to Grate Surface as a Factor in Power Plant Design.

A paper read before the American Institute of Electrical Engineers on Dec. 19 by Walter S. Finlay, Jr.

Power plant design, in its modern development, is controlled solely by the specific application of general laws modified and moulded to suit special requirements. To attempt the construction of a comprehensive ruling from the results of a particular line of investigation in some particular plant, and then to advise the general use of such ruling as conducive to economical operation, would cause confusion, possibly resulting in a wholesale rejection of the good with the bad. The value of specific results and their publication lies in the opening up of a line of technical thought, or in adding information to some subject, from which specific deductions or particular application may be made.

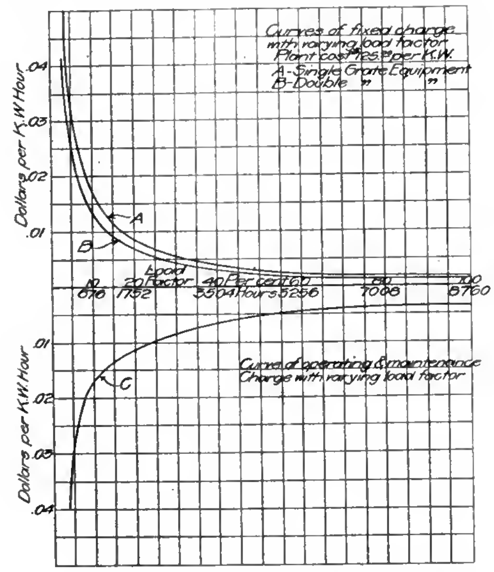


Fig. 1. Fixed Charges; $125 Base.

The results obtained in the investigation which was primarily the foundation of this paper should be looked upon merely as specific, but whose bearing upon the general subject by means of a general development may be of value, particularly in certain new phases of plant design.

As a fundamental and almost initial point of attack in the comprehensive subject of steam power-plant design, the ratio of heating surface to grate surface has been a value fixed from the beginning of results of commercial usage, and the expression of the same in empyrical formulas or figures suited to the requirements of this or that designer, builder or manufacturer.

A summation of practice from early engineering times to values developed by the most modern idea, gives a great range to this ratio; namely, from the extreme value, as advised by Dalton in 1839, of ten to one, to modern values up to seventy to one used, not only in locomotive but even in power-plant practice. Of course, the primary object in view has been the adaptation of values to produce the maximum useful effect; but the question now arises as to whether or not "maximum useful effect" is not being interpreted as maximum economical efficiency, with reference to fuel only, as a primary consideration, and with an undue subordination of total plant costs. By total plant costs are meant, of course, the combined fixed charges resulting from interest on plant investment, depreciation, taxes, etc., and operation and maintenance charges.

Properly to investigate the subject in its particular applications would require an extremely tedious and complicated study of innumerable individual requirements; but for a general survey assumptions based upon commonly accepted values would suffice to direct the attention to the point involved.

Assuming a plant first cost of $125 per kilowatt, equipment, including turbo-generators, boilers equipped with stokers, with, say, sixty to one ratio, the following relative costs may be assumed:

	Per kw.	Per cent.
Total cost	$125.00	100.0
Building	43.75	35.0
Boilers	6.875	5.5
Grates	1.75	1.4
Piping	5.625	4.5
Coal-handling app. per kilowatt	2.30	1.84
Balance of equipment	64.70	....

The value of the building as assumed might be considered low, particularly in the case of a turbine plant; boiler cost is possibly average; grates, high—a stoker valuation; piping value is about average.

Assuming as a fair value for determining fixed charges: Interest on investment, 5 per cent.; depreciation, 6 per cent.; taxes and insurance, 1 per cent; then the total fixed-charge rate would equal 12 per cent.

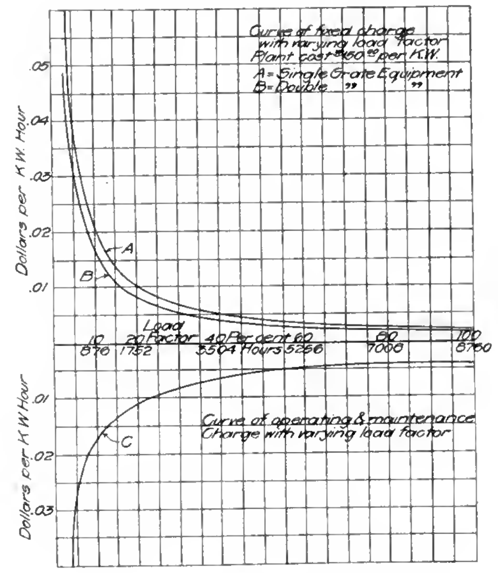

Fig. 2. Fixed Charges; $150 Base.

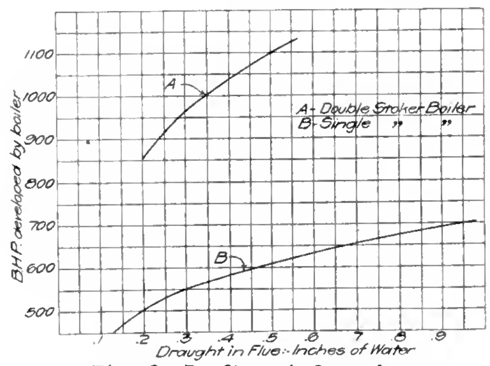

Fig. 3. Draft and Capacity.

Upon bases of load-factor and charges, a curve has been drawn showing the relative value of the fixed charges over a range of factor variation from approximately 3 to 100 per cent. in the case of the plant as assumed. (Curve A, Fig. 1.)

To determine total charges, the variation of maintenance and operation charges, relative to load-factor, must also be considered. It is rather difficult to assume this curve, as conditions in this respect vary rather widely. However, Curve C, Fig. 1, has been drawn through points located by comparative results obtained in actual cases of operation. The shape of the curve will practically be constant for any figure which may be assumed, and its relation to the general results will be such that the value of the principle involved will be unaffected. The sum of the ordinates between the two curves gives total charges per kilowatt-hour.

In a reconsideration of the plant design as affecting first cost, the natural method of procedure is to consider separately each item involved.

1. *Building.* In turbo-generator plant design it is a generally accepted rule that total plant dimensions are controlled by boiler-room dimensions; that, for instance, a diminution in the actual size of the boiler room may be accompanied by a proportional diminution in the size of the turbine-room, the output remaining the same. The methods of accomplishing such results are perhaps various; change in size of units, difference in type, closer grouping of units, etc.

2. *Boilers.* The consideration of this feature is naturally interlinked with the subject of "Grates," and the two can better be discussed together.

Rules of boiler-practice have been derived chiefly, if not entirely, by experiment and investigation; and those rules validated only by general acceptance can be quoted as bases for argument. Such a law is the following one:

All other conditions remaining constant, capacity developed is, with slight modifications, in direct ratio to the area of the active grate surface. An increase in capacity—heating surface remaining constant—caused by an increase in grate area, is accompanied by a loss in economical evaporation, due to the increased temperature of the escaping gases.

This loss in economy is the fundamental factor which must necessarily be the object of a careful study, involving the complete investigation of the heat interchanges taking place in a boiler. The research work of such men as Newton, Péclet, Joule and Rankine, together with recent investigation, has not, as yet, produced sufficiently definite and authoritative results, which may be used as bases of rational calculation in this regard. Under normal conditions of present boiler practice, estimates of loss vary from practically zero to as much as 15 per cent. fuel economy for an increase of 100 per cent. in boiler capacity.

Lately, however, the opinion has been advanced that considerable increase in capacity can, without great sacrifice in economy, be obtained by proportional increase in grate area. This idea is based upon the possibilty that combustion and heat distribution and transfer could be much improved under the new conditions, when in increasing the grate area careful attention is given to details of design most conducive to these features. Other conditions being favorable, and with a belief in the correctness of this theory, a change was made in the design of eighteen of the boiler furnaces in the 59th St. plant of the Interborough Rapid Transit Co. (See Fig. 7.) Such a design gave the possibility of operating within the range of the original single-stoker boiler together with the higher range of the double stoker.

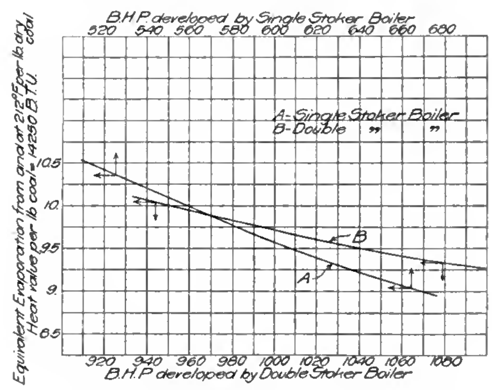

Fig. 4. Capacity and Evaporation.

The second stoker installed, that is, the one beneath the mud-drum, as shown in Fig. 7, has an area of 80 per cent. of that of the original stoker. Certain features in the construction of the plant prevented installation of a larger size. A detailed description of points in the design is unnecessary, save to call attention to the fact that the lower stoker is constructed practically within a so-called "Dutch oven," and whatever is conducive to good combustion is provided for therein.

The curve shown on Fig. 8 is given as corroborating this fact. Operation of these stokers has shown that such is practically done with but little more complication than existed in the single type.

Tests to determine the comparative economical operation of the double and single stokers show results given graphically in Figs. 3, 4, 5 and 6. The curves in Figs. 3 and 4 are self-explanatory. Fig 5 shows a curve plotted upon the values, as determined by curves in Fig. 4, this curve being indicative of the fact that operation with the double type was as economical in fuel values, as the single type increased in boiler capacity approximately 71 per cent. In the curves in Fig. 6 is shown the fact that the economical loss for an increase in rating of 80 per cent., as proportioned to the increase in grate area, varied between 2 and 3 per cent.

To summarize the results of these tests: It has been made evident that in this particular case double-stoker operation covers the entire range of single-stoker operation and adds an increase

lowered, although not in direct ratio to such change.

5. *Effect of change of ratio.* Suppose that in a reconsideration of the plant design it is decided to cut in half the ratio of heating surface to grate surface by the use of double grates or stokers under boilers of the same rating. Plant

Water	0.90	0.90
Engine-room mechanical labor..	1.70	1.70
Lubrication	0.44	0.44
Waste, etc.	0.38	0.38
Electrical labor	3.16	3.16
Total	100.00%	99.75%

The saving in boiler room maintenance and operation may be accounted for in the following itemized statement of boiler-room charges:

Maintenance.	Single Grate.	Double Grate.
Boilers	29.5%	14.75%
Economizers	2.78	2.78
Furnaces	17.29	17.29
Stokers and stoker engines	40.68	40.68
Boiler feed-pumps	5.42	5.42
Boiler feed-piping	2.20	1.10
Boiler blow-off piping	0.44	0.44
Water supply piping	1.52	1.52
Total	100.00%	83.98%
Operation.		
Water-tenders	20.82%	10.41%
Stoker operators	38.09	38.09
Assistant stoker operators	15.49	15.49
Stoker oilers	2.54	2.54
Economizer oilers and cleaners	5.84	2.92
Boiler feed-pump men	5.08	5.08
Boiler cleaners	10.41	5.21
Miscellaneous labor	1.73	1.73
Total	100.00%	81.47%

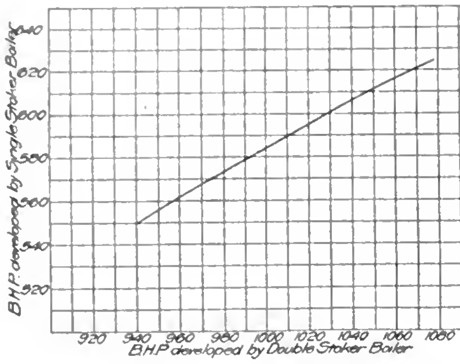

Fig. 5. Stoker Relations.

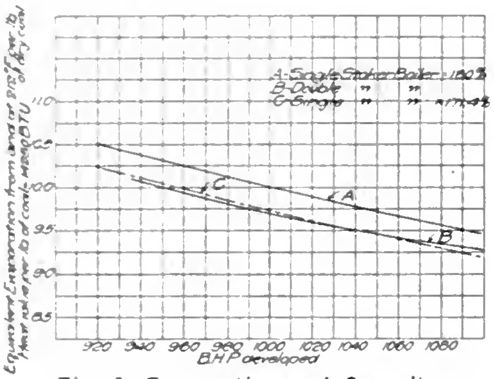

Fig. 6. Evaporation and Capacity.

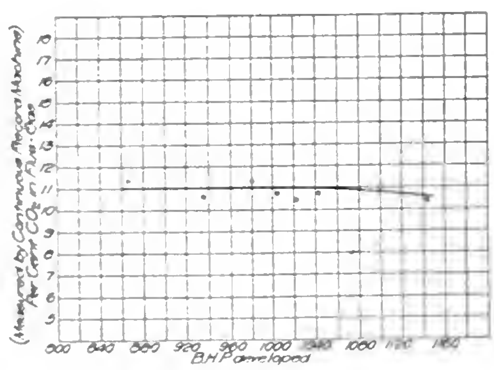

Fig. 8. Curve of Carbon Dioxide.

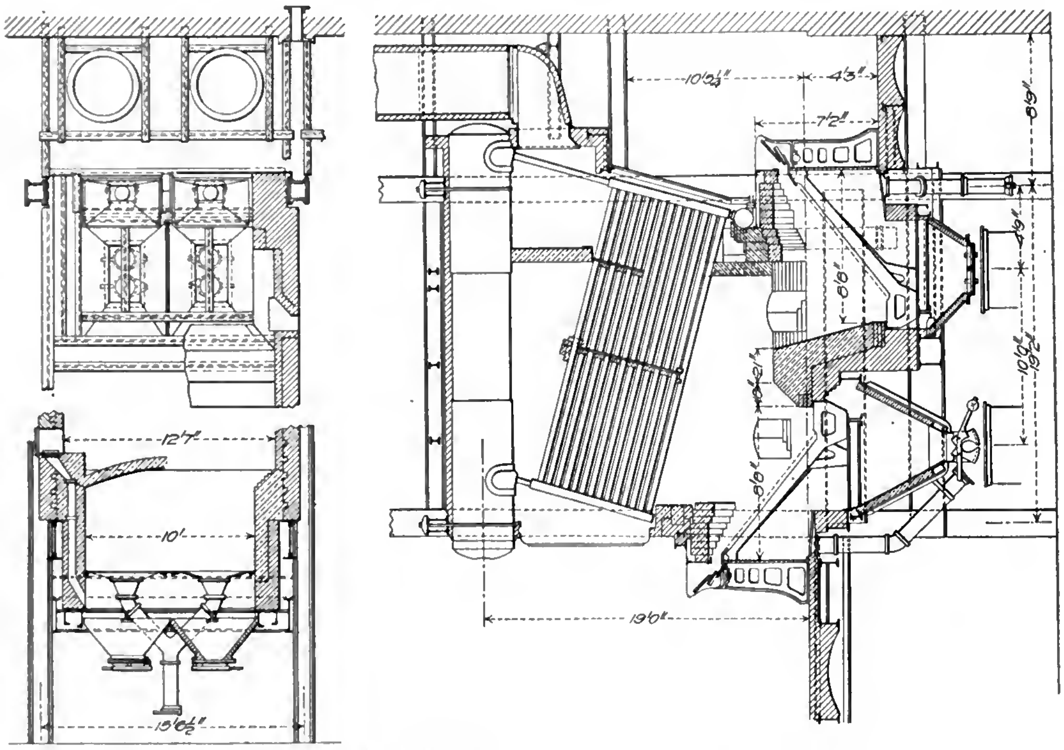

Fig. 7. Double Stoker Installation, Interborough Rapid Transit Co.

of capacity proportionate to its larger grate surface, with but slight loss in economy, and that the increase of 71 per cent. in capacity was accomplished with no loss in economy.

With these results as a basis, let it be assumed that boiler caapcity is increased in ratio to increase in grate surface with but little loss of economy. This view might be further strengthened when consideration is taken of the possibilities of economizer practice, the increase in saving, by proper design, being high in ratio to extra cost involved.

To return to the consideration of the items under the power plant whose first cost has been assumed to be $125 per kilowatt, the next point is:

3. *Piping.* In the case involved the cost of steam piping between boilers and manifolds, plus boiler feed piping, plus boiler blow-down piping, has alone been considered. With any change in number of boilers, capacity remaining the same, the cost of piping will vary in the same ratio times a factor due to change in size of pipe.

4. *Coal-handling apparatus.* Fixed plant capacity would seem to demand fixed cost of coal-handling apparatus, but the proportionate value of the conveying apparatus is so large that when any change is made affecting the length of carry the total system cost will be raised or

output is to remain the same. A tabulation of the costs as revised would be as follows:

	Per kw.
Building (reduced 40%)	$26.25
Boilers (reduced 50%)	3.438
Stokers (remain same)	1.75
Piping (reduced 40%)	3.735
Coal-handling app. (reduced 15%)	1.955
Balance (remains same)	64.70
	$101.468

A curve (B, Fig. 1) is plotted upon this new basis.

Summation: Plant first cost and fixed charges, each reduced 19.6 per cent.

The next consideration is that of the effect of such changes upon plant maintenance and operation charges. Properly to discuss this, the following tabulation, based upon the figures given by Mr. H. G. Stott in his paper on "Power Plant Economics," will furnish a means of comparison:

Maintenance.	Single Grate.	Double Grate.
Engine room mechanical	0.64%	0.65%
Boiler room	5.40—(16%) =	4.54
Coal- and ash-handling app.	0.68	0.68
Electrical apparatus	1.41	1.41
Operation.		
Coal- and ash-handling labor..	2.65	2.65
Removal of ashes	1.18	1.18
Dock rental	0.93	0.93
Boiler-room labor	8.38—(18.5%) =	6.83
Boiler-room oil, waste, etc.	0.21	0.21
Coal	71.94+(3%) =	74.10

Thus, with changes as noted, the decrease in maintenance and operation would be 0.25 per cent, the curve for same practically coinciding with Curve C, Fig. 1.

A second set of curves, based upon a plant cost of $150 per kilowatt, as shown in Fig. 2:

	Per kw.	Per cent.
Plant cost per kilowatt	$150.00	100
Building	60.00	40
Boilers	8.25	5.5
Stokers	2.25	1.5
Piping	6.75	4.5
Coal-handling apparatus	2.63	1.75
Balance	70.12	

Same plant double stoker.	
Building (reduced (40%)	$36.00
Boilers (reduced 50%)	4.13
Stokers (remain same)	2.25
Piping (reduced 40%)	4.05
Coal-handling apparatus (reduced 15%)	2.24
Balance	70.12
Total	$118.79

Showing a reduction in first cost and fixed charges of 20.8 per cent.

Summary. In the case of the $125 plant the following savings might be effected by use of double grate:

First cost, 19.6 per cent. saving.

Total plant charges varying from a saving of 5.64 per cent. at 100 per cent. load-factor to 7.54 per cent. at 50 per cent. factor to 9.65 per

cent at 4.16 per cent. factor (365 hours per year).

In the case of the $150 plant:

First cost, 20.8 per cent. saving.

Total plant charges vary from about 7.06 per cent. saving at 100 per cent. load-factor, to 9.26 per cent. at 50 per cent. factor to 11.5- at 4.16 per cent. factor.

Thus summarized, the remarkable effect that the grate area and heating surface ratio, when furance design is carefully considered, may have upon plant first cost and total annual costs should certainly place this particular feature well up in the list of subjects for careful investigation and make it a point of primary and fundamental consideration in advanced design.

Hydraulic Properties of Reground Cement Mortars.

A paper presented at the annual convention of the Association of American Portland Cement Manufacturers by Messrs. Henry S. Spackmand and Robert W. Lesley.

Observing in the course of our microscopic examination of cement mortars that a large proportion of the cement was unacted upon by water even after submergence for long periods, we decided to determine by actual test the extent of the hydraulic properties remaining in the cement after it had been gauged with water and allowed to harden. Having in the course of our regular routine cement testing, occasion to sample and test a large amount of one brand of cement, we determined to try the experiment on the broken neat briquettes from the seven and twenty-eight day tests of this cement.

The original cement, a well-known standard American brand, was sampled in carload lots, the sample being collected between July 17 and Sept. 16, 1905, and represented several thousand barrels. Each car was tested separately and all passed the requirements of the American Society for Testing Materials. In order to arrive at a standard of comparison, the results of the individual tests of the cars was averaged, giving the following as the mean of the different tests.

Fineness; 91.5 per cent. passed a No. 100 sieve and 76.2 per cent. passed a No. 200 sieve.

Setting time, as determined by Gilmore's needle; initial set, 170 minutes; final set, 334 minutes. Percentage of water, 21.

Soundness or constancy of volume; cold water pats, good; air pats, good; steam pats, good.

Specific gravity, 3.14.

Average tensile strength of standard briquettes; neat, 710 lb. at 7 days and 778 lb. at 28 days; 1:3 mortar, 261 lb. at 7 days and 360 lb. at 28 days.

As a further check an average sample was prepared from the various samples collected taking the same amount of cement from each sample and mixing thoroughly. The sample so prepared was tested in accordance with the standard specifications and gave the following result: Silica, 21.25; alumina and iron oxide, 11.09; lime, 62.96; magnesia, 2.35; sulphuric anhydride, 1.23; loss on ignition, 74; total, 99.12.

TENSILE TEST, STANDARD BRIQUETTES (AVERAGE OF 5 BRIQUETTES.)

Neat.		1-Cement, 3-Sand.	
7 days	610 lbs.	7 days	182 lbs.
28 days	752 "	28 days	338 "
3 months	754 "	3 months	487 "
6 months	646 "	6 months	415 "
9 months	593 "	9 months	350 "
1 year	706 "	1 year	322 "
2 years	670 "	2 years	325 "

The lower tensile tests obtained at the seven-day period can be accounted for by the cement having been exposed to air and aged considerably before the average sample was made up. For this reason, no test for setting time or specific gravity was made on the average sample.

In addition to the standard sieving tests the percentage of flour in the sample was determined by elutriation.

Percentage of cement passing 100-mesh sieve, 91.40.

Percentage of cement passing 200-mesh sieve, 76.30.

Percentage of cement remaining in suspension in dry kerosene after 30 seconds settling, 45.18.

Percentage of cement remaining in suspension in dry kerosene after 2 minutes settling, 29.85.

The broken neat seven and twenty-eight day briquettes made from the individual samples were saved, being stored in air in the cellar. After a sufficient quantity had accumulated they were dried at a temperature of 212° F. until of constant weight, then crushed and reground in a laboratory tube mill. The resultant product when tested as cement in accordance with the standard specifications gave the following results:

Fineness; 94.4 per cent. passed a No. 100 sieve; 74.4 per cent. passed a No. 200 sieve.

Setting time as determined by a Gilmore's needle; initial set, 60 minutes; final set, 310 minutes. Percentage of water, 25. Temperature of water, 62° F. Temperature of air 66° F.

Specific gravity, 2.57.

Soundness or constancy of volume; cold water pat, good; air pat, good; steam pat, good.

TENSILE TEST, STANDARD BRIQUETTES (AVERAGE OF 5 BRIQUETTES.)

Neat.		1-Cement, 3-Sand.	
7 days	123 lbs.	7 days	26 lbs.
28 days	253 "	28 days	63 "
2 months	340 "	2 months	145 "
3 months	383 "	3 months	179 "
4 months	402 "	4 months	227 "
1 year	401 "	1 year	198 "

The neat briquettes from the above test were in turn kept, being stored in air of cellar. On completion of the test, these were dried, reground and tested in the same manner as before, but the resultant cement was in addition analyzed. The results of the analysis after being twice gauged with water, were: Silica, 17.60; alumina, 5.67; iron oxide, 2.29; lime, 49.64; magnesia, 1.66; sulphuric anhydride, 1.13; water, 17.90; carbon dioxide, 3.84 = 8.27 $CaCO_3$.

The physical tests after three gaugings with water were as follows:

Fineness, 93.8 per cent. passed a No. 100 sieve and 73.6 per cent. passed a No. 200 sieve.

Setting time determined with a Gilmore's needle; initial set, 240 minutes; final set, 24 hours. Percentage of water, 26. Temperature of air, 73° F. Temperature of water, 70° F.

Soundness or constancy of volume; cold water pats, good; air pats, good; boiling pats, good.

Specific gravity, 2.35.

TENSILE TESTS, STANDARD BRIQUETTES (AVERAGE OF 3 BRIQUETTES.)

Neat.		1-Cement, 3-Sand.	
7 days	71 lbs.	7 days	17 lbs.
28 days	163 "	28 days	73 "
2 months	182 "	2 months	82 "
3 months	220 "	3 months	118 "
4 months	235 "	4 months	132 "
5 months	250 "	5 months	148 "

To confirm these results a similar test was made on another brand under conditions in all respects identical, with the following results:

Fineness: 96.3 per cent. passed No. 100 sieve, and 80 per cent. passed No. 200 sieve.

Setting time by Gilmore's needle: Initial set, 133 minutes; final set, 377 minutes. Percentage of water, 25. Temperature of water, 62° F. Temperature of air, 66° F.

Soundness or constancy of volume; coal water pat, good; air pat, good; steam pat, good.

TENSILE STRENGTH WITH STANDARD BRIQUETTES.

Neat.		1-Cement, 3-Sand.	
7 days	735 lbs.	7 days	265 lbs.
28 days	837 "	8 days	407 "

The test results obtained after regrinding the neat briquettes from the above cement were as follows:

The analysis of cement after the first gauging was: Silica, 19.88; alumina, 4.53; iron oxide, 2.03; lime, 55.30; magnesia, 2.64; sulphuric anhydride, .89; carbon dioxide, .68; water, 13.68.

Fineness: 97.1 per cent. passed a No. 100 sieve and 78.5 per cent. passed a No. 200 sieve.

Setting time by Gilmore's needle: Initial set, 209 minutes; final set, 434 minutes.

Soundness: Cold water pat, good; air pat, good; boiling pat, good.

Specific gravity, 2.56.

TENSILE TESTS, STANDARD BRIQUETTES (AVERAGE OF 5 BRIQUETTES.)

Neat.		1-Cement, 3-Sand.	
7 days	192 lbs.	7 days	57 lbs.
28 days	343 "	28 days	181 "
2 months	365 "	2 months	238 "
3 months	405 "	3 months	278 "
4 months	419 "	4 months	281 "
5 months	382 "	5 months	293 "
6 months	440 "	6 months	322 "
7 months	...	7 months	...

These experiments clearly show that even after cement has been twice gauged with water and allowed to harden under water, that all the cementing and hydraulic qualities are not destroyed, and that gauging with water and submergence in water does not retard the setting time of the reground cement as much as would be expected. Indeed, in the first test the setting time of the cement on being reground was quicker than in the original sample. A third conclusion is that it is only the very fine flour in the cement that is in condition to react when gauged with water and give strength to the mortars.

This last conclusion is further confirmed by other investigations undertaken at the same time to determine how fine the clinker had to be ground in order to be available for cementing action. Portland cement which had passed the 200-mesh sieve was further separated by elutriation into the following parts: (A) Material that settled out in 30 seconds. (B) Material that remained in suspension for 30 seconds, but settled out in one minute; (C) Material that remained in suspension for more than one minute. The cement thus divided into three portions according to size was treated with water in tightly stoppered tubes. "A" was only slightly acted upon by water, even after two years contact with it. "B" was only acted upon by water after three or four months, and only a portion became fully hydrated. "C" was acted upon almost immediately, swelling up and forming a very voluminous jelly.

Microscopic examinations of thin sections of neat Portland cement also show a large percentage of the cement unacted upon by water beyond a superficial or skin action. This being the case, then, in the regrinding of the neat briquettes after they had become hydrated, some of the coarser particles of the unacted-upon cement were reduced, by regrinding, to such a fineness as to become active. These three methods of investigation (first, microscopic study of set cement; second, the treatment of the various sizes of grains separated by elutriation; third, the regrinding of the neat cement after gauging with water and being allowed to harden under water), all lead to the same conclusion, that is, that only a comparatively small percentage of the original cement is ever acted upon by the water used in making the mortar, and that the portion of the cement which is acted upon is only the very fine impalpable flour which is not measured by present tests using sieves.

When cements were all ground in practically the same manner and on the same type of machinery, the use of sieves gave a fair indication of the flour present in the cement, it being a reasonable assumption that the finer the cement, the more flour present; but such is no longer the case with diversified methods of grinding and we have found more flour in cement ground on the burr stone showing a very poor degree of fineness as measured by the sieves than in some cements showing a very great fineness as measured by the 100-mesh and 200-mesh sieve. The fact that the sieving tests do not determine accurately the percentage of flour has been recognized in Europe, and various devices are being experi-

mented with to determine the percentage of flour. These investigations also show conclusively that all commercial cements contain a large amount of inert material and that the cement manufacturer is quarrying, grinding, burning, grinding again and paying freight upon from 50 to 60 per cent. of inert material which could as well be replaced by sand. Under present mechanical conditions it is commercially impossible to grind much finer than we are now doing, but one of the economies of the future in cement manufacture will be brought about by the perfection of grinding machinery that will avoid the waste above mentioned.

A study of the chemical analysis of the reground cement is also interesting. Taking up the first sample and disregarding the presence of calcium aluminate and arbitrarily assuming that the silica was present in the original cement as tricalcium silicate, and that, on hydrating, it is decomposed to the hydrated mono-calcium silicate (CaO, SiO_2, $3H_2O$) and calcium hydrate, and neglecting the calcium sulphate but deducting the amount of lime present as carbonate, the combined water will account for about 70 per cent. of the cement having been acted upon by water, after being twice gauged and once reground, leaving 30 per cent. still present and capable of developing hydraulic qualities on being ground sufficiently fine, as is proven by the tests obtained on the second regrinding.

These figures are, of course, only approximate, since they do not take into consideration the lime present as aluminate and it is not positive that the hydration takes place as indicated above, but they are borne out in a general way by the results of the physical tests, for on regauging the cement developed considerable hydraulic qualities.

The analysis of the second sample of cement shows, on the same arbitrary assumption, after the first gauging with water, the hydration of about 45 per cent. of the cement, leaving 55 per cent. unacted upon.

In a recent article in "The Engineer" of London, by Mr. W. Lawrence Gadd, entitled "Notes on the Le Chatelier Tests," he states in reference to Portland cement made by rotary kiln clinker that this "does not improve on aeration, but on the contrary almost invariably becomes more expansive, the increase being from 3 to 12 mm. after aeration for seven days; and many samples which, tested fresh, gave an expansion of only 2 to 5 mm., if again tested after seven days' aeration, would be condemned by the conditions of the British Standard Specifications as unsound. On the other hand, if the cement be kept for some time in a stoppered bottle or other closed receptacle, the expansion becomes less marked, and if kept long enough without exposure to air will become nil."

He explains this behavior of rotary kiln cement in Le Chatelier's tests as follows: "It is well known that rotary clinker is harder and therefore more difficult to grind than a chamber kiln clinker, and the ground product from the rotary kiln may be roughly divided into (a) flour; (b) comparatively large pieces of clinker grit, such as is retained on the 100 or 180-mesh sieve; (c) fine particles which are small enough to pass the 180-mesh sieve but are nevertheless particles of hard clinker grit. Tests show that although the chemical composition of this fine grit is practically identical with that of the flour, the former gives high expansion figures, whilst the latter gives rise to only slight divergence of the needles.

"The expansion appears to be as the proportion of fine grit, indirectly shown by the percentage of flour in the cement. Thus, to take an actual example: The respective products of two grinding mills were separately taken, carefully sampled, and tested by the Le Chatelier method. One of these mills (No. 1) was known to produce more flour and relatively less fine grit than did the other (No. 2). Both mills were concurrently fed with clinker from the same hopper, so that there should be no question of difference in composition or degree of calcination. The expansion results were: Cement from Mill No. 1, 3 mm.; cement from Mill No. 2, 17 mm.

"The fineness of the grinding in these two samples was practically the same, the residue on the 180-mesh sieve being in the one case 10 per cent. and in the other 10.5 per cent.

"The addition or removal of comparatively large pieces of clinker grit appear to have but little effect on the Le Chatelier test, and the addition of fine grit in the form of ground flints or sand has no appreciable action.

"It follows that the expansion, in the cases quoted, is due to changes in the fine particles of clinker grit under the influence of boiling water; and the view I wish to put forward is as follows: (1) At the time of gauging the cement the particles of fine flour, so called, are hydrated more or less completely. (2) Particles of clinker grit of comparatively large size are not hydrated, except, perhaps, on the surface, and act throughout as inert material. (3) Particles of fine grit clinker which are small enough to pass the 180-mesh sieve are only slightly hydrated at the time of gauging. The cement then sets hard, but under the influence of heat, when the block is boiled, the hydration of these small particles continues, with consequent expansion.

"The increase in expansion, after the cement has been subjected to aeration, may perhaps be explained by the assumption that the fine particles of clinker grit, on exposure to moist air, commence to disintegrate to some extent, and are thus rendered more easily hydrated when submitted to boiling heat. That something of this nature does happen is rather borne out by the fact that rotary clinker which has been weathered by exposure to air for some time is more easily ground, than if taken direct from the kiln, and such weathered clinker invariably gives lower expansion figures, provided of course, that it was properly burned, and contains no underburned portions."

While the behavior of the cement by the Le Chatelier tests for soundness is of little interest to us, however, as this test is not used in this country, of interest to us is the explanation offered by Gadd for the behavior of the cement, since this explanation is in line with the conclusions drawn in this article, that is, that the fine flour of cement is the only portion which is acted upon by water, hence comprises the portion of cement which gives to the mass its hydrated qualities.

Book Notes.

The exceptional value of the work done by the American Society for Testing Materials is clearly shown in the "Proceedings of the Tenth Annual Meeting," which has just appeared. It is a volume of 759 pages filled with information of the most important character for all engineers who have to do with the design of structures or machinery. This journal has held the opinion for a number of years that no engineer who has much designing to do can afford to be without a set of these volumes. They not only contain the latest ideas of thoroughly representative committees concerning the all-important subject of specifications, but they also cover all advances in testing materials and progress in research work to ascertain the strength of materials and standard products constructed from them, such as rails, castings, car wheels, reinforced concrete columns and beams, and the like. The object of the Society is, briefly stated, to furnish information concerning materials and the best methods of using them. The field is manifestly a wide one, and as the Society covers it thoroughly, its publications are invaluable to those who desire to keep abreast of the times. The proceedings which are recorded in the volume just issued were reported in the Current News Supplement of this journal of June 29, and it is therefore unnecessary to review the contents of the volume at length in this place. (Philadelphia, Prof. Edgar Marburg, University of Pennsylvania, $5.00.)

The twenty-first annual number of the "Mechanical World Pocket Diary" is an astonishing example of book making. It has nearly 400 pages, is bound in cloth, and yet it retails in Great Britain for only 12 cents. The diary gives ample space under each date to jot down all the notes that the average engineer keeps in such a book, while the mechanical information is comprehensive and accurate. This technical section has now assumed a comparatively permanent form, and the changes made from year to year are mainly to bring the contents up-to-date in those departments where new standards have been adopted or the progress of the art makes revision necessary. While the contents are by no means so complete as the information given in more elaborate engineering handbooks, there are few things which arise in the general run of mechanical drafting room work that cannot be answered at least in part, by reference to this little volume. (Manchester, England, Emmott & Co., 65 King St., 6 pence.)

A little book, professedly written for the engineer and engine man, but useful for a much wider circle of readers, is the "Engine-room Chemistry" of Prof. Augustus H. Gill, of the Massachusetts Institute of Technology. It aims to give such information concerning oils, fuels and the phenomena of combustion and steam-raising, all expressed in fairly non-technical language, as will enable the average reader to understand what is necessary from the point of view of chemistry to obtain the maximum efficiency in the power plant. The book opens with an explanation of those elements of chemistry which must be understood in order to study problems of this nature and describes the apparatus and chemicals used in making the tests under consideration. The author then takes up in detail fuels and their analysis, and gives in the next chapter an explanation of methods of regulating combustion and conducting gas analyses. Boiler scale, fitting and corrosion form the subject of the following chapter, in which the rather complicated subject of hard waters is outlined in a satisfactory manner. It is rather unfortunate, however, that this chapter was written before the presentation of the important paper by Dr. Cushman explaining the method of preventing pitting which is being followed with much success in some boiler plants in Washington. The remainder of the book is devoted to mineral, animal and vegetable oil and will be found particularly useful to those who have learned by experience the importance of more attention to this class of engine room supplies than is usually paid it. (New York, Hill Publishing Co., $1.00.)

Although there are many books on mechanical drawings available for self-instruction and classroom work, a new one entitled "Structural Drawing," by Mr. C. Franklin Edminster, of the Pratt Institute in Brooklyn, takes up a branch of the subject which has hitherto not been touched except very briefly. It gives a course of lessons in the drafting work in structural shops and the offices of architects and mill engineers, so far as steelwork is concerned. The book opens with the usual instructions concerning drafting materials, which are followed by a collection of geo-

metrical problems. Simple projection such as is used in preparing working drawings is then explained, after which structural drafting is taken up in detail. The first work is the drawing of cross sections of rolled shapes to scale and their lettering according to standard dimensions; the drawing to scale of nuts and bolts, tie rods, eye-bars and clevices, turn-buckles and anchors is then taken up and the more elementary connections are introduced. Afterward the student is taken along step by step as his skill increases until the most difficult forms of structural drafting connected with staircase details have been taken up. The many plates in the book are executed in the standard manner required in bridge shops, and the book as a whole is an excellent outline of the somewhat special class of drafting necessary for steel. (New York, David Williams Co., $2.50.)

The long-awaited "Municipal and Private Operations of Public Utility," the report to the National Civic Federation by its Commission on Public Ownership and Operation, has at last appeared in three bulky volumes, forming the latest and most complete word on this important subject. The first volume contains the final conclusions of the Committee and general summaries of the evidence upon the various phases of the question. These conclusions were reviewed at considerable length in The Engineering Record several months ago. The second volume is devoted to the reports of the experts upon conditions found in the United States, and the third volume is devoted to the situation in Great Britain. These volumes are made up of two entirely distinct parts. The first is a collection of information regarding public service undertaking, compiled by specialists in such work and approved as correct by the members of the committee who believed in municipal ownership and by those who believed in private ownership. The second portion of the volumes is a collection of monographs based on the data and written from the viewpoint of each interest. The reader desirous of making a thorough study of the relative advantages of municipal and private ownership will find the volumes of particular value on this account, for the advocates of each method of operation are here compelled to base their arguments on exactly the same basic facts. This is probably the first time that such a complete discussion of the subject has been presented under conditions so favorable for clearing away the unessential assumptions and disputed facts that make the usual article on the subject hardly worth reading. Inasmuch as the report has already been reviewed in this journal and an estimate of its value stated editorially it is hardly necessary to say more in this place than that the volumes should be in every library claiming to possess the more important works on the control of public service utilities. (New York, 281 Fourth Ave., National Civic Federation, $10.)

Letters to the Editor.

STRESSES ON RIVETS.

SIR: I notice that, while your standard specifications provide carefully for the effects of repeated stress in the members of a framework or structure, the effect on the rivets and pins is practically ignored, and constant values are assigned for safe shearing and bearing stresses on these. As a chief draftsman and designer of steel structures, I use the following formulas, which ensure that the connections are as strong as the pieces connected:

$$(1)\quad P = 9{,}000\left(1 + \frac{\text{minimum}}{2\ \text{maximum}}\right)$$

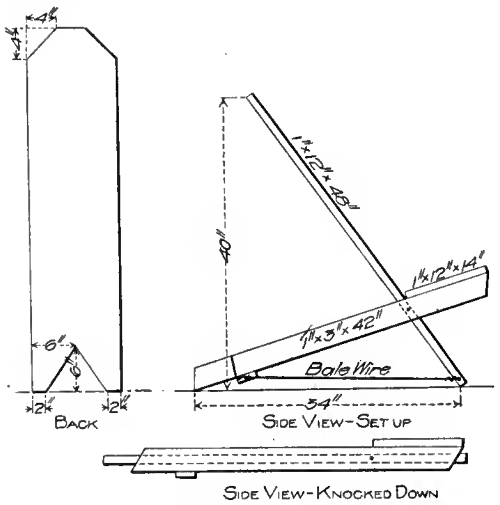
$$(2)\quad P = 9{,}000\left(1 - \frac{\text{minimum}}{2\ \text{maximum}}\right)$$

The first formula gives the unit stresses on mild steel rivets in single shear for repetition stresses, and the second gives the unit stresses for reversing loads. The safe bearing stresses and double shear stresses are double the amount given by these formulas. These formulas are original, so far as I know, and perhaps if you found space for them in The Engineering Record they would receive criticism and light would be thrown on the subject. Yours faithfully,

Bradford, Eng., Oct. 8. JAMES A ORREL.

CAMP COMFORTS.

SIR: When I arrived at the engineers' camp at Del Rio it was about as uninviting a place as I ever saw. The dirt floors of the tents consisted of an inch of dust—so fine that one could



A Camp Chair.

not stir without filling the tent with the powder. It seemed to me that the first night I spent there I breathed in my full "peck of dirt." This was intolerable and the next morning I had the men with our team get gravel from the river nearby and spread a layer of it 3 in. thick in each tent. We have had no dust since then. For seats we had boxes, and two roughly-made stools. Now, when I am working I work hard and when the time for rest comes I want to rest as thoroughly, which I cannot do on a tomato box nor very much better on a condensed milk box, so I determined to improve our sitting arrangements. The commissary had just received a quantity of 12-in. white pine boards for general camp use, and I ordered a half dozen of them sent to our camp. From these we made three easy chairs similar to those here shown. I had often seen these chairs in use, but always made rigid, and hence very unhandy to transport when moving camp. I therefore determined that the present lot should not have that defect. We first cut three pieces 4 ft. long for the backs, next six pieces 4 ft. 6 in. long by 3 in. wide, then three pieces 14 in. long and three 1 ft. 3 in. Placing the 4-ft. board on the ground, one of the 3x42-in. pieces was placed on edge on each side, and the pieces 14 in. long nailed crosswise to the 3-in. pieces. Turning the back board and sides over without disturbing their relative positions, one of the pieces 1 ft. long and 3 in. wide was nailed on 6 in. from the end opposite to where the seat was nailed. Next the back and side boards were set up as shown in sketch and a ten-penny wire nail driven in the center of the side piece just at the back of the seat and into the back piece 1 ft. from where it rests on the floor. The chair back can be fixed at any angle, but I found the angle shown to be the most satisfactory to all who tried it. The right slope of back board can be found by raising the top until it is 3 ft. 4 in. from the floor. To keep the chair in this position I used two bale wires, driving an eight-penny nail through the loop and into the bottom of the back piece and winding the other end around the 3-in. piece as shown. By unfastening the wire, the chair can be knocked down and occupies a space only 48 x 14 x 5 in.

For this work we had only a saw and hammer. We used fourteen nails and less than 8 sq. ft. of boards for each chair. I give this account of the work and sketch of the chair, not because I think I have made something new—I first saw this kind of chair thirty years ago—but because I have never seen a drawing of it, and I want to suggest to others to try it, and see if it is not one of the most comfortable a tired man ever threw himself into. HOWARD EGLESTON.

Del Rio, Mexico.

EXAMINATIONS FOR PHILIPPINE CIVIL ENGINEERS.

SIR: In an examination for civil engineer, in the Departmental and Phillipine Services, given by the United States Civil Service Commission at various points throughout the country on Oct. 16th and 17th, the subjects, with their weights, were as follows: (1) Pure and Applied Mathematics, "involving a fair knowledge of pure mathematics to and including calculus"; weight, 20. (2) Use and construction of instruments and surveying; transit, stadia, level, plane table, rod, chain, tape, current meter, etc.; weight, 30. (3) Design and construction, requiring knowledge of highways, railroads, dams, retaining walls, trusses, foundations, etc.; weight, 25. (4) Training and experience, rated from application form, answers to which are made under oath; weight, 25.

The time allowed for the examination was six hours on the first day and three hours on the second day, the first two subjects being given on the first day.

The questions asked, as nearly as I could recollect them the day after the examination, were as follows:

Mathematics; three questions to be answered.

(1) In a hollow cast-iron column 16 in. in diameter the thickness of metal is 1½ in., allowable stress is 9,000 lb. per square inch, column 24 ft. 5 in. high. $W = w + (wln^2/r^2)$, in which l = length of column in inches, $n = .002$, r = radius of gyration, W = load on column, and I for cylindrical form $= 11d^4/224$. Find w, in tons, to one decimal.

(2). The points, A, B and C, are in a straight line, $AB = 376.5$ ft., P is a point outside of the line. The angle $APB = 61° 20'$; and the angle $PAB = 42° 6'$. If D bisects ABC find angle ADP, to the nearest minute.

$$\frac{a-b}{a+b} = \tan \tfrac{1}{2}(A-B)\cot\frac{C}{2}$$

(3). In a triangular frame ABC, $AB = 15$ ft.; $BC = 12$ ft., and $AC = 20$ ft. There is a force of 6, normal to AB at A, one of 8 normal to BC at C, and a vertical one of 6 at B. The frame is fixed only at A. Find, by any method, the stresses in the parts of the frame.

(4). The bottom of a channel is 8 ft. wide, the water level is 16 ft. wide, the sides slope at 30° from the vertical, the flow is 288 cu. ft. per second and the grade 1 in 2,000. Find the mean depth, mean velocity and coefficient of friction.

Use and Construction of Instruments and Surveying; four questions to be answered.

(1). Name all of the ways errors can occur in the use of the transit, and state how to eliminate or reduce them.

(2) Give same for the wye level.

(3). State, in detail, how you would adjust the standards of a transit. What previous adjustment should be made and why?

(4). State, in detail, how you would proceed to make a topographic survey and map complete (a) of a very irregular plot of ground of not over 350 acres and showing 2-ft. contours to a large scale. (b) Give the same for a large similar plot on a small scale and showing 20-ft. contours.

(5) Give an account of the Government's method of surveying the public lands.

(6). Tell, in detail, how you would make a hydrographic survey of a river averaging 300 ft. wide and 15 ft. deep.

Design and Construction; three questions to be answered.

(1). Give a list of all the defects found in lumber and state the cause of each.

(2) Write as complete a specification as you can (*a*) for a brick pavement, (*b*) for an asphalt pavement.

(3). Given a town of 5,000 inhabitants. Describe in detail all the data you would collect before starting the design of a sewerage system.

(4). Given a reservoir of certain capacity. How would you determine the dimensions of dams, fills, walls, embankments, etc.? Show diagrams of same. How would you locate spillways and determine size of same?

(5). Give a list of the advantages and disadvantages of the different kinds of highways in use. Give sketches showing best methods of construction.

Competitor.

Cost Analysis Data.

Sir: In compliance with your request of Dec. 5, I send you a brief outline of my opinion regarding the practicability of using cost-analysis data with safety in estimating the probable cost of constructing engineering works.

It cannot be disputed that a complete system of cost keeping, in sufficient detail, is of great value to public works departments. If the work is performed by day labor such a system will serve as a useful guide to the engineer in charge, both in making his estimates of the probable cost of work and in checking from time to time the actual cost of construction with the cost of similar work previously done. Such a system is of nearly as much value to departments conducting work by contract. The greatest value of cost keeping in all cases, of course, results from the costs having been kept upon work under the direct personal supervision of the engineer who is using the cost system as a guide for estimates and for checking costs during construction. These observations imply that the use of such cost statistics is confined in each case to one locality, in which similar classes of work must be reasonably comparable. In making an estimate of the probable cost of work under these conditions the judgment of the engineer is of the utmost importance, and even with a satisfactory cost system his judgment must far exceed in comparative value the weight given to his statistics of cost upon past work.

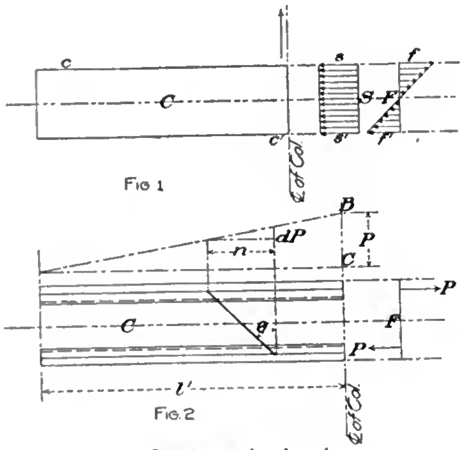
In the application of costs obtained by other engineers, or in other localities, the utmost care should be exercised, as it is impossible in almost all cases to have an accurate knowledge of the particular conditions surrounding the work done at the costs given. Such costs may serve as a very valuable general guide, but ought not to serve as the main basis of estimates, which should in every case be the result of personal judgment growing out of personal experience. If the engineer making the estimate has obtained the cost of other similar work under his own direction these costs would be of much greater value to him in assisting him to form his judgment than would be the costs obtained by other parties under conditions which must be largely unknown to him.

In fine, it is my opinion that cost statistics, as generally accessible from published records, are of very doubtful value for anything more than a general guide and may be exceedingly dangerous to follow. Very truly yours,

Harrison P. Eddy.

Boston, Mass., 14 Beacon St.

[This letter is an answer to a request made to Mr. Eddy to send for publication in The Engineering Record a statement of his conclusions regarding the value of cost analysis data. As superintendent of the sewer department of Worcester, Mass., from 1892 to 1907, he constructed by day labor all kinds of sewerage works, involving ordinary work in rock and earth, heavy trenching, difficult pile driving, tunneling in many kinds of material, and concrete structures. All payments for materials and labor were made by him directly, and for a number of years he kept very complete cost analysis records of these expenditures and the conditions of the construction. Probably very few engineers have had such an opportunity to



Stresses in Lacing.

study actual cost data on sewerage work, and for this reason Mr. Eddy's opinion deserves especial consideration.—Editor.]

Stresses in Lacing on Columns.

Sir: One of the fundamental features of short column design is the assumption that the compressive stress is distributed uniformly over the area of any cross-section. Suppose C in Fig. 1 to be such a column. Then S may represent the stress diagram. Now suppose the column becomes longer so that there is bending, or a tendency to bend in the direction shown by the arrow. There will then be set up in the column a flexure couple that we assume will take the form shown as F. It will be evident at once that the maximum stress under the second condition will be greater in compression and smaller in tension. The maximum stress on the tension side will be $(f-s)$. The maximum stress on the compression side will be $(f'+s')$. We might concentrate the entire stress shown by diagrams S and F about points respectively the centers of gravity of the parts of the diagram above and below the neutral axis. The stress shown by diagram S is balanced about the neutral axis, and therefore would not have a tendency to distort the column laterally. Lateral distortion of the column would depend on the flexure couple only. It is then this couple that has to do with the design of lacing in built-up columns.

Fig. 2 is a column composed of two channels laced back to back. The flexure diagram F is shown with forces concentrated at the centers of gravity of the channels. For practical purposes we may assume that $P=Af$ where A is the area of cross-section of one channel and f is to be taken as the maximum stress in the channel due to flexure at the point where the greatest bending, or the tendency to bend, occurs. In most cases, as that shown in Fig. 2, this point will be at the center of the column. In any practical case f should be taken as the difference between the allowable stress for the material in a short column and the calculated unit stress for the column in question. For instance, when the straight-line formula is used we have $s=s'-cl/r$, where s is the stress for a short column, c a constant, r the least radius of gyration, l the equivalent length, and s the stress for a long column. Then, in our discussion, the value of f is cl/r.

When Euler's formula is used

$$s-\frac{EI\pi^2}{A'l^2}=f$$

Where A' is the area of column cross section, and I is the moment of inertia about an axis perpendicular to the plane of bending.

Returning to Fig. 2, l' is the distance from section of maximum to section of no flexure. When l is equal to the length of the column in question l' may be equal to ½, ¼, etc., according to end connections. Upon the line AC at the point C we erect a perpendicular BC which shall equal to scale $P=Af$. Now at the points A and C we know the flexural stress. If we were to calculate it at all other points between A and C and plot to scale along AC as a base there would result a curve similar to a harmonic curve. A circular arc would not be greatly different, and for all practical purposes a straight line drawn from B to A will be sufficiently near. Then when n is the interval for lace spacing there results dP the change in flexural stress.

Then (1): $dP \csc\theta = G$,

Where G = stress in lace bar. From similar triangles $dP = nAf/l'$. Substituting in (1) this value of dP there results

(2) $G = nAf/l' \csc\theta$. Where there is a double system of lacing it is consistently accurate to take one-half the computed value of G as the stress in each bar of the panel.

The same reasoning makes it easy to derive formulas for the stress in lace bars where there are any number of leaves in the column. For example, we may assume a column where there are four leaves. The maximum stress will occur between the inner two leaves.

Let d_1 = distance from the neutral axis to the center of gravity of first leaf, and d_2 = distance from the neutral axis to the center of gravity of the second leaf. Let A_1 and A_2 be the area of the inner and outer leaves respectively. Then

(3) $P = (d_1/d_2)\, fA_1 + fA_2$.

$$G=\frac{fn}{l'}\left(A_1\frac{d_1}{d_2}+A_2\right)\csc\theta.$$

For the purpose of illustration assume a column made up of two 12-in., 20.5-lb. channels laced 13.75 in. out to out with square ends and an over all length of 24 ft. The area of a cross-section of this column is 12.06 sq. in. Assuming a factor of safety of 4, Gordon's formula gives a maximum safe unit stress of about 11,500 lb. Calling the safe stress for a short column of this steel 16,000 lb., there results f = 4,500 lb. Let $\theta = 45°$.

$$G=\frac{10\times 6\times 4{,}500\sqrt{2}}{6\times 12}=5{,}300\text{ lb.}$$

This would give for a 2x¼-in. lace bar a stress of 10,600 lb. which it is safe to allow under these conditions.

G. L. Bilderbeck.

East Berlin, Dec. 3.

Privately Owned Railroads in Belgium will shortly have their total length reduced to 200 miles, as the Belgian Parliament has authorized the purchase of a privately owned line 112 miles long. The 200 miles referred to are operated by six different companies.

SUBSCRIPTION RATES.

United States, Cuba and Mexico..........$3.00 a year
Canada ....$4.50 a year
Foreign subscription....................$6.00 a year
25 shillings. 25 marks. 31 francs.
Foreign subscriptions may be sent to our London office.

NOTICE TO ADVERTISERS.

Changes in advertisements intended for a particular issue should reach the office of THE ENGINEERING RECORD on Friday of the previous week. New advertisements can be received up to noon of Wednesday of the week of issue.

NOTICE TO SUBSCRIBERS.

REMITTANCES.—Remittances should be made by check, New York draft, or money order, in favor of THE ENGINEERING RECORD.

CHANGE OF ADDRESS.—The old address should be given as well as the new, and notice should be received a week in advance of the desired change.

BACK COPIES.—No copies of issues prior to July, 1906, are kept on sale, except in bound volumes.

DATE ON WRAPPER indicates the month at the end of which subscription expires. The sending of remittances for renewal prior to that date will be much appreciated by the publishers.

CLUB RATE.—In acknowledgment of assistance rendered by subscribers in the securing of new orders, a club rate of $2.50 per annum is quoted. This rate applies to subscriptions in clubs of two or more, at least half of the names in the club to be those of new subscribers.

Entered at the New York Post-Office as Second Class mail matter.

Of this issue of THE ENGINEERING RECORD 15,000 copies are printed. Total circulation for 1907 to date 763,000 copies, on average of 14,673 copies per week.

TABLE OF LEADING ARTICLES.

Fair Play for the Great Lakes Commerce.

A great deal is being said at this time about the improvement of rivers and harbors and the development of the water resources of the nation. It goes without saying that this journal is heartily in accord with everything of this nature that stands on a rational basis. It is necessary to bear in mind all the time, however, that the greatest inland waterway we have is the chain of Great Lakes. The water area of these lakes and the connecting and outflowing rivers is about 95,000 square miles, of which approximately two-thirds lies in the United States. The shore line is about 8,300 miles, and of this the American portion is 4,700 miles. These figures are worth comparing with the total shore line of the Atlantic, Pacific and Mexican seaboards of the United States, excluding Alaska and insular possessions, which is but 5,700 miles. The commerce of the Great Lakes is of great importance. It is nothing problematical, like the commerce which may be conducted on the improved rivers of the future, about which so much is now said, but is something that is existing and sure to increase further as facilities for its development are afforded. Therefore the people of the cities along the Great Lakes should instruct their representatives in Congress in no uncertain terms to make sure that in all the legislation for inland waterways the actual paramount character of the Great Lakes commerce and the imperative need of further improvements for Great Lakes navigation are not overlooked. Fortunately it is unnecessary to go beyond official documents to find full proof of the fact that the Great Lakes urgently demand the attention of Congress. The last annual report of General Mackenzie, Chief of Engineers, U. S. A., has a special section on this subject to which attention is drawn.

It will be a great surprise to many people to know that a thoroughly complete survey of the Great Lakes, such as is necessary for a comprehensive study of the needs of navigation before the actual shipping exists to make those needs felt, has never been made. In 1841 the first regular appropriation for the Lake Survey was made and since then annual appropriations have been made, except in 1847. The work has always been so well managed that the Survey has kept well in advance of the requirements of navigation in spite of the small sums available for its purposes and the great extent of the area to be covered. The time has now arrived, however, when the commerce of the Great Lakes requires more information than can possibly be given with the data obtained up to the present time, and it is necessary to adopt a general policy for the completion of the operations of the Survey. These operations must be conducted in part upon Canadian territory, for the fact that 95 per cent. of the commerce of the Great Lakes is American requires the extension of the work into those parts of the main traveled vessel tracks passing through Canadian waters. The area to be covered is about 70,000 square miles, and its shore line not less than 6,000 miles.

The time has certainly come when navigation on this great extent of inland waters should be made as safe as that along our seacoast, so far as reliable charts will accomplish this end. The essential difference between navigation on the Great Lakes and the deep seas is rarely appreciated except by those who have been aboard a lake steamer in a heavy storm. In the free ocean, when such a storm arises, it is only necessary to ease off from the course more or less, according to the severity of the gale, and everything is safe and comfortable. On the Great Lakes no such deviation from the true course is possible. The channels which must be followed by vessels of deep draught are comparatively restricted; a departure from them during a gale is absolutely certain to cause a wreck in some sections, and in other sections just what will happen is entirely unknown owing to the absence of careful hydrographic surveys. So the ship captain on the Great Lakes has to stick to his course, allowing his vessel to be battered by the wind in a manner that no deep-sea sailor would tolerate. Even this is not always practicable, for the storms are of great severity at times and drive vessels off their course in spite of everything that can be done. During the season of 1905 there were 230 casualties to vessels engaged on the Great Lakes, 173 lives were lost and property to the value of $3,953,000 was destroyed. One gale alone, that of Nov. 28, caused the loss of 30 lives, 35 vessels and property worth $1,881,000. During such storms the entire area of each lake must be known and made available by charts, for the lee of every island and the shelter of every bay and passage becomes a possible refuge when correctly charted. An inlet or a channel that is absolutely unimportant during pleasant weather may become a haven in times of distress and peril. It is manifest, therefore, that no time should be lost in surveying the 70,000 square miles of the water area of the Great Lakes.

As there may be confusion as to just what the Lake Survey does, a word concerning its work is in place here. The various Engineer Districts of the Great Lakes are charged with the duty of improving the terminal harbors and the connecting rivers. This work, however, covers but a small part of that which must be done to make navigation secure, and the Lake Survey, which is in charge of the remainder of this work, is engaged in the examination and exploration of the vastly larger and more dangerous areas of the lake. It prepares charts of the main routes, searches for undiscovered or obscure dangers, and studies the lake hydraulics in order to furnish data for the solution of the problem of maintaining more uniform surface levels, bettering draughts and protecting the lakes from the dangers that will follow any water diversion. It is manifest that the importance of the Lake Survey's work increases with the volume of traffic and the size of the individual carriers. The increase in the size of these carriers has been astonishing. When the Weitzel lock at Sault Ste. Marie was completed in 1881, 15-ft. draught of vessels was considered all that was probable for many years. In 1896 the Poe lock was opened with a depth of about 20 ft., which was considered ample for all time, but the project recently adopted for the new lock at the same place provides for a depth of 24½ ft. In 1906 the domestic lake traffic in freight alone amounted to 75,610,000 net tons. It was valued at about $780,000,000 and was carried by an American fleet worth approximately $125,000,000. This fleet saved the merchants of the country something like $100,000,000 excess freights charges which would have been paid out had the goods been carried by rail. As a matter of fact, railroad facilities do not exist for handling all this traffic. These figures take no account, moreover, of the enormous passenger traffic. Such statements show the extent of the already existing interests to be benefited by a suitable appropriation for placing the Lake Survey on a permanent basis.

It has been mentioned that the investigation of the hydraulics of the Great Lakes is a part of the duties of this Survey. The importance of this field of the work will be understood when it is considered that if, by regulating works, it is possible to enable the large vessels to have one additional foot of draught, this gain is equivalent to an increase of 10 per cent., in freight-carrying capacity with practically no added operating cost. And when it is considered that a single 600-ft. freighter, with its cargo, which may be saved from wreck by prompt charting of obscure or recently created dangers, is worth more than the total cost of maintaining the Lake Survey for over three years, there is manifestly every reason for granting the sum which General Mackenzie requests for this great undertaking. He asks for only $115,000 for the next year, an amount so insignificant in comparison with the benefit to follow its appropriation, that the congressional representatives of the Great Lake district should see that the money is voted.

Lord Kelvin.

In the death of William Thomson, Baron Kelvin, mentioned last week, the world loses not only its greatest physicist but one who in wideness of useful achievement and complete grasp of both theory and practice must rank among the few really colossal figures in the history of science. To him providentially had been given a span of life commensurate with his splendid activity. In the present generation he has been revered as the Nestor of physical science, pure and applied; in the last generation he was the commanding form that in useful research towered above his contemporaries.

It is sixty-six years since William Thomson, a lad of seventeen in the University of Glasgow, published his first contribution to the world's knowledge—a time so long that his early work has passed out of popular knowledge, effaced by the importance of his later investigations. His earliest paper was a rigid proof of some of the principles set forth in Fourier's theory of heat, and he pursued that line of investigation so industriously that he must be given place with Joule and Clausius as one of the founders of the present mechanical theory of heat. To him we owe the concept of absolute temperature and the foundation of the absolute thermometric scale, the experimental proof of the lowering of the freezing point of water by pressure, and the far-reaching doctrine of the dissipation of energy.

His thermal studies did not, however, confine his ceaseless activity, and at the age when the student of to-day is generally killing time as a swaggering sophomore, William Thomson had discovered the theory of electrical images and was writing papers about it in the chief French mathematical journal. A little later he followed it up with a study of the determination of electromotive force in absolute measure, and a brilliant mathematical investigation of the properties of transient electric currents, a study later destined to bear fruit in the engineering problems connected with the Atlantic cable. A few years more and he was plunged in cable work, bringing to bear upon it his extraordinary power of mathematical analysis, mechanical ingenuity and inventive genius. Technically the submarine cable was in very large measure his personal work. In the course of this labor he set up for the first time a conductivity specification for copper wire. The commercial wire available sixty years ago varied over a range all the way from the commercial wire of to-day to that having scarcely more than half the proper conductivity.

In this period, during which the Atlantic cable was evolved, he began the long series of inventions of electrical instruments which are familiar in laboratories the world over, and which need no commendation here. With it all, he found time for brilliant excursions into other fields, magnetism, resulting in his invention of the standard compensated compass tha guides the world's fleets over the seven seas, physical astronomy, with his studies of the source and cosmic history of solar energy and world-building and elasticity, with its fruition in theoretical optics.

From the very beginning of modern applied electricity, Sir William Thomson, knighted more than forty years ago for his achievements, bent his energies to its development in both theory and practice. His enunciation of the law of economy in conductors, his investigation of the skin effect in conductors, following the curious experience of Lord Armstrong, and a dozen other researches are familiar history.

There is no need to bespeak William Thomson's title to fame, but to those who have endeavored to gauge the breadth and depth of his career, or who have come into even casual contact with his inspiring personality, this thing stands out above all others, that he did with his might whatever he understood, whether the dynamics of a molecule or the design of a commercial instrument, and never left either problem until the world was the richer. He neither turned aside from pure science to pursue the practical, nor despised the practical when it confronted him. He never posed as a wizard or hesitated to give his confréres at least all the credit that was their due. No man in the century past has so fully combined the acumen of the trained investigator with the calm and sane judgments and practical common sense of the engineer.

As a lecturer, he was clear, suggestive, inspiring, working with simple apparatus and making every experiment count. A profound mathematician, he never forgot the physical concepts that lay behind his equations and never let his hearers forget them. And he never lost sight of the unity of physical phenomena. His famous Baltimore lectures on the dynamical theory of light are in no wise an attack upon the electromagnetic theory, but a vivid demonstration that the same ultimate reality lies behind them both. In dealing with the electronic theory of to-day he was equally ready to apply its analysis to familiar phenomena or to rebuke those who were tempted by it to essay speculative flights beyond the realm of cautious experimentation. He had outlived too many theories of matter to bespeak eternal life for the latest one.

And now his splendid career has ended. Revered of all men for his learning and loved of all who knew him for himself, he sleeps in the great Abbey amid the dust of forgotten kings, beside Newton and Darwin, his only peers in England's intellectual history. With them, he belongs not to England alone, but to the world's scant list of those who have borne the torch for generations yet to come.

The New Jersey Sewerage Commission.

It is gratifying to learn from the report of the New Jersey State Sewerage Commission, recently submitted to the Legislature, that there has been a steady progress in public appreciation of the importance of good sewerage and sewage disposal work. The conditions of water supply in Northern New Jersey and the manner of distribution of the very large population will probably make the general problem of sanitation in that section of the State approach in importance the sewage disposal and water supply problems that confront the average British city to-day. A considerable proportion of the male population in this section is engaged in business in the larger cities, and consequently the public affairs of the smaller towns where these men live, and even of some of the larger ones, have not received the careful attention that they required. Sewerage work is always liable to be unappreciated, for it is out of sight; a resident of one of these small towns who will vigorously oppose any failure to furnish and maintain fairly good roads will pay little or no attention to failure to provide proper sewerage. Moreover, when plans for good sewerage works are proposed and the amount of money they will cost is stated, a strong opposition often has arisen, nominally on the ground that the works are an unnecessary luxury, but actually because the importance of public sanitation is not thoroughly appreciated.

For years the New Jersey Sewerage Commission has therefore been obliged to carry on missionary work. It has been compelled to deny "that streams of water are God-given natural sewers, designed by Omnipotence to bear away human wastes, and that man is wiser than his Maker in providing that filth shall filter through soil." It has had to combat the idea that dangerous gases are emitted from disposal works, and that the winds will bring from such plants to all people within a radius of a mile a devastating swarm of bacteria which will cause desolation and death. The Commission has learned how to handle the difficult cases of objection based on ignorance and, since that ignorance is disappearing, the outlook for improved sanitation in the State is very bright. One unfortunate feature of its recent experience has been the necessity of a controversy with the State Board of Health, apparently due to a jealousy on the part of the latter board that was not only unwarranted but also lowered its standing in the eyes of those citizens who were acquainted with the facts. Both Boards have more than enough work to do, and it is unfortunate that the Board of Health endeavored to reach beyond its proper legal powers and interfere with the work of another commission which has been striving for many years, often against great difficulties, to improve the condition of public sanitation in certain directions. In view of the Commission's success and the manifest desirability of preventing any further conflict of authority, it would be a wise step to define its power clearly by new legislation. Such legislation is demanded, moreover, on account of an unfortunate decision of the Court of Errors and Appeals that creamery wastes do not come within the existing laws giving the Commission jurisdiction in questions relating to "sewage and other polluting matter." As a matter of fact, industrial wastes of all sorts are just as much sewage as the discharges from dwellings, and they are sometimes extremely difficult to deal with. For this reason a new law should be enacted at once giving the Commission authority over the disposal of every class of sewage.

One interesting feature of the Commission's work of late has been connected with the prevention of river pollution. At present most of the large cities are discharging their sewage directly into streams or bodies of water in a manner which is either already causing a nuisance or will undoubtedly do so within a comparatively few years. The city of Elizabeth has voluntarily undertaken to relieve the Elizabeth River of the sewage pollution which has formerly been taking place, and work done in other communities is praiseworthy. While the Commission has been forced to take legal action in order to accelerate better methods of disposal in some cases, the opposition which was at first encountered has generally disappeared entirely, and in the remaining cases is of little significance. The authorities of Pennsylvania and New York are co-operating with the Commission to reduce the pollution of interstate streams, and a good beginning has been made to stop the pollution of bathing beaches and waters where shell fish are taken. So far as stream pollution is concerned, the Commission takes the position that a safe water supply cannot be obtained from a stream draining a populated district, but that such a supply, if used at all, should be carefully filtered. Its duty is done when it reduces the pollution of a stream to an amount which is not an inequitable infringement on the rights of any party having a legal interest in the water. The position is that held by most authorities on sewage disposal and water supply and is the only one that is fair to all concerned.

It is interesting to learn that the Commission has already experienced the difficulties attending the disposal of sewage where an effluent of a high degree of purity is required, and has been forced to carry on investigations to determine the practicability of disinfecting the effluents of disposal works. Work done in 1906 by the Commission and the Hydrographic Division of the

United States Geological Survey jointly at Red Bank showed that, while chlorine would kill bacteria, yet a much larger quantity of chlorine was needed to treat septic sewage than was the case in treating raw sewage. During the present year the Geological Survey was unable to participate in the investigation, on account of inadequate funds, and the work was carried on by the Commission, with the assistance of Prof. Earle B. Phelps, of the Massachusetts Institute of Technology, whose individual interest led him to supervise the experiments. The results have been highly satisfactory and indicate that a practicable and economical method of destroying bacteria in a septic effluent like that of the Red Bank works is available. The chlorine for the purpose was obtained from a solution of chloride of lime and applied in the proper proportions to the flow of the sewage by a float regulator. It was found that a practically sterile effluent was obtained by a two-hour detention of the septic sewage in transit through a tank, after the chlorine solution was applied. Various other facts of value were determined, and the experiments, as a whole, show that it is practicable to sterilize sewage for discharge into waters where bathing is carried on or shell fish are taken at a far lower cost than has hitherto been practicable with septic tanks and filters.

Reinforced Concrete Construction and a Proposed Building Code.

The building code of the City of New York has recently been undergoing a process of revision. In fact there are few codes, building or other, which have been so frequently and so thoroughly revised as the New York building regulations. It is pretty well known that all parts of these revisions are not exclusively the outcome of disinterested efforts to secure types of construction calculated to be consistent with the best interests of the city in this particular field. Various parties have probably combined to influence revision committees in the interests of certain materials or systems to the obstruction of others. When the present revision was begun it was hoped by many that it would result in material improvements over any heretofore completed. This may still be so in general, but there are features of this last revision, lately submitted to the Board of Aldermen, which appear to indicate that some of the older methods of securing a new building code still prevail.

Reinforced concrete construction has been carried on in this city under the existing building code in a fairly satisfactory manner, although it is not what may be considered one of the formally recognized standard materials. Regulations have been adopted by the Bureau of Buildings of the Borough of Manhattan which, while not entirely satisfactory to those directly interested, have been at least sufficiently effective to secure some of the best reinforced concrete buildings yet constructed in this or any other country. It is not clear, therefore, nor can any satisfactory reason be given why the proposed new building code should be so written as to exclude hereafter what has already been so satisfactorily accomplished.

Among other provisions is one limiting the height of reinforced concrete buildings to 85 ft., while another requires the floors and roofs of a large class of buildings devoted to industrial purposes to be formed with steel beams placed not more than 5 ft. from centre to centre. The limitation of the height of this class of buildings to 85 ft. practically irrespective of the form of column employed, is without any valid reason whatever, and is calculated to prevent entirely the development of the best types of reinforced concrete columns yet devised. Doubtless there are classes of concrete-steel columns which are not well adapted to tall building construction, the use of some of which might properly be restricted to less than 85 ft., but to exclude such a type of column as that used in the Thirty-ninth Street Building, from which this journal is issued, is bad engineering.

Similarly the arbitrary maximum distance of 5 ft. between centres of floor beams is without any structural or other sensible or creditable reason. It would not be much of an exaggeration if any, to state that acres of floors have already been constructed for the satisfactory carrying of the heaviest warehouse and running machinery loads, in all of which this provision is disregarded. Innumerable flat and curved arches of greater span than 5 ft. are standing up under the heaviest loads, both static and dynamic.

It is probably true that the present regulations are, as a whole, meager and that they need amplification in a number of directions together with a revision of some of the working stresses. Criticism has been made in some quarters that a working stress of 750 lb. per square inch is too high for any type of reinforced concrete column, but as there are a large number of tests of 12-in. concrete cubes in existence, showing that the ultimate compressive resistance of such material at the age of three to six months may run from 3,000 to 4,500 lb. per square inch, it is clear that the working stress in question for such columns as those used in the Thirty-ninth Street Building, or any other column of equivalent carrying capacity, is amply justified. The prevailing maximum stresses of compression in the reinforced concrete arches of both this country and Europe are 500 to 600 lb. per square inch for the concrete and those values in such structures indicate a much more severe duty than 750 lb. per square inch in concrete so effectively supported as in the latest and best forms of combined concrete and steel columns.

Many years experience with modern concrete structures, as well as old Roman concrete remains, conclusively prove the durability of this material. Furthermore great conflagrations during the past half dozen years have demonstrated the eminently satisfactory fire resisting qualities of both plain and reinforced concrete. In every case of collapse of a concrete building during construction it has not been difficult to find a reason based either in ignorance or recklessness, wholly inconsistent with good engineering, just as is the case with the many collapses of iron and brick buildings. There is every reason why reinforced concrete contruction should receive rational treatment like every other type in the new building code.

Notes and Comments.

TRACK ARRANGEMENTS at small stations have apparently received very little attention in this country. The business of such stations is so small that a shed and a platform located anywhere have been considered ample for all purposes. Sidings have been put in without much regard to the real advantages of different places for them or consideration for the agent. As a result we hear from time to time of fatal accidents due to one defect or another at such stations. Attention must have been paid to the subject on some of the lines of this country, but the results of these studies have apparently never been made public. The recent killing by a passing train at one of these country stations of an intelligent man well acquainted with the dangers of the place led The Engineering Record to spend some time in endeavoring to find what had been published regarding track details at minor stopping places. The only comprehensive article it has been able to find up to the present time is the interesting paper elsewhere in this issue.

THE HOUSE FLY comes in for another heavy indictment in a complaint filed with Governor Hughes a few days ago by the Merchants' Association of New York City. The Association had an elaborate investigation made last summer of all cases of typhoid fever and intestinal diseases in the city. This work was done under the direction of Dr. Daniel D. Jackson, and is stated in an elaborate report written by him to show that such diseases are due primarily to the sewage in the waters about New York. Flies are stated to carry the germs of disease from this sewage to the food stuff in the markets, most of which are near the water front, or to the homes of the people. On the strength of this investigation the Governor is asked to call the attention of the city to its alleged violation of the public health laws of the State, which, according to the Association, renders the city liable to a daily fine of $31,200. There can be no question that flies are a source of danger as carriers of the germs of intestinal diseases. This has been established by elaborate investigations so that it is beyond question. The charts and statistics gathered by Dr. Jackson indicate that there is a possibility that flies may carry germs from the sewage contaminated waters about the city, in the manner he indicates. The decision as to the completeness of the proof is one for biologists and physicians to make, but as there are a good many things to be considered before it can be definitely shown where and how the flies of this great city first become the vehicles of the disease germs, it is hardly to be expected that the Governor will order the City of New York to cease disposing of its sewage in the manner now followed on the strength of one investigation.

THE 80-CENT GAS RATE law passed by the New York Legislature on April 3, 1906, has been declared unconstitutional by the United States Circuit Court, on the ground that it is confiscatory of the property rights of the Consolidated Gas Co. While this decision is apparently favorable to that company, an examination of its text indicates that really the victory is a pretty barren one. This case was first heard by a referee, who decided it in favor of the company, but Judge Hough of the Circuit Court has scaled down the referee's valuation of the company's property required for manufacturing gas to such a figure that, even with $12,000,000 allowed as the value of the franchises, it would not require much more than 80 cents per thousand cubic feet to earn 6 per cent. on the sum allowed. The case will undoubtedly be appealed to the United States Supreme Court where two important things will probably have to be settled, first, whether a public service corporation is warranted in claiming 6 per cent. as the proper rate of net income, and, second, whether franchises are to be considered assets upon which income must be earned. The latter point is particularly interesting. In some places, particularly in New England, franchises are bought at rates fixed by public agreement with the city; in other parts of the country, it is understood, franchises are bought at a private sale by those responsible for their delivery to the interested parties, and the amounts paid for them are hardly matters of public record except by investigations such as were recently made in San Francisco. If a company openly pays a sum to a city for the privilege of carrying on business, it is, of course, warranted to claim the right to earn a certain amount on that investment, but if it pays the same sum to private individuals to secure a franchise which is not exclusive and for which the city itself receives no payment, on what decent grounds can any return on that investment be claimed?

THE COAL-HANDLING APPARATUS OF A LARGE COKE OVEN PLANT.

An installation of coal handling apparatus of unusual magnitude and arrangement is operated in connection with the extensive new coke-oven plant of the By-Products Coke Corporation at Selvay, Ill., which is about $2\frac{1}{2}$ miles southwest of South Chicago and adjacent to the Calumet River. The plant covers an area approximately 1,200 x 2,500 ft. in plan, and at present contains 160 coke ovens, with various buildings for the by-product processes and other purposes. The main line of the New York, Chicago & St. Louis R. R. parallels one side of the plant; the tracks of the Chicago & Western Indiana R. R., over which the Wabash, the Erie and the Chicago, Indianapolis & Louisville roads obtain entrance to the city, cut across one corner of the plant on the opposite side; the tracks of a terminal belt-line railroad are parallel to the side opposite to the New York, Chicago & St. Louis R. R., and a freight line of the Pennsylvania R. R. is adjacent. With these numerous railroad connections exceptionally good facilities are available for receiving coal and shipping coke by rail. But notwithstanding these rail facilities, the principal part of the coal supply for the plant is now delivered by water, as the Calumet River is less than one-half mile distant and a slip has been built which brings deep water within a few hundred feet of the present work.

The coal handling apparatus consists essentially of two hoisting towers, which travel along the slip and unload coal from vessels in the latter; a main conveying belt, extending from the slip into the coke oven plant, with a total length of over 3,300 ft.; a large traveling bridge for delivering coal from the main conveyor to or from a large stock pile, and several auxiliary conveyor belts to handle the coal through various breaker, mixing and storage houses. The two hoisting towers at the slip are driven by steam engines, but all of the conveyor belts and other coal-handling equipment are driven by electric motors supplied with power generated in the plant.

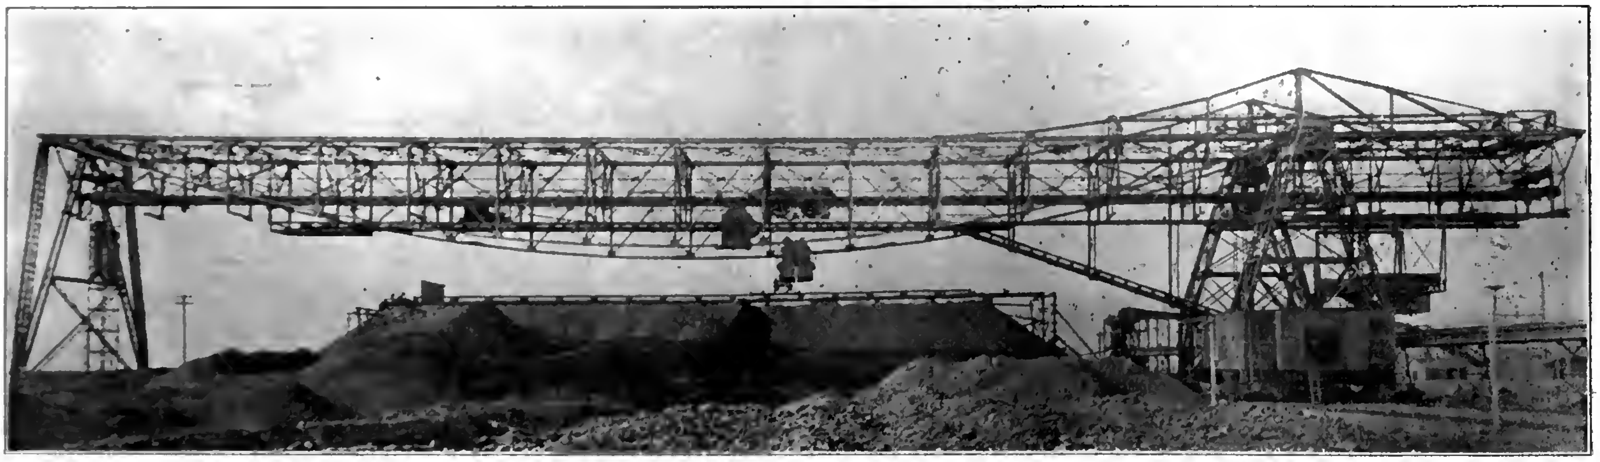
The slip along which the two hoisting towers are operated was built as a part of the coke-oven plant by the By-Products Coke Corporation. It is 1,200 ft. long, 175 ft. wide and affords a minimum depth of 21 ft. of water. The slip was made by dredging through ground which rose a few feet above the water level in the river, the excavated material being utilized in raising the grade of the land in the vicinity. The excavation was made through sand and sandy soil, which necessitated the use of close sheeting on both sides and the inshore end of the slip.

The two hoisting towers both travel on two pairs of rails, laid on heavy pile foundations along one side of the slip. Each of these towers is carried by two double column tower legs, one close to the edge of the slip and the other back far enough to permit the belt conveyor and two standard-gauge tracks to be placed between the tower legs. Each column of the latter is mounted on a four-wheel truck running on the rails on the dock. In each tower is an overhead receiving hopper, the bottom of which is high enough to provide a clearance of 16 ft. over the conveyor and the tracks. This hopper is 12 x 26 ft. in plan and has three 15-ton compartments, each with a separate gate and chute through which coal may be discharged. Over the hoppers and normal to the slip the tower has a bridge for a bucket trolley carriage. This bridge has a total length of 151 ft., a hinged cantilever section extending out over the slip at one end and a fixed cantilever over a storage pile at the other end. The hinged cantilever permits the trolley carriage to travel out 54 ft. 3 in. from the center line of the front tower leg and can be raised to allow the passage of boats with spars.

A 2-ton clam-shell bucket is swung from cables on two winding drums on the trolley carriage and is hoisted and lowered at a speed of 450 ft. per minute by a duplex Lidgerwood hoisting engine mounted over the trolley bridge on the front tower leg, the total lift being 54 ft. This engine is semi-automatically controlled so the bucket cannot be over-hoisted and comes to rest at the full working height. The trolley is operated by a separate engine, a device being provided which prevents over-travel on the bridge; this device is adjustable so the trolley can be stopped automatically at any predetermined position. The trolley carriage is of the Robins balanced type, which permits the trolley to be moved in and out without varying the height of the bucket; the trolley may also be moved along the bridge as the bucket is being raised or lowered. A counterweight is provided to give good efficiency for the combined operation of closing, hoisting and lowering the bucket.

Idlers for the Main Belt.

Conveyor Flights at the Plant.



Coal Storage and Reclaiming Bridge at the Plant.

Each tower has an average capacity for unloading 200 tons of coal per hour. The machinery of the tower is arranged so when it is working to this full capacity it can be operated by one man. Three levers are provided for controlling the movements of the trolley and bucket, two of which levers manipulate pilot valves governing the motion of the engines. Auxiliary direct-connected hand levers are also provided to be used in emergencies.

A separate engine geared to the truck wheels of the tower traverses the latter at a speed of 40 ft. per minute. The towers are both arranged to travel the full length of the dock and to unload coal from a vessel into the receiving hopper or into a storage pile along the land side of the dock, and to reclaim it from the latter at any point in the travel.

The continuous mouth of the three compart-

ments forming the receiving hopper has vertical sides of sufficient height to prevent any coal being spilled and also to act as a guard to limit the side swing of the bucket. As now arranged the central hopper delivers to the conveying belt and each of the side hoppers to cars on a track beneath them. The present consumption of the coke ovens is between 1,600 and 2,000 tons of coal a day, so the capacity of the unloading towers is sufficient to permit a part of the coal delivered by vessels to be transhipped by rail if desired. The conveying belt leading to the coke ovens can carry the full output of the unloading towers, however, and is supplied from the central hopper by an adjustable feeding device, which can deliver 400 tons an hour to it when operating at a reasonable speed.

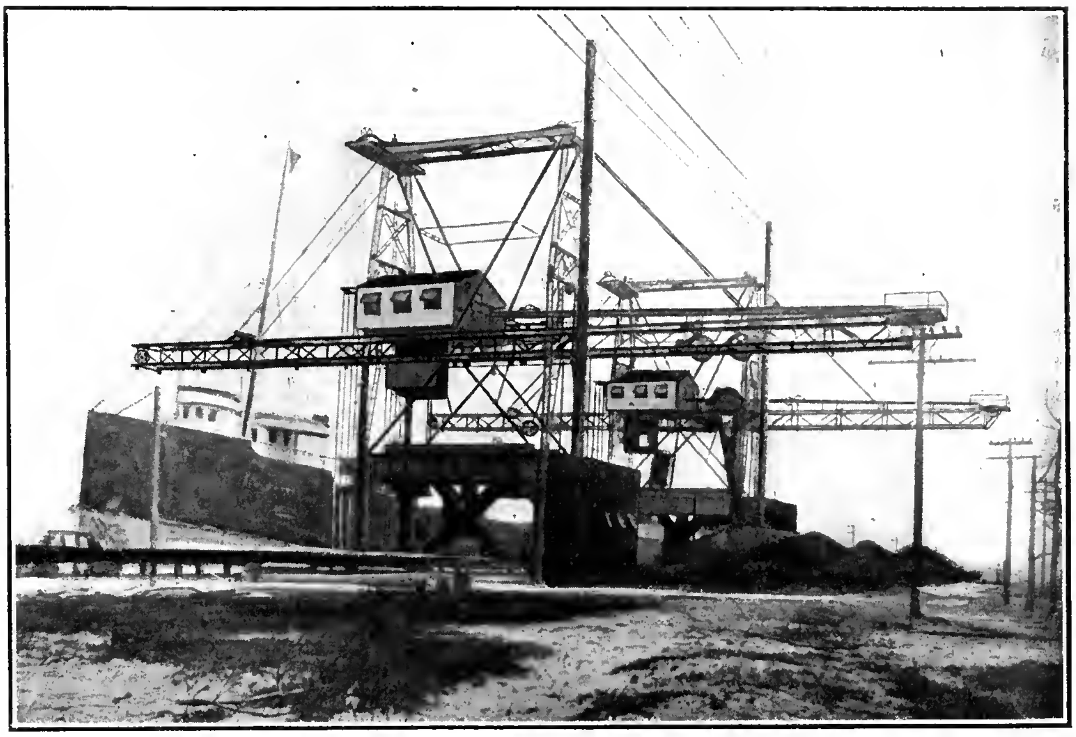
The frame for the idler pulleys of the main conveying belt extending from the slip to the coke ovens is on small concrete piers erected on the ground for a distance of about 1,000 ft. The conveyor then drops down into a subway, nearly 850 ft. long, in order to pass under the tracks of the various railroads on that side of the plant. At the end of this subway it rises on a 15 per cent. grade to a steel trestle, 1,000 ft. long and 35 ft. high, which provides an elevated crossing over the yard of the plant. From the end of this 35-ft. elevated trestle, a trestle, 15 ft high, extends for 1,340 ft. along the space provided for the coal-storage piles. Provisions are also made for extending this 15-ft. trestle in the opposite direction from the end of the higher trestle that is taken by the existing part of the 15-ft. trestle, so that a space for storing 300,000 tons of coal will be available along this low trestle and within the range of the large traveling bridge.

The main conveyor is made up of several belts of various lengths. A short belt has been installed temporarily at the slip end of the main conveyor, but will be replaced later by one 770 ft. long between centers of the end pulleys. This belt delivers to one of the same length, which extends down into the subway and to an angle of 40 deg. in the latter, where it delivers to a belt, 980 ft. long between end pulleys, that continues through the balance of the subway and thence up to the end of the high trestle. The conveyor on the existing part of the 15-ft. trestle along the storage piles is made up of two belts, each about 670 ft. long

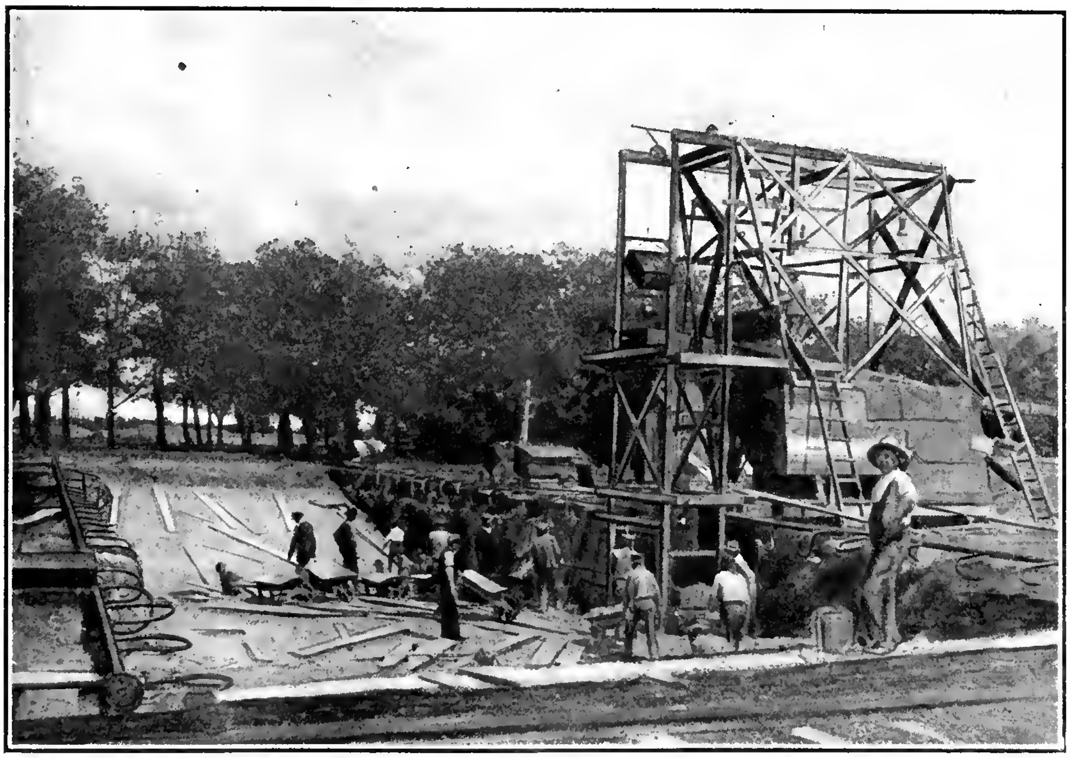
An alternating current motor is provided to drive each of the belts of the main conveyor. These motors are each placed in a closed house built to exclude dust. The belts from the dock to the end of the high trestle are all 36 in. wide and travel at a speed of 375 ft. per minute. A 30-h.-p. motor drives the first 770-ft. belt that has been installed, and a 50-h.-p. motor the 980-ft. belt. With these speeds and motors this leg of the conveyor has a capacity for handling about 400 tons of coal an hour. The switches controlling the operation of the motors driving the various belts which make up the main conveyor are arranged so when any belt is stopped all of the belts between it and the slip are also stopped.

The 980-ft. belt discharges at the end of the elevated trestle into a hopper carried by a steel tower. This hopper is arranged so coal may be supplied from it to a belt leading in either direction on the low trestle along the coal storage piles. The tower also carries a coal crusher, which may be fed from the hopper and delivers to the belts extending along the storage piles. This crusher is used as a spare when the main crusher is being repaired.

The belts on the 15-ft. trestle are 36 in. wide and travel at 375 ft. per minute. The breaker, mixing and storage buildings are placed midway on the leg of the main conveyor, the part of the 15-ft. trestle which has been installed, a 670-ft. belt extending from the end of the 35-ft. trestle to them, and one of the same length from them to the end of the storage space. Coal delivered from vessels in the slip, or from cars on the railroad tracks by the main conveyor is either placed in the storage piles by the traveling bridge, and then reclaimed by the latter to the main conveyor, as required, or is delivered immediately to the breakers prior to being passed through the mixers.



Unloading Towers at the Dock.



Sluicing Material at East End of Subway to Dump.

The traveling bridge is carried by a four-leg tower at the front end along the low trestle and by a shear leg at the other end. Each leg of the tower is carried by a four-wheel truck, and the shear leg is carried by two four-wheel trucks. The bridge has a total length of 340 ft., made up of a span of 280 ft. between the tower and shear leg and a 60-ft. cantilever extending out over the conveyor on the trestle. The span between the tower and the shear leg is an inverted parabolic bow-string truss, which has a clear width of 28 ft. between chords. The lowest point of the bottom chords of the truss are 35 ft. above the ground, and coal can be piled to a height of 30 ft.

Both of the belts which make up the section of the main conveyor on the low trestle each have a traveling tripper that permits coal to be discharged from either belt at any part of the latter onto a belt carried by the traveling bridge. This belt is 36 in. wide and a trifle over 262 ft. long between end pulleys; it extends from the receiving hopper up to floor beams carried by the lower chords of the bridge span and then horizontally to a point near the shear leg. This belt has a capacity for handling 750 tons an hour and is arranged with a tripper so coal can be discharged from it into the storage piles at any point in its horizontal run.

The bridge also carries a trolley carriage, which travels the full length of the structure from the shear leg to the end of the cantilever over the main conveyor on the 15-ft. trestle. A

5-ton clam-shell bucket mounted on this trolley carriage delivers coal from the storage piles to a hopper under the cantilever of the bridge. The main conveyor belts are supplied from this hopper by an automatic shaking feeder device. The trolley is moved back and forth along the bridge at a speed of 350 ft. per minute by a hoist driven by a 75-h.-p. motor; the bucket is hoisted and lowered by a second hoist driven by a 150-h.-p. motor, the hoisting speed being 275 ft. per minute. At these speeds the bucket has a capacity for rehandling 200 tons of coal an hour from the storage piles to the main conveyor. Both of the motor-driven hoists are in a house on the tower of the bridge; but they are arranged for remote control from an operator's cab on the trolley carriage, one man handling all of the operations of the bridge from this cab. The trolley is of Robins special balanced type, with the operating cables rove so it will remain in any desired position while the bucket is hoisted and lowered. The cables are also roved so there is no tendency for the trolley to run away in either direction at any time.

The traveling tripper on the belt leading from the end of the high trestle to the breaker, mixer and storage building is arranged to discharge coal in three ways; first, into the hopper of the traveling bridge; second, forward on the same belt, or to the belt extending along the storage piles from the buildings; and, third, into either of two belt conveyors leading to a tower in which seven belts leading to and from the various buildings converge. The conveyor belt extending along the storage piles from the buildings is arranged so it will run in either direction, in order that it can be reversed to deliver coal to the tower when supplied from the storage piles by the traveling bridge.

The tower is about 20 x 30 ft. in plan and 58 ft. in height to the eaves line. The two conveyors leading into it from the main conveyor on the 15-ft. trestle are placed one above the other in the same covered incline. The lower one of these conveyors is a 36-in. belt, about 79 ft. 4 in. long between end pulleys, and is driven at a speed of 375 ft. per minute by a 25-h.-p. motor. It delivers to a 36-in. belt, 196 ft. 5½ in. long, which is carried up to a storage bin in the top of the breaker building by a covered incline. This belt is driven at a speed of 375 ft. per minute by a 35-h.-p. motor, and is arranged to discharge into either of two compartments in which the storage bin is divided. These two compartments, with a combined capacity of 300 tons, are provided because two kinds of coal are mixed for use in making the coke produced by the plant.

The breaker building is 40 x 40 ft. in plan and has an extreme height of 65 ft. Each of the two compartments of the storage hopper at the top of the building supplies a 12-ft. diameter Bradford breaker, each of the latter being driven by a 50-h.-p. motor. Part of the product of the breakers is passed through a 30 x 60-in. Heyl & Patterson crusher driven by a 50-h.-p. motor, and thence through a Jeffery pulverizer, also driven by a 50-h.-p. motor. The pulverizer discharges on a short horizontal 48-in. conveyor belt, which delivers the fine coal to an inclined 36-in. conveyor belt leading from the bottom of the breaker house to storage bins in the top of a mixer house on the opposite side of the tower. The balance of the output of the breakers is delivered directly to this inclined belt. The latter is 264 ft. 10 in. long between end pulleys and is driven a speed of 375 ft. per minute by a 35-h.-p. motor.

The mixer building is 30 x 35 ft. in plan and 65 ft. high, 750 tons of storage capacity being provided in two hoppers in the top of it. One kind of crushed coal is supplied to each of these hoppers, and the two are mixed in proper proportions to make first-grade foundry coke by a mixer in the lower part of the building. The mixture is carried back to the tower by a 36-in. belt, 123 ft. 10 in. long, that is driven at a speed of 375 ft. per minute by a 25-h.-p. motor. This belt delivers to the upper one of the two conveyors, which enter the tower from the main conveyor on the trestle along the storage piles. This upper conveyor extends through the tower to a storage bin beyond the latter and carries the coal from the mixer to this bin. It is a 28-in. belt, 175 ft. long between end pulleys, and is driven by a 25-h.-p. motor. Ordinarily the belt below it carries coal from the conveyor on the trestle to the tower, but arrangements are made so the upper belt can perform this service and also deliver coal directly to the storage bin from the conveyor on the trestle in an emergency.

The storage bin is at the middle of a row in which the 160 coke ovens that are in operation have been placed. It is 40 x 80 ft in plan and has an extreme height of 80 ft. and a capacity of 1,000 tons, being elevated sufficiently to permit tracks to be run under it level with the tops of the ovens. The conveyor which carries coal to the bin delivers to a cross conveyor in a cupola at the top of the building; this cross conveyor is arranged to distribute coal to both ends of the bin. The bottom of the latter is built with several hopper-shaped outlets, through which coal is drawn into large electrically-operated larries that run on tracks laid on top of the ovens and supply the latter through holes in the top.

The main parts of the coal handling system are arranged so they may readily be altered and supplemented to provide sufficient capacity to supply a plant having 640 coke ovens. The subway and both trestles for the main conveyor belt are built to carry a second belt of the same size and capacity, and the traveling bridge can place in the storage piles practically all the coal that could be delivered by two conveyors of the same capacity as the existing main conveyor. The driving machinery of the present breaker, mixer and storage plant is large enough to supply 320 ovens, or 550 tons an hour. A duplicate arrangement of breaker, mixer and storage buildings and a row of ovens could also be placed on the opposide side of the low trestle from the present buildings and ovens.

The provision of the large amount of coal storage capacity that is available is one of the most salient features of the plant. The ovens require from 1,600 to 2,000 tons of coal a day under normal operating conditions, but from 100,000 to 200,000 tons are carried in the stock piles. With this arrangement the coke company is able to assure the consumer of almost immediate deliveries, so the consumer is required to provide for only enough coke storage to insure against delay in shipments between the ovens and the plant. Since it costs about 50 cents a ton to handle foundry coke into and out of storage, the actual saving is evident.

The coal handling system which has been described herewith was installed by the Robins Conveying Belt Co., of New York, the various apparatus being largely of special types controlled by that company. The guide and return idler pulleys and the troughing are built so the conveyor belts are subjected to very little wear. The idlers are heavy cast-iron pulleys on hollow cold-drawn steel tube shafts. The latter are provided with large grease cups at the ends and are lubricated internally, thus insuring freedom from dust and grit. The pillow blocks are of the ball and socket type, with heavily babbitted bearings four times the diameter of the shaft. The take-ups for the belts are also of the ball and socket type and have encased screws.

The construction of the long subway under the various railroad tracks involved considerable difficult work, owing to the necessity for handling the heavy traffic over the railroads without delay. The work was finished, however, practically without interfering with traffic. The soil conditions at the site also offered rather serious difficulties, which were overcome by a method of operations that was adopted. The soil is largely lake sand, in which the ground-water level was close to the surface. A row of well-point strainers was driven about 2 ft. outside the limits of the work, on each side and down below the subgrade of the latter. The strainers in each of these rows were then connected to a suction header attached to a pump, which drew the ground-water level down below the bottom of the excavation. The latter and the construction of the concrete bottom and sides of the subway were thus handled in sections about 100 ft. in length without any interference from water.

The material was also handled out of the excavation very economically by a system of hydraulic sluicing that was installed. A portable tower for a counterbalanced double hod hoist was erected on the side of the excavation in a position to permit the hoists to be lowered to the bottom of the latter. The material was loaded into wheel-barrows as it was excavated, and the wheel-barrows hoisted to the surface, where the material was dumped into a sluicing trough. Water was supplied to the trough through three 1-in. pipes by the pump attached to the well-point strainers. The pipes were arranged so the material was quickly placed in suspension in the trough and could be carried away by the water and used for filling. The well-points and portable hoisting tower were moved along as the work progressed, thus requiring very little wheeling in the excavation.

This plant of the By-Products Coke Corporation was installed under the supervision of Mr. W. T. Snively, engineer in charge.

Fittings for Superheated Steam.

Remarkable expansion and permanent set of cast-iron parts and fittings in superheated steam lines were reported in the discussions of papers on superheated steam before the recent New York meeting of the American Society of Mechanical Engineers. Valve bodies and fittings under the influence of the superheat are found to increase in dimensions at a much more rapid rate than at the lower temperatures of saturated steam, and after being subject to these temperatures for a considerable length of time, take on a permanent set in the increased dimensions. Fittings in 6 to 10-in. superheated lines are found to "grow" as much as ½ in. in length or more, and in many instances they warp into irregular shapes. In one instance, a cast-iron body globe valve, with inserted bronze seat, used for superheated steam, showed signs of leaking, and upon examination it was found that the body had expanded away from the inserted seat. A new seat was made and fitted to screw very tightly into the body, but after a short period of further service it again expanded sufficiently to cause leakage around the seat. Then a second new seat was made to the increased size necessary to screw very tightly into the body, and no further trouble was experienced, it being thought that permanent set had taken place. In other cases irregular expansion has been experienced, one fitting, 36 in. long, having expanded nearly an inch in length and ¼ in. more on one side than the other. It was the general experience that if the castings are symmetrical the tendency is toward regular expansion, but if they have lugs, arms or are irregular, warping will accompany the expansion. This extreme expansion occurs only with the higher degrees of superheat, little trouble being found at temperatures of 500° Fahr. and under, and is first noticed after periods of time, varying from a few weeks to a year or more.

The Engineering Features of the Proposed Henry Hudson Memorial Bridge.

A report to C. M. Ingersoll, chief engineer, Department of Bridges, New York City, by Leon S. Moisseiff, engineer in charge, Henry Hudson Memorial Bridge.

The proposed Henry Hudson Memorial Bridge is a concrete bridge of a total length of about 2,840 ft. It consists mainly of seven circular arches of about 108 ft. clear span each, with corresponding piers, and one main arch of 703 ft. clear span between skewbacks, flanked by two monumental piers of about 108 ft. width and 180 ft. height. The approaches are designed to be of concrete masonry reinforced by embedded steel wherever required, the piers being faced with natural stone.

The bridge is designed with an upper and lower deck providing for surface and subway traffic. The upper deck has a clear width of 80 ft. between balustrades, occupied by a 50-ft. roadway and two sidewalks of 15 ft. each. The lower deck is 70 ft. wide from outside to outside of walls and about 65 ft. on the inside. It is occupied by four railroad tracks and has sufficient space for pipe galleries and the like. The subway tracks on the main span are supported by steel beams and posts resting in turn on the secondary or relieving arches and on the vertical piers designed to be of reinforced concrete.

The provision for the subway tracks will, undoubtedly, prove of great ultimate value to the city, as it provides both local and express tracks at small additional cost. But the utilization of these tracks immediately on the completion of the bridge may not be expected. The location of the bridge, near the most northwestern point of Manhattan Island, is not likely to require and warrant rapid transit transportation before the next ten years. Several years will thus elapse after the completion of the bridge before the subway tracks will be required. Considering this situation, it will be in the interest of good economy not to install the tracks nor to put the steel supports in position before the time requiring their use. It is therefore intended to provide, for the present, the footings for the posts and the means for ready connection with the structure, and to leave the fabrication and construction of the track beams and posts for future time. This is stated here because it has, as will be seen later, some bearing on the strength of the structure when first put in operation.

The design of the approaches, as laid out, conforms with standard engineering practice, and their construction offers no special difficulties and requires only the attention and execution which should be bestowed on engineering works of this character. They need not be considered here further.

It is in the planning and building of the main span arch that the engineering problems to be solved and the difficulties to be overcome are centered. The clear span of the great arch is about 703 ft. between skewbacks and it has a greatest vertical clearance above the mean high water datum of 183 ft. Expressing it in a more technical way, the span center to center of skewbacks is 725 ft. and the rise, center to center, is 177 ft., or about one-fourth of the span. The longest span of any built masonry arch is that of the bridge over the Syra Valley at Plauen, Germany. It has a span of 295 ft. and a rise of 56 ft. or less than one-fifth of the span. It is built of hard slate. The longest span arch in this country is the Walnut Lane bridge in Philadelphia. It has a span of 233 ft. and is built of concrete without metal reinforcements. About five years ago at a prize competition for plans for a bridge over the Neckar River at Mannheim, Germany, the prize was awarded to an arch bridge with a main span of 365 ft. and a rise of one-twelfth of the span. The material proposed was brick. Because of conditions independent of the engineering problem, the bridge was not built of masonry.

It may be well to state here that the upper Niagara steel arch has a span of 840 ft. center to center of hinges and that the plans for the connecting railroad bridge at Hell Gate call for a steel arch of 1,000 ft. span.

Thus the span of the Henry Hudson Memorial Bridge, while not the longest arch, by far exceeds that of any built or proposed masonry arch. To arrive, however, at a correct basis for comparison, it should be considered that while the span of an arch apparently determines its position in the heirarchy of engineering achievements it is the ratio of the rise to the span that is determining. But the dimension really most characteristic of the boldness of an arch is the radius of curvature at the crown. It has also the advantage of furnishing a means for ready comparison. Thus the Plauen arch has a radius at the crown of 344 ft. and the above mentioned prize design for a Neckar bridge a radius of 558 ft. The radius at the crown of the Hudson Memorial arch is 489 ft., or less than that of the proposed Neckar bridge. It means that the Neckar arch with a span of only 365 ft. will strain the material of the arch rib more than that of the Hudson Memorial Bridge with twice that span. This general conclusion is verified by the comparison of the stresses as determined by careful computations.

The above discussion tends to show that while the Henry Hudson Memorial arch by far exceeds in magnitude any masonry arch in existence, its general proportions have been so chosen as to bring the resulting conditions within the limits of modern engineering practice.

There remains, then, to consider the main factors and physical conditions entering into the construction of a structure of like magnitude. These will be discussed in the following under several headings.

Foundations.—No other engineering structure is as much dependent on the stability and immovability of its foundations as the fixed arch. Even a relatively very small displacement may cause considerable strains in the arch ribs. For a reinforced concrete arch of the dimensions of the main arch of the Henry Hudson Memorial Bridge an immovable, incompressible and imperishable foundation is a prerequisite.

The geological conditions of the site selected for the bridge are quite well known, Manhattan Island and its adjacent territory having been made a subject of study by many geologists. The deep diamond drill borings made by the Department of Bridges, some of which went down to more than 138 ft. below the water level, affirm the information supplied by the former.

The south or Manhattan side of the bridge site is covered with "thin till with numerous rock exposures." The underlying rock is a hard rock known as Hudson schist. It is a sedimentary rock of the Silurian period and is essentially a mica schist consisting of biotite and quartz. It covers the greater part of Manhattan Island.

The surface condition on the north or Bronx side is described as a "till with occasional small rock exposures." The underlying rock here is known as Fordham gneiss. It is an ancient crystalline rock of the Pre-Cambrian period and consists of a gray banded gneiss of orthoclase, quartz, and biotite. It begins at Spuyten Duyvil and extends far up the Hudson River.

On both sides the rock slopes rapidly upward to a greatest elevation of 200 ft. above mean high water. The foundations for the main arch are practically all on dry land with the hard rock on the average 10 ft. below mean high water. It is intended to fix the bottom of the foundation at a level of 20 ft. below datum. The abutments, which will be of concrete, will thus rest on the hard rock and also abut against a wall of the same material. The pressure on the foundation is far below its bearing resistance, and to displace the abutments the rocky mountains behind them would have to be moved. The foundations are thus admirably adapted for their purpose and will furnish an absolutely immovable abutment in accordance with the requirements of rigid theory.

Methods of Computation.—In considering the methods of computation used it should be stated here that the construction of the upper and lower decks and of the secondary arches and vertical piers offers no theoretical or practical difficulties which should deserve special consideration. The following discussion refers, therefore, mainly to the great arched rib.

In deciding on the methods of computation to be used and on the degree of accuracy to be obtained, the consideration of the magnitude of the structure has exerted a determining influence. The most accurate available theory is applied; the assumptions it is based on have been scrutinized; simplifications generally made have been evaluated numerically as to their degree of accuracy. The computations are checked by as widely independent methods as physical facts will permit. The most modern procedures of engineering science are resorted to in determining the stresses at every section of the arch. Instead of the common practice of finding the stresses for certain assumed positions only of the moving load, the position of the moving load causing the greatest stress in any section of the rib is determined, and even the loading causing the greatest strain in upper and lower faces has been found. This more accurate method, of course, shows stresses in excess of those determined by the common procedure.

It is realized that the importance of the structure requires that all possible causes of stress in the arch be foreseen and provided for. Not only is, therefore, the effect of a change of temperature within reasonable limits computed but even that of the possible shrinkage of the concrete after the rib has been swung free of its falsework. The stresses caused in the arch by its greatest distortion from the original curve are also included in the resulting total. This again is not done in common practice.
